JOURNAL OF THE CHEMICAL SOCIETY

Committee of Publication :

Chairman : C. N. HINSHELWOOD, M.A., Sc.D., D.Sc., F.R.S.

N. K. ADAM, M.A., Sc.D., F.R.S.
M. P. APPLEBEY, M.B.E., M.A., D.Sc.
W. BAKER, M.A., D.Sc., F.R.S., F.R.I.C.
G. M. BENNETT, M.A., Sc.D., F.R.S., F.R.I.C.
E. G. COX, D.Sc.
F. P. DUNN, B.Sc., F.R.I.C.
H. J. EMELEUS, D.Sc., F.R.S., A.R.C.S.
M. G. EVANS, D.Sc., F.R.S.
C. N. GIBSON, O.B.E., M.A., Sc.D., F.R.S.
D. L. HAMMICK, M.A.
D. H. HEY, Ph.D., D.Sc., F.R.I.C.
C. K. INGOLD, D.Sc., F.R.S., F.R.I.C.
D. J. G. IVES, D.Sc., A.R.C.S., F.R.I.C.
E. R. H. JONES, D.Sc., F.R.I.C.
F. E. KING, M.A., D.Sc., Ph.D., D.Phil.
G. A. R. KON, M.A., D.Sc., F.R.S.
R. P. LINSTEAD, C.B.E., D.Sc., F.R.S.

H. W. MELVILLE, Ph.D., D.Sc., F.R.S.
R. G. W. NORRISH, B.A., Sc.D., F.R.S.
S. G. P. PLANT, D.Phil., M.A., B.Sc.
M. POLANYI, Ph.D., M.D., F.R.S.
H. RAISTRICK, Sc.D., F.R.S., F.R.I.C.
E. K. RIDEAL, M.B.E., M.A., D.Sc., Ph.D.,
F.R.S.
F. L. ROSE, B.Sc., Ph.D., F.R.I.C.
B. C. SAUNDERS, M.A., Ph.D., F.R.I.C.
J. L. SIMONSEN, D.Sc., F.R.S., F.R.I.C.
D. W. G. STYLE, Ph.D.
S. SUGDEN, D.Sc., F.R.S.
H. W. THOMPSON, M.A., B.Sc., D.Phil., F.R.S.
A. R. TODD, M.A., D.Sc., F.R.S.
W. WARDLAW, D.Sc., F.R.I.C.
F. G. YOUNG, D.Sc., Ph.D., F.R.I.C.

Editor :

J. E. DRIVER, M.A., Ph.D., M.Sc., F.R.I.C.

Assistant Editor :

A. D. MITCHELL, D.Sc., F.R.I.C.

Indexer :

MARGARET LE PLA, B.Sc.

1947. Part II., pp. 881-1709.

LONDON: THE CHEMICAL SOCIETY.

1947.

PRINTED IN GREAT BRITAIN BY
RICHARD CLAY AND COMPANY, LTD.,
BUNGAY, SUFFOLK.

CONTENTS.

PAPERS COMMUNICATED TO THE CHEMICAL SOCIETY.

General, Physical, and Inorganic.

	PAGE
164. The Crystal Structure of Strontium Azide. By F. J. LLEWELLYN and F. E. WHITMORE	881
165. The Crystal Structure of <i>p</i> -Dinitrobenzene. By F. J. LLEWELLYN	884
NOTE.—Infra-red Spectrum and Structural Diagnosis: Substituted Carbazoles. By R. E. RICHARDS	978
Twelfth Report of the Committee on Atomic Weights of the International Union of Chemistry. By G. P. BAXTER (Chairman), M. GUICHARD, O. HÖNIGSCHMID, and R. WHYTLAW-GRAY	980
Thirteenth Report of the Committee on Atomic Weights of the International Union of Chemistry. By G. P. BAXTER (Chairman), M. GUICHARD, and R. WHYTLAW-GRAY	983

Organic.

166. Synthetic Antimalarials. Part XVI. 4-Dialkylaminoalkylaminoquinazolines. Variation of Substituents in the 6- and 7-Positions. By NORMAN B. CHAPMAN, GEOFFREY M. GIBSON, and FREDERICK G. MANN	890
167. Synthetic Antimalarials. Part XVII. Some Arylaminoaminoalkylaminoquinoline Derivatives. By F. H. S. CURD, C. G. RAISON, and F. L. ROSE	899
168. Synthetic Antimalarials. Part XVIII. 3-Dialkylaminoalkylaminodiphenylamines. By FREDERICK G. MANN and J. W. GEOFFREY PORTER	910
169. Synthetic Antimalarials. Part XIX. Dialkylaminoalkylaminodiphenylguanidines By FREDERICK G. MANN, FREDERICK T. NAYLOR, and J. W. GEOFFREY PORTER	914
170. Synthetic Antimalarials. Part XX. Cinnolines. Part XIII. Synthesis and Antimalarial Action of 4-Aminoalkylaminocinnolines. By J. R. KENEFORD and J. C. E. SIMPSON	917
171. The Effect of Temperature on the Proportions of Isomers formed in the Mononitration of Toluene. By W. W. JONES and M. RUSSELL	921
172. The Reaction of 1-Nitropropane with Formaldehyde and Ammonia. By E. L. HIRST, J. K. N. JONES, (MRS.) S. MINAHAN, F. W. OCHYNSKI, A. T. THOMAS, and T. URBANSKI	924
173. Some Catalysed Gas-phase Reactions of Aromatic Hydrocarbons. Part I. The Interaction of Benzene with Methyl Ether. By P. H. GIVEN and D. L. HAMMICK	928
174. Curare Alkaloids. Part VI. Alkaloids from <i>Chondrodendron tomentosum</i> R. and P. By HAROLD KING	936
175. The Friedel-Crafts Reaction in the Carbazole Series. Part III. By S. G. P. PLANT and (MRS.) J. F. POWELL	937
176. Polycyclic Aromatic Hydrocarbons. Part XXXII. 2'-Methoxy- and 2'-Methoxy-9:10-dimethyl-1:2-benzanthracene. By G. M. BADGER	940
177. New Potential Chemotherapeutic Agents. Part VII. Experiments on the Synthesis of 8-Aminopurines. By F. E. KING and T. J. KING	943
178. The Constituents of Natural Phenolic Resins. Part XXI. The Structure of Diisoeugenol. By NEVILLE J. CARTWRIGHT and ROBERT D. HAWORTH	948

	PAGE
179. Substituted Benzoic Acids and Benzophenones. By A. H. FORD-MOORE	952
180. Some Heterocyclic Methylene Bases and their Anilomethyl Derivatives. By FRANCES M. HAMER, RUSSELL J. RATHBONE, and BARBARA S. WINTON	954
181. Symmetrical Tricarbocyanines having One or More Methyl Groups as Substituents on the Chain. By FRANCES M. HAMER and RUSSELL J. RATHBONE	960
182. Some Alkoxy- and Alkylenedioxydi-amines and Alkoxy- and Alkylenedioxydi- guanidines. By A. T. FULLER and HAROLD KING	963
183. 3-Deoxy-1-xylose. By S. MUKHERJEE and A. R. TODD	969
184. An Experimental Study of the Alkylation of Aromatic Amines using (1) Aluminium Alkoxides and (2) Alumina with Alcohols. By J. CAMPBELL EARL and NOEL G. HILLS	973
185. Reactions of Alkylisoformanilides. Part III. With Phenols. By EDWARD B. KNOTT	976
OBITUARY NOTICE	989

ERRATA.

VOL., 1947.

Page	Line	
383	11*	for " <i>N</i> -benzyl- <i>N'</i> -methylbenzamadinium hydrochloride" read " <i>N</i> -benzyl- <i>N'</i> -methyl- benzamadinium chloride".
386	6*	for "(2.65 g. or 48%)" read "(5.15 g., 93%)"
388	28	for " <i>N</i> -benzyl- <i>N'</i> -methylbenzamidine" read " <i>N</i> -Benzyl- <i>N'</i> -methylbenzamidine".
499		In the last line of the formulæ, for " $= p\text{-Me}\cdot\text{C}_6\text{H}_4$ " read " $(\text{T} = p\text{-Me}\cdot\text{C}_6\text{H}_4)$ ".

* From bottom.

CONTENTS.

PAPERS COMMUNICATED TO THE CHEMICAL SOCIETY.

General, Physical, and Inorganic.

	PAGE
187. The Crystal Structure of the Orthorhombic Modification of 1 : 2 : 5 : 6-Dibenzanthracene. A Quantitative X-Ray Investigation. By J. MONTEATH ROBERTSON and J. G. WHITE	1001
188. The Chemistry of Plutonium. By B. G. HARVEY, H. G. HEAL, A. G. MADDOCK, and (Miss) E. L. ROWLEY	1010
203. The Preparation, Properties, and Chlorination Products of Carbon Diselenide. By D. J. G. IVES, R. W. PITTMAN, and W. WARDLAW	1080
204. The Relation of Yttrium to the Lanthanons: A Study of Molecular Volumes. By JOSEPH K. MARSH	1084

Organic.

186. Photochemical Reactions in Sunlight. Part XII. Reactions with Phenanthraquinone, 9-Arylxanthenes, and Diphenyl Triketone. By ALEXANDER SCHÖNBERG and AHMED MUSTAFA	997
189. Production of Antibiotics by Fungi. Part III. Javanicin. An Antibacterial Pigment from <i>Fusarium javanicum</i> . By H. R. V. ARNSTEIN and A. H. COOK	1021
190. The Course of Cyclisation in the Formation of Alicyclic Rings. Part I. Effect of Alkyl Groups on the Cyclisation of Esters of Polycarboxylic Acids. By R. N. CHAKRAVARTI	1028
191. Olefinic Acids. Part II. The Reactivity of α -Bromoacrylic Acid and Some Related Compounds. By L. N. OWEN and H. M. BABATUNDE SOMADE	1030
192. Tetrahydroacridones and Related Compounds as Antimalarials. By (Miss) J. M. L. STEPHEN, (Miss) I. M. TONKIN, and JAMES WALKER	1034
193. β -Phellandrene Tetrabromide. By P. A. BERRY and A. KILLEN MACBETH	1039
194. Molecular Rearrangement and Displacement of Arylamine Residues in α -Arylamino-ketones. Part I. By R. M. COWPER and T. S. STEVENS	1041
195. Experiments with Diazomethane and its Derivatives. Part XIII. Action of Diazomethane on Hydroxyanils. By ALEXANDER SCHÖNBERG, AHMED MUSTAFA, and (in part) MUSTAFA KAMAL HILMY	1045
196. The Quantitative Determination of Galactose, Mannose, Arabinose, and Rhamnose. By E. L. HIRST, J. K. N. JONES, and E. A. WOODS	1048
197. A Synthesis of Cytidine. By G. A. HOWARD, B. LYTHGOE, and A. R. TODD	1052
198. The Constitution of Cherry Gum. Part II. The Products of Hydrolysis of Methylated Cherry Gum. By J. K. N. JONES	1055
199. Some Reactions and Derivatives of 6- and 7-Nitro-2-naphthylamines. Part II. Nitration and Diazo-coupling. By HERBERT H. HODGSON and EDWARD R. WARD	1060
200. The Synthesis of 3-Methyl and 3 : 5-Dimethyl <i>l</i> -Arabinose. By E. L. HIRST, J. K. N. JONES, and (Miss) E. WILLIAMS	1062
201. The Constitution of Egg-plum Gum. Part I. By E. L. HIRST and J. K. N. JONES	1064
202. The Hydrogenation of Furfuraldehyde to Furfuryl Alcohol and Sylvan (2-Methylfuran). By JOHN G. M. BREMNER and RICHARD K. F. KEEYS	1068

	PAGE
205. The Preparation and Ultra-violet Light Absorption of Some Substituted Phenylpropenyl- and Styrylmethyl-carbinols and 1-Phenylbutadienes. By ERNEST A. BRAUDE, E. R. H. JONES, and E. S. STERN	1087
206. The Kinetics of Anionotropic Rearrangement. Part VI. The Effects of Methyl, Methoxy-, and Halogen Substituents attached to a Phenyl Group. By ERNEST A. BRAUDE and E. S. STERN	1096
207. Studies in Light Absorption. Part IV. Nitro-olefins. By ERNEST A. BRAUDE, E. R. H. JONES, and G. G. ROSE	1104
208. Syntheses in the Thiopyran Series. Part I. Tetrahydro-derivatives. By RALPH F. NAYLOR	1106
NOTES—Activating Influence of <i>para</i> -Groups on the Lability of Chlorine in Chlorobenzenes. By G. M. BADGER, J. W. COOK, and (Miss) WENDY P. VIDAL	1109
An Improved Preparation of 1:8-Dinitronaphthalene. By HERBERT H. HODGSON and EDWARD R. WARD	1109
OBITUARY NOTICE	1110

CONTENTS.

PAPERS COMMUNICATED TO THE CHEMICAL SOCIETY.

General, Physical, and Inorganic.

	PAGE
211. The Kinetics of the Reaction between Copper and Iodine in Various Solutions. Part II. Solutions of Iodine in Organic Solvents. By L. L. BIRCUMSHAW and M. H. EVERDELL	1119
215. The Crystal and Molecular Structure of Certain Dicarboxylic Acids. Part III. Diacetylenedicarboxylic Acid Dihydrate. By J. D. DUNITZ and J. MONTEATH ROBERTSON	1145
217. The Kinetics of Aromatic Halogen Substitution. Part III. Iodination by Iodine Chloride. By L. J. LAMBOURNE and P. W. ROBERTSON	1167
218. The Kinetics of Halogen Addition to Unsaturated Compounds. Part XII. Iodine Catalysis of Chlorine and Bromine Addition to Ethyl Cinnamate. By H. D. C. WATERS, A. R. CAVERHILL, and P. W. ROBERTSON	1168
219. Potassium Fluoaluminates. By F. A. PAINE and J. PEARSON	1172
223. Nitration in Sulphuric Acid. Part V. Nitration of 2:4-Dinitrotoluene in a Two-phase System. By G. M. BENNETT, J. C. D. BRAND, D. M. JAMES, T. G. SAUNDERS, and GWYN WILLIAMS	1185
226. The Photochemical Polymerisation of Vinyl Acetate Vapour. By H. W. MELVILLE and R. F. TUCKETT	1201
227. Radical-sensitised Polymerisation of Vinyl Acetate Vapour. By H. W. MELVILLE and R. F. TUCKETT	1211
234. The Reduction of Oxides by Hydrogen and Carbon Monoxide. By W. E. GARNER	1239
235. Heat of Adsorption of Gases on Manganous-Chromic Oxide at Room Temperature. By T. WARD	1244
237. Spectroscopic Studies of the Amide Linkage. By R. E. RICHARDS and H. W. THOMPSON	1248
238. Vibrational Spectra of Phenolic Derivatives and Phenolic Resins. By R. E. RICHARDS and H. W. THOMPSON	1260

Organic.

209. Amidines. Part VII. Preparation of Amidines from Cyanides, Aluminium Chloride, and Ammonia or Amines. By P. OXLEY, M. W. PARTRIDGE, and W. F. SHORT	1110
210. The Preparation of Benzylamines from Benzyl Halides and Hexamethylene-tetramine. By JOHN GRAYMORE	1116
212. Deoxypentose Nucleic Acids. Part I. Preparation of the Tetrasodium Salt of the Deoxypentose Nucleic Acid of Calf Thymus. By J. MASSON GULLAND, D. O. JORDAN, and C. J. THRELFALL	1129
213. Deoxypentose Nucleic Acids. Part II. Electrometric Titration of the Acidic and the Basic Groups of the Deoxypentose Nucleic Acid of Calf Thymus. By J. MASSON GULLAND, D. O. JORDAN, and H. F. W. TAYLOR	1131
214. Deoxypentose Nucleic Acids. Part III. Viscosity and Streaming Birefringence of Solutions of the Sodium Salt of the Deoxypentose Nucleic Acid of Calf Thymus. By J. M. CREETH, J. MASSON GULLAND, and D. O. JORDAN	1141
216. The Constitution of ψ -Santonin. Part IV. A Study of the Butenolide System. By WESLEY COCKER and STANLEY HORNSBY	1157

	PAGE
220. Unsaturated Lactones. Some Esters of Aconic and Coumalic Acids. By N. R. CAMPBELL and J. H. HUNT	1176
221. Pyrazine Derivatives. Part III. Conversion of Diketopiperazines into Pyrazine Derivatives. Synthesis of 2-Hydroxy-3 : 6-di- <i>sec</i> .-butylpyrazine from <i>iso</i> Leucine. By R. A. BAXTER and F. S. SPRING	1179
222. Pyrazine Derivatives. Part IV. Pyrazine <i>N</i> -Oxides and their Conversion into Chloropyrazines. By G. T. NEWBOLD and F. S. SPRING	1183
224. β -Cycloylpropionitriles. Part I. A General Synthesis and Conversion into Pyrrole Dyes. By EDWARD B. KNOTT	1190
225. β -Cycloylpropionitriles. Part II. Conversion into Bis-2-(5-cyclylpyrrole)azamethine Salts. By EDWARD B. KNOTT	1196
228. Pectic Substances. Part V. The Molecular Structure of Strawberry and Apple Pectic Acids. By G. H. BEAVAN and J. K. N. JONES	1218
229. Pectic Substances. Part VI. The Structure of the Araban from <i>Arachis Hypogaea</i> . By E. L. HIRST and J. K. N. JONES	1221
230. Pectic Substances. Part VII. The Constitution of the Galactan from <i>Lupinus albus</i> . By E. L. HIRST, J. K. N. JONES, and (MRS.) W. O. WALDER	1225
231. The Reactions of <i>N</i> -Benzenesulphonylbenzisoctiazolone with Aromatic Amines. By (the late) ERNEST W. MCCLELLAND and RAYMOND H. PETERS	1229
232. A Method of Synthesis of Trinitromethane Derivatives. By W. S. REICH and (in part) G. G. ROSE and W. WILSON	1234
233. The Reaction of Benzoic Anhydride with Aromatic Compounds Catalysed by Boron Trifluoride. By P. H. GIVEN and D. LL. HAMMICK	1237
236. The Constitution of a By-product from the Preparation of Trichloropyrimidine from Barbituric Acid. By F. E. KING, T. J. KING, and P. C. SPENSLEY	1247
NOTE.—2- <i>cyclo</i> Hexenones from 2-Methylpyridines. By ARTHUR J. BIRCH	1270

**Address and Lectures delivered during or in connexion with the
Centenary Celebration of the Chemical Society.**

ADDRESS.

By THE PRESIDENT, PROFESSOR C. N. HINSELWOOD, M.A., Sc.D., D.Sc., F.R.S. 1271

LECTURE.—A Century of Chemistry.

By SIR HAROLD HARTLEY, K.C.V.O., M.C., F.R.S. 1278

THE EIGHTEENTH FARADAY LECTURE.—The Development of Electrochemical Theories of the Course of Reactions of Carbon Compounds.

By SIR ROBERT ROBINSON, M.A., D.Sc., LL.D., P.R.S. 1288

CONTENTS.

PAPERS COMMUNICATED TO THE CHEMICAL SOCIETY.

General, Physical, and Inorganic.

	PAGE
239. Theory of Chromatography. Part II. Chromatograms of a Single Solute. By E. GLUECKAUF	1302
240. Theory of Chromatography. Part III. Experimental Separation of Two Solutcs and Comparison with Theory. By J. I. COATES and E. GLUECKAUF	1308
241. Theory of Chromatography. Part IV. The Influence of Incomplete Equilibrium on the Front Boundary of Chromatograms and on the Effectiveness of Separation. By E. GLUECKAUF and J. I. COATES	1315
242. Theory of Chromatography. Part V. Separation of Two Solutcs Following a Freundlich Isotherm. By E. GLUECKAUF	1321
249. Qualitative Semimicro-analysis with Reference to Noyes and Bray's System: Partial Analysis of the Combined Nickel, Zirconium, and Rare-earth Groups. By CHRISTINA C. MILLER	1347
250. Magnetic Studies on Polymerisation. Part I. Magnetic Optical Rotatory Powers and Diamagnetic Susceptibilities of Certain Polymethyl Methacrylates. By (Miss) M. E. BEDWELL	1350
THE TILDEN LECTURE—Some Applications of Surface Chemistry to Problems in Colloid Science. By A. E. ALEXANDER, B.Sc., M.A., Ph.D.	1422

Organic.

243. The Minor Alkaloids of <i>Duboisia myoporoides</i> . Part IV. Valeroidine. By WILLIAM MITCHELL and E. M. TRAUTNER	1330
244. Contributions to the Chemistry of Synthetic Antimalarials. Part IV. Hydrazine Hydrolysis and Radical Exchange Reactions of <i>N</i> -Substituted Phthalimides in Relation to the Constitution of the Antimalarial R.63. By H. J. BARBER and W. R. WRAGG	1331
245. The Constitution of Copæne. By LINDSAY H. BRIGGS and WILLIAM I. TAYLOR	1338
246. Some Derivatives of D-Galacturonic Acid. By J. K. N. JONES and M. STACEY	1340
247. Synthesis of Some Derivatives of D- and L-Arabinose. By J. K. N. JONES, P. W. KENT, and M. STACEY	1341
248. The Quantitative Separation of Methylated Sugars. By F. BROWN and J. K. N. JONES	1344

164. The Crystal Structure of Strontium Azide.

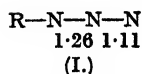

By F. J. LLEWELLYN and F. E. WHITMORE.

The structure of strontium azide has been completely determined by means of three-dimensional Fourier sections and lines using all the $\{hkl\}$ structure amplitudes obtainable with Cu- $K\alpha$ X-radiation. The structure is ionic, each strontium ion being surrounded by 8 azide ions, arranged in two sets, at distances 2.63 and 2.77 Å., severally. The azide ion is linear and symmetrical, the nitrogen-nitrogen separation being 1.12 Å.

THE azide grouping (N_3) has been shown by X-ray and electron-diffraction studies to be linear in both electrovalent and covalent substances. In the former, typified by sodium and ammonium azides (Frevel, *J. Amer. Chem. Soc.*, 1936, 58, 779; *Z. Krist.*, 1936, 94, A, 197) the two nitrogen-nitrogen separations in the azide ion are equal; the ion resonates between the three structures (a), (b), and (c),

each of which is equally important, and stabilisation is effected by the considerable resonance energy; the nitrogen-nitrogen separation is 1.15 Å. In the latter case, typified by cyanuric triazide (Knaggs, *Proc. Roy. Soc.*, 1935, 150, A, 576), these two nitrogen-nitrogen bonds are not equivalent and the azide grouping has the dimensions shown in (I).

The three most probable resonance forms for the covalently linked azide group are (d), (e), and (f):

the last probably does not contribute to any appreciable extent, for it involves adjacent positive charges which render this form more unstable. Resonance therefore occurs between (d) and (e), leading to an unsymmetrical grouping of lower stability than the azide ion.

The stability of metallic azides to heat, friction, and impact varies considerably and is determined, at least in part, by the bonding between the metal and the azide group. Thus, the alkali-metal azides, which are ionic, are stable both to friction and to impact and are only decomposed gently by heat at 300–400°. The alkaline-earth azides are decomposed more violently by heat at a lower temperature (*ca.* 110–160°) but remain insensitive to friction and impact. On the other hand, azides of the heavier metals, *e.g.*, lead, and those of many of the B-sub-group elements, *e.g.*, copper and silver, decompose sometimes with explosive violence when lightly struck or rubbed.

Between these two extremes there is a large number of azides of intermediate properties in which it may be assumed that the linkage of the azide group is more or less covalent. The following investigation of the structure of strontium azide is the first of a series in which it is hoped to trace the development of covalent bonding with increasing instability.

Preliminary Crystallographic Data.—Small, well-defined, orthorhombic, bipyramidal (pseudo-tetragonal) crystals of strontium azide exhibiting the form $\{111\}$ were obtained by slowly evaporating the aqueous solution to dryness in an Erlenmeyer flask. Single-crystal rotation photographs using Cu- $K\alpha$ X-radiation gave the cell dimensions: $[a] = 11.82$, $[b] = 11.47$, $[c] = 6.08$ Å. Oscillation photographs about the three principal axes revealed the halvings $\{hkl\}$ absent when $h + k \neq 2n$, $h + l \neq 2n$, $k + l \neq 2n$; $\{0kl\}$ absent when $k \neq 2n$, $l \neq 2n$, $k + l \neq 4n$; $\{h0l\}$ absent when $h \neq 2n$, $l \neq 2n$, $h + l \neq 4n$; and $\{hkh0\}$ absent when $h \neq 2n$, $k \neq 2n$, $h + k \neq 4n$. The space-group is therefore F_{dd} . The observed density is 2.73 g./c.c.; calculated for eight molecules in the unit cell, 2.77 g./c.c.

The space-group F_{dd} accommodates 32 general positions, five sets of 16-fold special positions, and two sets of 8-fold special positions. Since there are 8 strontium ions in the unit cell, these must be located in one of the sets of 8-fold special positions, and because the choice between these is arbitrary, the co-ordinates may be written down as (000), $(0\frac{1}{2}\frac{1}{2})$, $(\frac{1}{2}0\frac{1}{2})$, $(\frac{1}{2}\frac{1}{2}0)$, $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$, $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$, $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$, $(\frac{1}{2}\frac{1}{2}\frac{1}{2})$.

The azide grouping can conveniently be dealt with in two parts: (a) the central nitrogen atoms, of which there are 16, must lie in one of the 16-fold special positions; and (b) the end nitrogen atoms, of which there are 32 located in the general positions, or in two sets of 16-fold positions.

(a) The five sets of 16-fold positions can be classified into two kinds; the first is centro-

symmetrical, and the second possesses two-fold axial symmetry. Thus, whatever the actual position of the azide group, it must possess either a centre of symmetry or a two-fold axis.

Measurement of Intensities.—The intensities of the diffracted beams from all the planes $\{hkl\}$ observed by using Cu-K α X-radiation were obtained by visual estimation using a simple comparator on which a number of photographic spots produced by beams of known intensity had previously been recorded. From these intensities a set of structure amplitudes, on an arbitrary scale, can be obtained by using the relation $F = k\sqrt{IDp/L}$, the symbols of which are defined in an earlier paper (this vol., p. 838).

Usually it is convenient to render a set of relative structure amplitudes absolute by comparing directly a number of diffracted beams with some standard beam—normally the 400 reflection from the ground cleavage face of rock-salt. In this particular case we did not consider this to be necessary since the phases of nearly all the structure amplitudes could be deduced from the known position of the strontium atoms. When the structure was completed, the experimental structure amplitudes were made absolute by multiplying by the factor $F_{\text{calc.}}/F_{\text{obs.}}$. The table includes a list of the experimental structure amplitudes and also the calculated phases and structure amplitudes.

<i>hkl.</i>	<i>F</i> _{calc.}	<i>F</i> _{obs.}	<i>hkl.</i>	<i>F</i> _{calc.}	<i>F</i> _{obs.}	<i>hkl.</i>	<i>F</i> _{calc.}	<i>F</i> _{obs.}

Determination of the Structure.—The strontium atoms located at (000), etc., will be in phase and contribute to all the observed $(h\bar{h}0)_x$, $(h0l)$, and $0kl$ planes. Since the contributions of the

strontium atoms will in general be greater than that of the nitrogens, as a first approximation, the phase of these planes was taken as 0° , or, in other words, these structure amplitudes are positive. A Fourier projection on the c -plane using all the $hk0$ structure amplitudes was therefore computed in order to determine the approximate co-ordinates of the atoms of the azide group. Two peaks were observed having (xy) co-ordinates $(0.125, 0.000)$ and $(0.125, 0.075)$. It therefore appeared likely that the central nitrogen atom was located on the two-fold axis which passes through the origin and is parallel to the $[a]$ axis. That the atoms of the azide group have x co-ordinates approximately equal to 0.125 is indicated by the relative magnitudes of F_{400} — very small, F_{800} — very large, F_{1200} — very small; F_{h00} being calculable by the equation

$$F_{h00} = 8f_{\text{Sr}} + 16f_{\text{N centre}} \cos 2\pi hx + 32f_{\text{N}} \cos 2\pi hx$$

Having thus established that the central nitrogen atom lies along the $[a]$ axis, two possibilities arise: the peak observed at (xy) co-ordinates $(0.125, 0.000)$ may be due to an atom having (xyz) co-ordinates $(0.125, 0.000, 0.000)$ leading to the 16 positions $(0.125, 0.000, 0.000)$, $(-0.125, 0.000, 0.000)$, $(0.375, 0.250, 0.250)$, $(0.125, 0.250, 0.250)$, $(0.125, 0.500, 0.500)$, $(-0.125, 0.500, 0.500)$, $(0.375, 0.750, 0.750)$, $(0.125, 0.750, 0.750)$, $(0.625, 0.000, 0.500)$, $(0.375, 0.000, 0.500)$, $(0.875, 0.250, 0.750)$, $(0.625, 0.250, 0.750)$, $(0.625, 0.500, 0.000)$, $(0.375, 0.500, 0.000)$, $(0.875, 0.750, 0.250)$, $(0.625, 0.750, 0.250)$, or to an atom at $(0.375, 0.000, 0.000)$ leading to 16 positions as above. It will be readily seen that these two possibilities reduce to the same set of (xy) co-ordinates.

FIG. 1.

The atomic co-ordinates $(0.125, 0.000, 0.000)$ for the central nitrogen are extremely improbable since the separation from the strontium atom at the origin would then be only 1.47 \AA , considerably less than the sum of the Sr^{2+} and N^- radii. Attention was therefore directed to the other possibility in which the two nitrogen atoms have the approximate co-ordinates

$$\text{N}_1 \text{ centre } 0.375 \quad 0 \quad 0 \quad \text{N}_2 \quad 0.375 \quad y \quad z$$

The three-dimensional Fourier line, parallel to the $[a]$ axis, passing through the point $x = 0$, $y = 0$ showed a large maximum at $z = 0.375$. A three-dimensional Fourier section parallel to the a -plane at a height $z = 0.375$ led to (yz) co-ordinates $(0.075, 0.083)$ for the terminal nitrogen atom of the azide group. Further, three-dimensional Fourier lines and sections were then computed in order to refine these co-ordinates; during this process only a small number of those structure amplitudes towards which the strontium atoms contribute changed sign, but there was a general rearrangement in those for which the strontium contribution is zero. The final co-ordinates, derived from the Fourier section shown in Fig. 1 and the three-dimensional Fourier lines parallel to the $[a]$ axis, are:

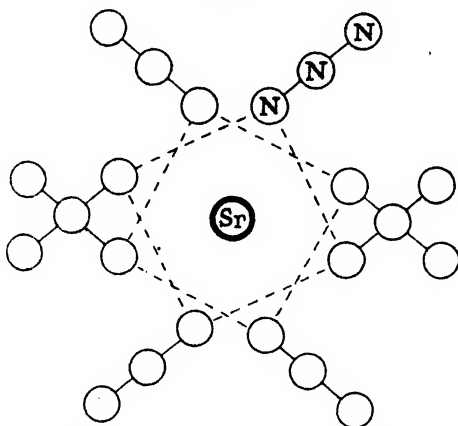

$$\text{Sr } 0 \quad 0 \quad 0 \quad \text{N}_1 \quad 0.383 \quad 0 \quad 0 \quad \text{N}_2 \quad 0.383 \quad 0.058 \quad 0.148$$

The agreement between the observed and the calculated structure amplitudes (the average discrepancy is 27%) is not of the same order as it is now customary to expect in structural determinations of organic substances; this may be attributed to the presence of the very heavy

strontium atom, which renders intensity measurements difficult; the contribution of the azide ion to the observed intensity is probably of the order of the experimental error for a high proportion of the planes.

Discussion of the Structure.—The equivalence of the two nitrogens at either end of the azide group—each is separated from the central nitrogen by 1.12 Å.—shows that the structure is ionic. Fig. 2 represents the disposition of the nearest azide ions around any strontium ion. The

FIG. 2.

strontium ion has eight near neighbours; these can conveniently be classified in two sets of four. In the first set the strontium–nitrogen separation is 2.63 Å., and in the second set 2.77 Å. Each azide ion is disposed between four strontium ions, two at a distance of 2.77 Å. and two at 2.63 Å.

Experimental. Strontium carbonate (5 g.) was dissolved in 2% hydrazoic acid (30 ml.) and the solution concentrated on a water-bath; on cooling, a mass of extremely small crystals was deposited. Larger crystals suitable for X-ray photography were obtained from the mother-liquor by slow evaporation in an Erlenmeyer flask.

This work forms part of a programme of fundamental research sponsored by the Ministry of Supply at the University of Birmingham; approval for publication has been granted by the Director General of Scientific Research and Development, Ministry of Supply.

[Received, September 9th, 1946.]

165. The Crystal Structure of *p*-Dinitrobenzene.

By F. J. LLEWELLYN.

The crystal structure of *p*-dinitrobenzene has been completely determined by utilising all the diffracted beams obtainable with Cu- $K\alpha$ X-radiation. The molecule is centrosymmetrical, and the carbon atoms of the benzene nucleus are located on a regular hexagon such that the C–C distance is 1.38₈ Å. The nitro-group is planar, and coplanar with the rest of the molecule; its dimensions are C–N = 1.41, N–O = 1.23 Å.

THE crystal structure of *p*-dinitrobenzene has been previously investigated by Hertel (*Z. physikal. Chem.*, 1930, 7, B, 188), Bannerjee (*Phil. Mag.*, 1934, 18, 1004), and James, King, and Horrocks (*Proc. Roy. Soc.*, 1935, 153, A, 225); in the last investigation Mo- $K\alpha$ radiation was used to determine the intensities of the diffracted beams from the $\{h0l\}$, $\{hk0\}$, and $\{0kl\}$ planes—about 200 in all—the atomic parameters being determined by means of Fourier projections on the (a), (b), and (c) faces. The main features of the results are as follows: (i) The molecule of *p*-dinitrobenzene is centrosymmetrical; the benzene ring is not, however, a regular hexagon, as has previously been reported in other solid benzenoid substances, e.g., benzene (Cox, *Proc. Roy. Soc.*, 1932, 135, A, 491), hexamethylbenzene (Lonsdale, *ibid.*, 1929, 123, A, 494). (ii) The nitro-group and the carbon of the benzene ring to which it is bonded are not coplanar. (iii) The two oxygen atoms of the nitro-group are not equidistant from the nitrogen atom.

The irregularity of the benzene ring and the non-equivalence of the two oxygen atoms of the nitro-group are not compatible with the usual conceptions of the function of resonance

which is to be expected in such a substance; various objections to, and criticisms of, these results have been made (see Pauling, "Nature of the Chemical Bond," p. 201). It seemed probable that, whilst the general arrangement of the molecules in the unit cell had been correctly determined, the detailed description of the molecule was inaccurate, mainly because the number of intensities used in computing the Fourier synthesis was insufficient, and also because of the considerable overlapping which occurs in projecting the structure on to both the *a*- and the *c*-planes.

It was decided, therefore, to repeat the structure determination, utilising all the $\{hkl\}$ intensities obtainable with Cu-K α X-radiation—about 450 in all—and to ascertain the atomic co-ordinates by means of three-dimensional Fourier lines and sections.

Preliminary Crystallographic Data.—Small, well-defined, single crystals of *p*-dinitrobenzene were readily obtained by slow evaporation of an acetone solution; they exhibited the forms $\{110\}$, $\{100\}$, $\{101\}$, $\{011\}$, $\{111\}$; the symmetry appeared to be monoclinic holohedral and the habit was variable. X-Ray rotation and oscillation photographs confirmed the monoclinic symmetry and the axial dimensions previously reported by James *et al.* (*loc. cit.*), viz., $[a] = 11.05$ Å., $[b] = 5.42$ Å., $[c] = 5.65$ Å., $\beta = 92^\circ 18'$; whence $a : b : c = 2.039 : 1 : 0.42$. Axial ratios quoted by Bodewig (*Ann. Physik*, 1876, **158**, 239) are $a : b : c = 2.038 : 1 : 0.43$, $\beta = 92^\circ 18'$.

Various values for the density (g./c.c.) appear in the literature: 1.546 (Barker, *Z. Krist.*, 1908, **44**, 154), 1.625 (Lobry de Bruyn, *Rec. Trav. chim.*, 1894, **13**, 111), 1.623 (Brandl, quoted by Groth, "Chemische Kristallographie," **4**, 14), 1.64 (James *et al.*, *loc. cit.*); the density calculated from the X-ray data on the basis of two molecules in the unit cell is 1.64 (obs., by flotation, 1.63).

The only systematic halvings observed in the analysis of the X-ray oscillation photographs are $\{h0l\}$ absent when $h + l \neq 2n$, and $\{0k0\}$ absent when $k \neq 2n$. The space-group is therefore $P2_1/n(C_{2h}^2)$, which accommodates the four general positions $\pm(x, y, z)$ and $\pm(x + \frac{1}{2}, \frac{1}{2} - y, \frac{1}{2} + z)$ in each unit cell. Since there are only two molecules in the cell, it follows that these must be orientated about special two-fold positions, i.e., each molecule is centrosymmetrical.

Measurement of Intensities.—In order to make the structure determination as accurate as possible, the intensities of the diffracted beams from all the $\{hkl\}$ planes with spacings greater than 0.77 Å. were determined photographically. Since photographic density is proportional to X-ray intensity only over a limited range (from 0 to 1.2 approximately) it was necessary to take a number of oscillation photographs covering the same range of crystal orientation in order that all the diffracted beams which occur should be recorded as photographic spots whose density was within the proportionality limits. Two methods were adopted: (a) to vary the exposure, in which case the whole photograph was either more or less dense in proportion to this variation, or (b) to maintain the exposure constant but to screen (with aluminium sheets of known absorbing power) those parts of the photographic film on which the more intense diffracted beams fell such that their photographic impression lay within the proportionality limits.

The latter method was finally adopted, since it permitted an easy correlation between the strongest and weakest spots on a given photograph and considerably reduced the number of photographs necessary with (a) to achieve the same end. The actual measurement was carried out visually by matching each of the spots on the photographic film, in turn, with one of a series of spots of known density on a previously prepared comparator. The standard series of spots on the comparator was obtained as follows. A piece of X-ray film was exposed to a suitably collimated X-ray beam for a short measured time such that on development a photographic image was just discernible; a second piece of film was then exposed to the same X-ray beam for this time, then moved to a new position and exposed again for a longer time, this operation being repeated with successive increases in exposure until the necessary range of density was covered. The film was developed under conditions exactly similar to those obtaining in the photography of the crystal. In order to facilitate the matching of the spots, those on the comparator were made to approximate in both size and shape to those produced on the oscillation photographs.

A set of intensities on an arbitrary scale was thus produced, and these were converted to an absolute scale by direct photometric comparison of the intensities of the orders of (100) with the (400) reflection from the ground cleavage face of rock-salt. The experimental structure amplitudes ($F_{\text{obs.}}$) derived from the observed intensities Q by the relation

$$Q = \frac{N^2 e^4 \lambda^3}{2m^2 c^4} \cdot \frac{1 + \cos^2 2\theta}{\sin 2\theta} \cdot F^2$$

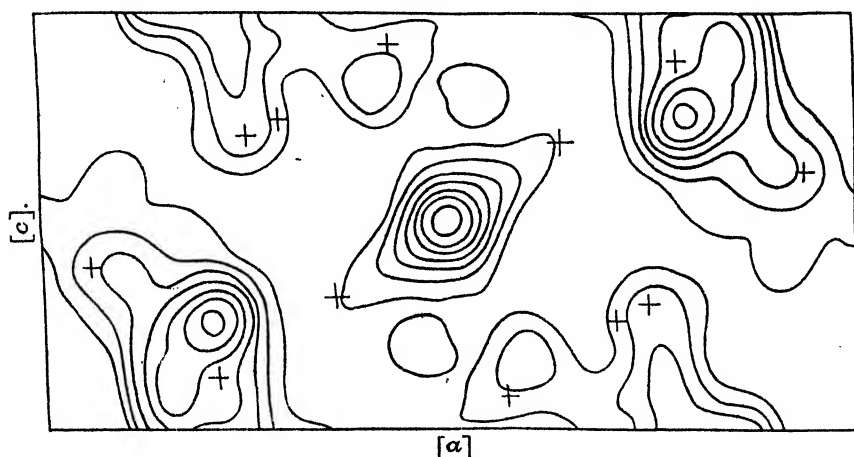

are listed in the table together with the calculated structure amplitudes ($F_{\text{calc.}}$) and the phase angles derived from the final atomic co-ordinates.

Determination of the Structure.—In order to define the structure it is necessary to determine the co-ordinates of six atoms, *viz.*, three carbons of the benzene ring, and one nitrogen and two oxygens of the nitro-group. The other half of the molecule is determinable by the operation of the centre of symmetry, and the second molecule by the operation of the glide plane. Since all the atoms in the structure are located in general positions, $\pm(x, y, z)$, $\pm(x + \frac{1}{2}, \frac{1}{2} - y, \frac{1}{2} + z)$, it is to be expected that a three-dimensional Harker-Patterson synthesis (*J. Chem. Physics*, 1936, 4, 381) evaluated at $y = \frac{1}{2}$ would exhibit maxima in the Patterson function P_{xzs} , where

$$P_{xzs} = \sum \sum \cos 2\pi(hx + lz) \left(\sum_k F_{hkl}^2 \cos 2\pi k/2 \right)$$

at the points $\pm(\frac{1}{2} - 2x_r, \frac{1}{2} - 2z_r)$, (x_r, z_r) being the co-ordinates of an atom, and thus provide for the direct determination of the (xz) co-ordinates of all the atoms in the structure. Such a three-dimensional synthesis was evaluated, and the resulting contour map (Fig. 1) plotted over the whole unit cell; it is obvious that the maxima are too diffuse to be of any great service in determining accurate atomic co-ordinates.

FIG. 1.

Patterson-Harker Section at $y = \frac{1}{2}$.

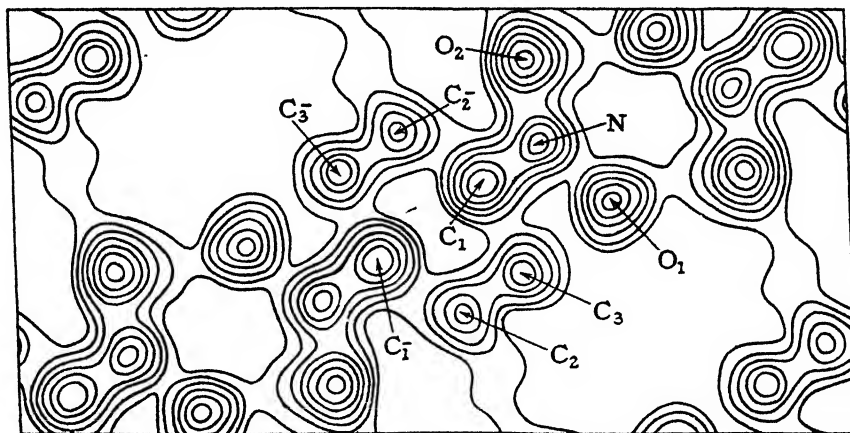

This result is in sharp contrast with that obtained in the determination of the structure of pentaerythritol (Llewellyn, Cox, and Goodwin, *J.*, 1937, 883) in which a Patterson-Harker three-dimensional summation gave rise to sharp maxima in the function P_{xy0} and permitted the accurate determination of the (xy) co-ordinates of the pentaerythritol molecule. It is interesting to compare the positions of the maxima P_{xzs} as represented by the peaks in Fig. 1 with the positions (represented by crosses) of the maxima calculated from the final atomic co-ordinates. Although it may be allowed that there is qualitative coincidence, yet the value of the Patterson synthesis in determining even approximate atomic co-ordinates is practically negligible. This question is further discussed by Booth and Llewellyn (this vol., p. 839).

It became necessary therefore to postulate a molecule and a molecular orientation and to refine the resulting atomic co-ordinates in three stages: (i) by trial-and-error methods using the $\{h0l\}$ structure amplitudes to determine the x and z co-ordinates; (ii) to refine these co-ordinates by two-dimensional Fourier syntheses; (iii) to obtain approximate y co-ordinates from a consideration of the x and z co-ordinates determined in (ii) and the bond lengths postulated in the molecule, and to refine these (xyz) co-ordinates by three-dimensional Fourier sections and lines.

The model used in the first stages consisted of a regular hexagon for the benzene ring with carbon-carbon separations of 1.39 Å., a planar $\text{R}\cdot\text{NO}_2$ group which was coplanar with the benzene ring with carbon-nitrogen separation of 1.47 Å., and a nitrogen-oxygen separation of 1.23 Å. This model was placed in the unit cell with the centre of the benzene ring coincident with the centre of symmetry (origin) and orientated by trial-and-error methods until approx-

imate agreement between the observed and calculated values of a few $\{h0l\}$ structure amplitudes was obtained. The (xz) co-ordinates were then refined by means of a number of two-dimensional Fourier projections involving all the $\{h0l\}$ amplitudes. The resulting contour map is shown in Fig. 2.

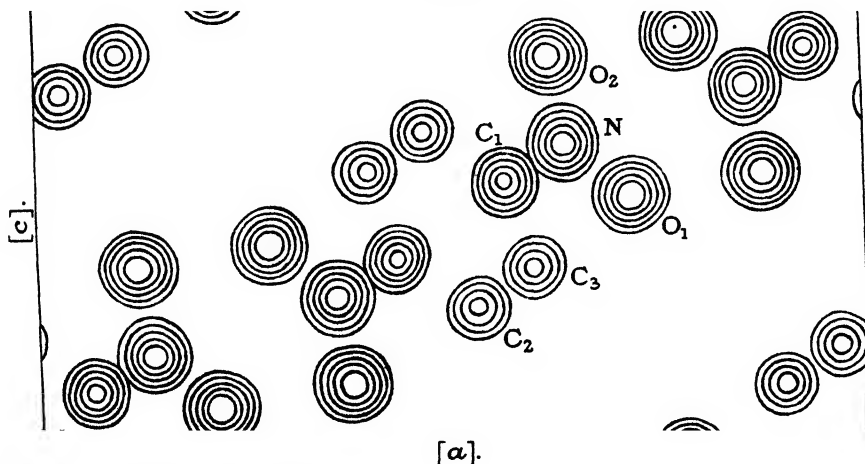

FIG. 2.

Fourier Projection on to 010.

These co-ordinates were then used in conjunction with the model to calculate approximate y co-ordinates. With these (xyz) co-ordinates the phase angles of all the $\{hkl\}$ structure amplitudes were calculated, and then the co-ordinates refined by successive three-dimensional Fourier lines parallel to $[010]$ at the xy co-ordinates of each atom in turn and by three-dimensional Fourier sections parallel to (010) at the y co-ordinates of each of the atoms. After two such complete cycles of operations the agreement between the calculated and the observed structure amplitudes became satisfactory; a third set of syntheses resulted in no alteration of the phase angles. The various Fourier sections are illustrated in a composite drawing in Fig. 3.

FIG. 3.

The final atomic co-ordinates are :

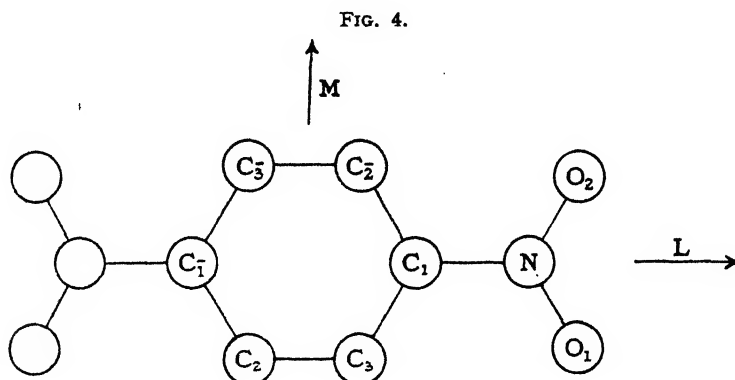

Atom.	x .	y .	z .	Atom.	x .	y .	z .
C ₁	0.070	0.192	0.090	N	0.142	0.387	0.184
C ₂	0.032	-0.117	-0.206	O ₁	0.220	0.472	0.057
C ₃	0.102	0.075	-0.115	O ₂	0.124	0.460	0.385

The average discrepancy between observed and calculated structure factors is 24%.

Description of the Structure.—A diagrammatic representation of the *p*-dinitrobenzene molecule is shown in Fig. 4. The atoms C_1, C_2 , etc., are obtained by inversion of the atoms C_1, C_2 , etc., across the centre of symmetry coincident with the centre of the molecule. Within the limits of experimental error all the atoms lie in a plane which is so orientated within the

unit cell that the molecular axes, L and M , make angles of $48^\circ 42'$ and $5^\circ 42'$ respectively with the plane 010. Bond angles and bond lengths calculated from the measured atomic co-ordinates and cell dimensions are as follows:

$C_1-C_2 = 1.38_5 \text{ \AA.}$	$C_1-N = 1.41 \text{ \AA.}$	$\angle O_1-N-O_2 = 124^\circ$
$C_2-C_3 = 1.38_5 \text{ \AA.}$	$N-O_1 = 1.23 \text{ \AA.}$	$\angle O_1-N-C_1 = 117_4^\circ$
$C_3-C_4 = 1.38_5 \text{ \AA.}$	$N-O_2 = 1.23 \text{ \AA.}$	$\angle O_2-N-C_1 = 118_4^\circ$

Other distances within the molecule are: $O_1-O_2 = 2.17$; $C_1-O_1 = 2.25$; $C_1-O_2 = 2.25 \text{ \AA.}$ The error in the bond lengths is probably not more than $\pm 0.02 \text{ \AA.}$, and the angles are probably accurate to within $\pm 2^\circ$.

The anomalies in the bond lengths and bond angles reported by James (*loc. cit.*) are not substantiated by the present investigation. The benzene ring is a regular hexagon, and in this respect falls into line with the results of earlier structural work on benzenoid substances.

The two oxygen atoms of the nitro-group are equidistant at 1.23 \AA. from the nitrogen atom. This result is in agreement with the resonance mechanism suggested by Pauling in which the two principal forms are:

The observed distance, 1.23 \AA. , is greater than the calculated value of 1.19 \AA. and agrees more nearly with the value of 1.21 ± 0.02 found in nitromethane. The ONO bond angle is 124° as compared with 127° found in nitromethane and the theoretical value of $125^\circ 16'$.

This work forms part of a programme of fundamental research sponsored by the Ministry of Supply at the University of Birmingham; approval for publication has been granted by the Director General of Scientific Research and Development, Ministry of Supply.

THE UNIVERSITY, BIRMINGHAM 15.

[Received, September 9th, 1946.]

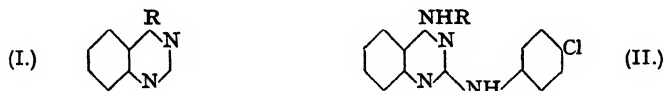

166. Synthetic Antimalarials. Part XVI. 4-Dialkylaminoalkylamino-quinazolines. Variation of Substituents in the 6- and 7-Positions.

By NORMAN B. CHAPMAN, GEOFFREY M. GIBSON, and FREDERICK G. MANN.

A series of seven quinazolines having different dialkylaminoalkylamino-groups in the 4-position has been prepared. Series of 4-dialkylaminoalkylaminoquinazolines, having in addition the 6-chloro-, 7-chloro-, 7-nitro-, 6-methoxy-, and 7-methoxy-substituents, have also been synthesised. This wide range of quinazolines has been tested for antimalarial activity and some noteworthy variations have been revealed.

THIS investigation originated in the observation made in the laboratories of Imperial Chemical Industries Ltd. that 4- γ -diethylaminopropylaminoquinazoline (I; $R = \text{NH} \cdot [\text{CH}_2]_3 \cdot \text{NEt}_2$) showed activity against *P. gallinaceum* in chicks. This result was apparently at variance with those of Magidson and Golovchinskaya (*J. Gen. Chem. Russia*, 1938, 8, 1797) who first prepared this compound, its 6-chloro-derivative, and several other 6-substituted 4-dialkylaminoalkylaminoquinazolines and reported that they possessed no antimalarial activity. It appeared that the apparent discrepancy might possibly be due to a species specificity which these quinazoline derivatives might show in their antimalarial action, the Russian workers having probably tested the compounds against *P. præcox* (cf. Magidson *et al.*, *J. Microbiol. and Immunobiol.*, 1934, 13, 685; *Trop. Dis. Bull.*, 1935, 32, 419).

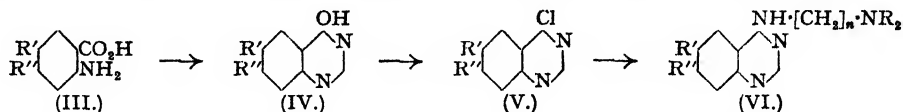

In view of the fact that 2-*p*-chloroanilino-4-dialkylaminoalkylaminoquinazolines of type (II; $R = \text{dialkylaminoalkyl}$) had also been shown to possess marked antimalarial activity against *P. gallinaceum* in chicks (Curd, Landquist, and Rose, Part XIV, this vol., p. 775) it became desirable to make a systematic study of the relationship between structure and antimalarial activity in 4-dialkylaminoalkylaminoquinazolines of type (I). Accordingly, we first prepared a series of compounds of type (I) having no substituent in the benzene ring, but

having in turn seven different dialkylaminoalkylamino-groups in the 4-position. We then prepared five similar series of compounds having in turn the 6-chloro-, 7-chloro-, 7-nitro-, 6-methoxy-, and 7-methoxy-substituents. Our choice both of these groups and their position was determined largely by the presence of the same groups in analogous positions in various quinoline and acridine compounds of known antimalarial activity. Thus, for instance, Magidson and Rubtsov (*J. Gen. Chem. Russia*, 1937, 7, 1896) and Schönhöfer (*Z. physiol. Chem.*, 1942, 274, 1) have reported on the antimalarial activity of 4-dialkylaminoalkylamino-6-methoxyquinolines, and D.R.-P. 683,692 relates *inter alia* to 7-halogeno-4-dialkylaminoalkylaminoquinolines which are stated to possess antimalarial activity. 7-Nitro-4- β -diethylaminoethylamino-3-ethoxyacridine (Magidson and Grigorowsky, *Ber.*, 1936, 69, 396) is an example of an active antimalarial containing a nitro-group.

Over forty 4-dialkylaminoalkylaminoquinazolines have thus been prepared. In addition, some of the 4-hydroxyquinazoline derivatives utilised as intermediates in the synthesis of these quinazolines (*vide infra*) have also been submitted for test for prophylactic action because they were seen to be distantly related to Endochin (4-hydroxy-7-methoxy-3-*n*-heptylquinaldine) (C.I.O.S. Reports Nos. XXIII, 12, 13; XXIV, 20; XXV, 54, H.M. Stationery Office; see also Fitch, *Pharm. J.*, 1945, 182) which is stated to possess prophylactic activity against avian malaria.

The general route employed for the preparation of all these quinazolines consisted first in heating the appropriate anthranilic acid (or ester) (III) with formamide to obtain the

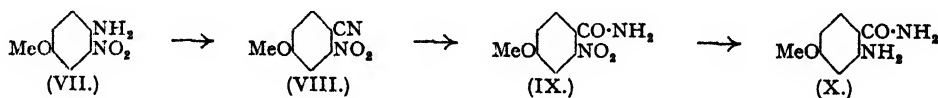

corresponding 4-hydroxyquinazoline (IV), which when suitably treated with a mixture of phosphorus pentachloride and phosphorus oxychloride gave the 4-chloroquinazoline (V). This when boiled in alcoholic solution with the dialkylaminoalkylamine furnished the 4-dialkylaminoalkylaminoquinazoline (VI), which was isolated either as the free base or directly as the hydrochloride.

The various substituted anthranilic acids and quinazoline intermediates were prepared as follows. Direct chlorination of methyl anthranilate (Freundler, *Bull. Soc. chim.*, 1911, 9, 606) gave methyl 5-chloroanthranilate (as III; $R' = \text{Cl}$, $R'' = \text{H}$) which readily condensed with formamide to give 6-chloro-4-hydroxyquinazoline (IV; $R' = \text{Cl}$, $R'' = \text{H}$) and thence 4:6-dichloroquinazoline (V; $R' = \text{Cl}$, $R'' = \text{H}$) (cf. Magidson *et al.*, *loc. cit.*). 4-Chloroanthranilic acid (III; $R' = \text{H}$, $R'' = \text{Cl}$) was prepared by a modification (Curd *et al.*, forthcoming communication) of Cohn's method (*Monatsh.*, 1901, 22, 485), 4-chloroaceto-*o*-toluidide being oxidised to 4-chloroacetylthranilic acid, and then hydrolysed in turn to

4-chloroanthranilic acid. This acid furnished 7-chloro-4-hydroxyquinazoline (IV; $R' = H$, $R'' = Cl$) and 4:7-dichloroquinazoline (V; $R' = H$, $R'' = Cl$). 4-Nitroanthranilic acid (III; $R' = H$, $R'' = NO_2$), similarly prepared from 4-nitroaceto-*o*-toluidide, furnished 7-nitro-4-hydroxy- and 4-chloro-7-nitro-quinazolines (IV and V; $R' = H$, $R'' = NO_2$).

5-Methoxyanthranilic acid (III; $R' = OMe$, $R'' = H$) was prepared by oxidising 2-nitro-5-methoxybenzaldehyde (Mason, *J.*, 1925, 1195) to 2-nitro-5-methoxybenzoic acid and reducing the latter. This acid gave 4-hydroxy-6-methoxy- and 4-chloro-6-methoxy-quinazoline (IV and V; $R' = OMe$, $R'' = H$).

4-Methoxyanthranilamide (X) was prepared by converting 2-nitro-4-methoxyaniline (VII) into 2-nitro-4-methoxyphenyl cyanide (VIII) (cf., Cook, Heilbron, Reed, and Strachan, *J.*, 1945, 861), which on short treatment with sulphuric acid yielded 2-nitro-4-methoxybenzamide

(IX); reduction with ferrous hydroxide then gave (X). 4-Hydroxy-7-methoxyquinazoline (IV; $R' = H$, $R'' = OMe$) was readily prepared by the action of formic acid on this amide; it was also prepared, but less effectively, by the action of formamide on 4-methoxyanthranilic acid or its methyl ester. The usual treatment then furnished 4-chloro-7-methoxyquinazoline (V; $R' = H$, $R'' = OMe$).

In addition to the above quinazolines in which substituents in the pyrimidine ring were limited to the 4-position, the preparation of 2-amino-4-dialkylaminoalkylaminoquinazolines has been investigated, since Hull, Lovell, Openshaw, Payman, and Todd (Part III, *J.*, 1946, 357) have reported that the corresponding 2-amino-4-dialkylaminoalkylamino-5:6-dimethylpyrimidines possessed antiparasitic activity. For this purpose 2-chloro-4- β -diethylaminoethylaminoquinazoline (XI; $R = NH \cdot [CH_2]_2 \cdot NEt_2$) was heated with alcoholic ammonia to give 2-amino-4- β -diethylaminoethylaminoquinazoline (XII; $R = NH \cdot [CH_2]_2 \cdot NEt_2$), but the yield, which was never high, was markedly decreased by even small changes in the time and temperature of heating. 2-Chloro-4- β -diethylaminoethylaminoquinazoline (cf. Part XIV, *loc. cit.*) was very conveniently prepared by boiling 2:4-dichloroquinazoline (Lange, Roush, and Asbeck, *J. Amer. Chem. Soc.*, 1930, 52, 3698) in alcoholic solution with one equivalent of β -diethylaminoethylamine. 2-Chloro-4- δ -diethylamino- α -methylbutylaminoquinazoline (XI; $R = NH \cdot CHMe \cdot [CH_2]_3 \cdot NEt_2$) was similarly prepared, but this compound could not be satisfactorily converted into the 2-amino-derivative by the action of either alcoholic ammonia or potassium phthalimide. Many attempts were also made to convert 2-chloro-4-methylthioquinazoline (XI; $R = SMe$) (Part XIV) and 2-chloro-4-phenoxyquinazoline (Lange *et al.*, *loc. cit.*) by the action of alcoholic ammonia into their 2-amino-derivatives, in the expectation that the 4-substituent might then be replaced by the δ -diethylamino- α -methylbutylamino-group, but conditions sufficiently vigorous to replace the 2-chlorine atom by the amino-group appeared always to replace similarly the 4-substituent.

Attempts to prepare the 2-amino-compound from 2-chloro-4- β -diethylaminoethylamino-7-methoxyquinazoline also failed. This compound, although first prepared in the laboratories of Imperial Chemical Industries Ltd., has not yet been reported and is therefore described in this paper. Its synthesis involved the preparation of 2:4-dihydroxy-7-methoxyquinazoline from 2-carbamido-4-methoxybenzoic acid, followed by conversion into 2:4-dichloro-7-methoxyquinazoline and condensation with β -diethylaminoethylamine.

The antimalarial activity (against the blood invasive forms of *P. gallinaceum*) of all the above 4-dialkylaminoalkylaminoquinazolines has been estimated by tests in chicks, by the method described by Curd, Davey, and Rose (*Ann. Trop. Med. Parasit.*, 1945, 39, 139). The results are summarised in Table I where the usual method of expressing antimalarial activity is employed. For the antimalarial tests, certain of the 4-substituted quinazolines were weighed as free base (anhydrous or hydrated) which was then solubilised with dilute lactic acid: others were weighed as hydrochlorides or sulphates. The particular compound (base or salt) is accordingly indicated in column 4.

TABLE I.
Antimalarial Activity of 4-Substituted Quinazolines.

The following 4-hydroxyquinazolines were tested for prophylactic activity against *P. gallinaceum* in chicks by the method described by Davey (*Ann. Trop. Med. Parasit.*, 1945, 40, in the press) but found to be inactive: 5681 and 5682 at 4 mg./50 g., and 5683 at 1 mg./50 g. In addition, 5622 was found to be inactive prophylactically at 8 mg./50 g., and 5246, which showed the highest activity against the blood forms of *P. gallinaceum* of all the 4-dialkylaminoalkylaminoquinazolines investigated, likewise showed no prophylactic activity (at 4 mg./50 g.).

Although the detailed biological results, summarised in Table I, will be published and discussed elsewhere, it may be noted that, in each of the six series of 4-dialkylaminoalkylaminoquinazolines investigated, highest activity was found in the compound containing the δ-diethylamino-α-methylbutylamino-side chain and that substitution by a chlorine atom in the 7-position led to the highest activity.

EXPERIMENTAL.

Notes on the Preparation of the Substituted Anthranilic Acids and/or their Derivatives.—Methyl 5-chloroanthranilate (as III: R' = Cl, R'' = H). Direct chlorination of methyl anthranilate (405 g.) by Freunder's method (*loc. cit.*) gave methyl 3:5-dichloroanthranilate (174 g.) and methyl 5-chloroanthranilate (200 g.). The latter had m. p. 67–69° after recrystallisation from light petroleum (b. p. 60–80°), and contained a trace of methyl anthranilate which did not interfere with the preparation of 6-chloro-4-hydroxyquinazoline.

4-Chloroanthranilic acid (III; R' = H, R'' = Cl) and 4-nitroanthranilic acid (III; R' = H, R'' = NO₂). See Curd *et al.*, forthcoming communication.

5-Methoxyanthranilic acid (III; R' = OMe, R'' = H). 2-Nitro-5-methoxybenzaldehyde (Mason, *loc. cit.*) was oxidised by alkaline permanganate at 20° to the corresponding acid in 92% yield; m. p. 132–133°. The nitro-acid was reduced to 5-methoxyanthranilic acid with hot stannous chloride and hydrochloric acid, the tin removed by addition of ammonia, a slight excess of acetic acid added to the filtrate, and the amino-acid isolated by continuous extraction with ether in a percolator; yield, 90%; m. p. 144–147° (decomp.).

2-Nitro-4-methoxybenzamide (IX) and 4-methoxyanthranilamide (X). Concentrated sulphuric acid (1 l.) and water (1 l.) were mixed and heated to boiling. 2-Nitro-4-methoxyphenyl cyanide (200 g.) (Cook *et al.*, *loc. cit.*) was then added during 2 minutes, and the mixture hand-stirred and gently boiled for 4 minutes. It was then rapidly cooled, diluted to 8 l. with ice and water, set aside for 1 hour, and the crude 2-nitro-4-methoxybenzamide (IX) collected and extracted with ammonia. The 2-nitro-4-methoxybenzoic acid (39 g.) in the extract was converted into the amide in the usual way (thionyl chloride, aqueous ammonia), and added to the main portion (m. p. 150–157°) which was then suspended in a solution of hydrated ferrous sulphate (2200 g.) in water (3 l.). The mixture was boiled and stirred, and a slight excess of ammonia gradually added. When cold, the solid was collected and extracted with boiling alcohol. The extract afforded 4-methoxyanthranilamide (X) (137 g.), m. p. 150–153°. A portion of the nitro-amide (IX) had m. p. 161–161.5° after recrystallisation from water (charcoal), unchanged after recrystallisation from alcohol (Found: N, 14.6. C₉H₉O₄N₂ requires N, 14.3%). A portion of the anthranilamide (X) had m. p. 155–155.5° after recrystallisation from water (charcoal), unchanged after recrystallisation from alcohol (Found: N, 17.4. C₉H₁₀O₄N₂ requires N, 16.9%).

In one reduction the amide-iron oxide mixture was dried, pulverised, and extracted with boiling acetone in an automatic apparatus. Removal of the solvent gave 2-isopropylideneamino-4-methoxybenzamide, m. p. 196–196.5° after recrystallisation from much water (charcoal) (Found: C, 63.8; H, 7.0; N, 14.0. C₁₁H₁₄O₄N₂ requires C, 64.1; H, 6.8; N, 13.6%). This anil was hydrolysed to the anthranilamide in 95% yield on boiling for 20 minutes with 25% sulphuric acid.

2-Nitro-4-methoxybenzoic acid. The cyanide (VIII) (20 g.) was refluxed for 2.5 hours with sulphuric acid (75 c.c.) and water (100 c.c.), the mixture cooled and diluted with water, and the 2-nitro-4-methoxybenzoic acid purified by dissolution in ammonia (yield, 20.4 g.); m. p. 195–197° after recrystallisation from water (charcoal).

4-Methoxyanthranilic acid (III; R' = H, R'' = OMe). This acid was prepared from 2-nitro-4-

methoxybenzoic acid in the same way as its 5-methoxy-isomer above, and was precipitated from the ammoniacal solution on addition of acetic acid. Since the amino-acid is nearly completely decarboxylated by boiling for 0.5 hour with 2*N*-hydrochloric acid, the reduction was carried out as rapidly as possible at 85–90°, and the solution then immediately cooled; yield, 85%; m. p. 166–166.5° (decomp.) after recrystallisation from water (charcoal). The methyl ester was prepared by boiling the hydrochloride of the acid with 10% methanolic hydrogen chloride for 3 hours, and purified by washing with ammonia and recrystallisation from aqueous methanol (charcoal); m. p. 75–77°.

Preparation of the 4-Hydroxyquinazolines.—4-Hydroxyquinazoline (IV; $R' = R'' = H$) was obtained in 55% yield by heating anthranilic acid (1 mol.) and formamide (2 mols.) at 135° for 3 hours and recrystallising the product from alcohol.

6-Chloro-4-hydroxyquinazoline (IV; $R' = Cl, R'' = H$) was prepared by heating methyl 5-chloroanthranilate (188 g.) and formamide (200 c.c.) at 180° for 9 hours, the methanol produced being allowed to escape. The product was extracted with cold 3% aqueous sodium hydroxide, the insoluble material (31 g.) removed, and the hydroxyquinazoline (129 g.) obtained from the extract by addition of aqueous ammonium chloride followed by recrystallisation from acetic acid. The alkali-insoluble material gave on recrystallisation from alcohol a compound, m. p. 220–221.5°, which appeared to be a 6-chloro-4-hydroxydihydroquinazoline (Found: C, 52.6; H, 3.9; N, 15.0; Cl, 19.5. $C_8H_7ON_2Cl$ requires C, 52.6; H, 3.8; N, 15.3; Cl, 19.5%).

7-Chloro-4-hydroxyquinazoline (IV; $R' = H, R'' = Cl$) was obtained in 56% yield by heating 4-chloroanthranilic acid (1 mol.) and formamide (2 mols.) at 160° for 3 hours and recrystallising the product from alcohol.

7-Nitro-4-hydroxyquinazoline (IV; $R' = H, R'' = NO_2$) was prepared by heating 4-nitroanthranilic acid (150 g.) and formamide (180 c.c.) at 160° for 6 hours, extracting the product with hot 3% aqueous sodium hydroxide, and acidifying the solution with acetic acid; yield, 152 g.

4-Hydroxy-6-methoxyquinazoline (IV; $R' = OMe, R'' = H$) was prepared by heating 5-methoxyanthranilic acid (84 g.) and formamide (100 c.c.) at 140° for 4.5 hours. The product was extracted with warm 10% aqueous sodium hydroxide, hydrochloric acid and then ammonia added, and the precipitated hydroxyquinazoline recrystallised from alcohol; yield, 75 g.

4-Hydroxy-7-methoxyquinazoline (IV; $R' = H, R'' = OMe$). (a) 4-Methoxyanthranilamide (66 g.) and formic acid (d, 1.20; 70 c.c.) were refluxed at 140° for 2.5 hours. The product was treated with 5% aqueous sodium hydroxide, and hydrochloric acid followed by ammonia added to the extract; this precipitated the hydroxyquinazoline (66 g.).

(b) Methyl 4-methoxyanthranilate (4.2 g.) and formamide (4 c.c.) were heated at 140° for 3 hours. Extraction of the product with cold, dilute sodium hydroxide gave the hydroxyquinazoline (1.3 g.) and a compound (2.2 g.), m. p. 76–78°, which was probably the unchanged ester.

(c) 4-Methoxyanthranilic acid (5 g.) and formamide (3 c.c.) were heated at 140° for 3 hours. The product, boiled with alcohol and cooled, gave the hydroxyquinazoline (1 g.). The alcoholic filtrate was evaporated, and the residue extracted with ether in the presence of aqueous sodium hydroxide. The extract gave a solid (2.4 g.), m. p. 56.5–57.5° after recrystallisation from ether–light petroleum, which appeared to be formo-*m*-anisidine (Reverdin and Luc, *Ber.*, 1914, 47, 1539, give m. p. 57°); it gave *m*-anisidine on hydrolysis with hydrochloric acid. The yield of hydroxyquinazoline was unaffected when the above reaction was carried out with a large excess of formamide. When the amino-acid (0.5 g.) and formamide (1 c.c.) were heated at 100° for 7 hours, the hydroxyquinazoline (0.03 g.) and an unidentified ammonia-soluble substance (0.15 g.), m. p. 189–190°, were obtained.

Preparation of the 4-Chloroquinazolines.—The hydroxyquinazoline (50–100 g., 1 mol.) was boiled with phosphorus pentachloride (1 mol.) and pure phosphorus oxychloride (150–300 c.c.) until the liquid was substantially clear (and no longer), the solvent removed by vacuum distillation, and the residue extracted with boiling light petroleum in a dry atmosphere. The extract deposited the 4-chloroquinazoline on cooling. This method gave products which were almost pure, and were collected as soon as the liquid was cold; otherwise, they tended to decompose. In this way, the following compounds were obtained, the reaction time, the b. p. of the light petroleum used for their isolation, and the yield being indicated in parenthesis: 4-chloroquinazoline (V; $R' = R'' = H$) (2 hours, 60–80°, 45%); 4:6-dichloroquinazoline (V; $R' = Cl, R'' = H$) (3 hours, 80–100°, 90%); 4:7-dichloroquinazoline (V; $R' = H, R'' = Cl$) (1 hour, 80–100°, 60%); 4-chloro-7-nitroquinazoline (V; $R' = H, R'' = NO_2$) (0.5 hour, 80–100°, 70%); 4-chloro-6-methoxyquinazoline (V; $R' = OMe, R'' = H$) (1.5 hours, 40–60°, 57%); 4-chloro-7-methoxyquinazoline (V; $R' = H, R'' = OMe$) (0.25 hour, 60–80°, 50%).

Preparation of the 4-Dialkylaminoalkylaminoquinazolines.—The appropriate 4-chloroquinazoline (10 g., 1 mol.) and the appropriate amine (1.1 mols.) were refluxed in alcohol (50 c.c.) for 0.5–1 hour; the required reaction had then occurred quantitatively. The material was then worked up in either of two ways: (a) the crystalline 4-dialkylaminoalkylaminoquinazoline monohydrochlorides, which were occasionally deposited during the initial refluxing, were isolated either by direct addition of ether or by concentration and dissolution of the resulting syrup in acetone followed, if necessary, by addition of ether. Reference to these salts in Table II indicates when this method of working up was used for the particular compound in question. (b) The solutions were freed from solvent, the residues were taken up in acidulated water, sodium hydroxide was added, and the liberated bases were isolated by extraction with chloroform. When the bases were so hygroscopic as to be difficult to manipulate, or when it was desired to purify them through their salts, they were converted into their disulphates by dissolution in excess of concentrated alcoholic sulphuric acid followed by addition of acetone until just turbid; the salts crystallised out on being kept at 0° for a few hours.

The essential data concerning the above quinazolines and their derivatives are collected in Table II; the following notes give additional information concerning the properties and manipulation of certain of these compounds.

Simple quinazoline series. The dimethylaminopropylamino-compound was hygroscopic. The diethylaminoethoxypropylamino-compound was distilled (b. p. 196–200°/0.03 mm.) before the

TABLE II.
4-Substituted Quinazolines.

All compounds were colourless, except those of the nitro-series which were yellow (hydroxy-compound, brown).
All compounds are new except those indicated by a reference letter in the last column.

recrystallisation indicated in Table II. The monobutylaminopropylamino-compound had b. p. 150—170°/0.0001 mm.

6-Chloroquinazoline series. During m. p. determinations on the diethylaminopropylamino-hydrochloride the melt occasionally solidified and then remelted at 186—187°. In the preparation of the dibutylaminopropylamino-hydrochloride, the cooled reaction mixture deposited waxy plates of a compound which had the same composition as γ -dibutylaminopropylamine dihydrochloride; m. p. 326—327° (decomp.) after recrystallisation from alcohol containing a trace of water (Found: C, 50.8; H, 11.1; N, 10.4; ionic Cl, 27.9. $C_{11}H_{20}N_2 \cdot 2HCl$ requires C, 51.0; H, 10.8; N, 10.8; ionic Cl, 27.4%). Evidence that it was not identical with this diamine salt is: (a) a high m. p. and sparing solubility in pure alcohol would not be expected for such a salt; (b) addition of sodium hydroxide to its aqueous solution precipitated an almost odourless oil; (c) γ -dibutylaminopropylamine dihydrochloride was obtained, either by confinement over solid sodium hydroxide of a solution of the base in a slight excess of concentrated hydrochloric acid or by passing dry hydrogen chloride into a solution of the base in absolute ether, as an uncrystallisable syrup, an alcoholic solution of which failed to crystallise after being kept for several weeks, either alone or after being seeded with the unidentified compound. The latter was encountered during the preparation of all the dibutylaminopropylaminoquinazolines reported in this paper, and evidently arose from an impurity in the γ -dibutylaminopropylamine used.

7-Nitroquinazoline series. The diethylaminopropylamino-, diethylaminomethylbutylamino-, dibutylaminopropylamino-, and diethylaminoethoxypropylamino-bases became dark brown on exposure to light. The last compound was hygroscopic, and formed a syrup on exposure to air. The syrup, which was a monohydrate, ultimately crystallised, and the pure anhydrous base was prepared from the purified hydrate by desiccation over sulphuric acid.

6-Methoxyquinazoline series. On very humid days the diethylaminopropylamino- and dibutylaminopropylamino-bases were hygroscopic, rapidly forming syrups on exposure to air. The piperidinopropylamino-disulphate underwent marked dissociation to the monosulphate on recrystallisation from slightly aqueous alcohol; the dibutylaminopropylamino-disulphate also dissociated when recrystallised in the absence of free sulphuric acid, although much less readily than the previous salt. The diethylaminomethylbutylamino-base monohydrate withstood the drying action of sulphuric acid, and hence must have considerable stability.

7-Methoxyquinazoline series. The diethylaminopropylamino-, dibutylaminopropylamino-, and diethylaminoethoxypropylamino-bases were hygroscopic, and formed syrups on exposure to air. The syrup from the last compound crystallised as the monohydrate on standing, and the pure anhydrous base was obtained from the purified monohydrate by confinement in a vacuum over sulphuric acid. The dibutylaminopropylamino-base could not be satisfactorily recrystallised, and was therefore prepared from its purified disulphate by basification, extraction with pure ether, and removal of solvent, finally in a desiccator over sulphuric acid. The diethylaminomethylbutylamino-base was hygroscopic to an extent depending on the climatic conditions, and was purified through its oxalate as follows: the crude base, dissolved in acetone, was added to excess of a dilute solution of hydrated oxalic acid in acetone. Next day, the acetone was decanted, and the hard residue boiled with alcohol to give a crystalline solid, m. p. 166—167° (decomp.) unchanged after recrystallisation from alcohol containing a trace of water. The constitution of this compound was uncertain, but it appeared to be either the base mono-oxalate monoalcoholate monohydrate or the dihydrated monoethyl oxalate salt of the base (Found for material dried in a vacuum over sulphuric acid: C, 55.9; H, 7.9; N, 12.0. $C_{11}H_{18}ON_2 \cdot C_2H_2O_4 \cdot C_2H_5O \cdot H_2O$ or $C_{11}H_{18}ON_2 \cdot C_2H_5O \cdot 2H_2O$ requires C, 56.2; H, 8.1; N, 11.9%). The base was recovered from this salt by dissolution in water, addition of sodium hydroxide, and extraction with pure ether.

2-Chloro-4- β -diethylaminoethylaminoquinazoline (XI; R = NH \cdot [CH $_2$] $_2$ ·NEt $_2$).—A mixture of 2:4-dichloroquinazoline (6 g.), β -diethylaminoethylamine (4 g., 1.1 mols.), and alcohol (25 c.c.) was refluxed for 30 minutes. After cooling, the hydrochloride of the quinazoline (XI; R = NH \cdot [CH $_2$] $_2$ ·NEt $_2$) which had separated was collected and crystallised from alcohol (yield, 90%), m. p. 202° in agreement with Curd, Landquist, and Rose (Part XIV, *loc. cit.*) (Found: N, 17.5. Calc. for $C_{14}H_{19}N_4Cl \cdot HCl$: N, 17.8%).

2-Amino-4- β -diethylaminoethylaminoquinazoline (XII; R = NH \cdot [CH $_2$] $_2$ ·NEt $_2$).—Several experiments in which the degree and period of heating were varied showed the following conditions to be the most satisfactory. The above hydrochloride (10 g.) was dissolved in a minimum amount of warm alcohol and then treated with cold alcohol previously saturated with ammonia (50 c.c.). The solution was filtered to remove precipitated ammonium chloride and then heated at 120° for 2 hours. Alcohol and ammonia were then removed from the product by evaporation at 20 mm. pressure, the residue was treated with 30% aqueous sodium hydroxide, and the base extracted with ether and dried (K $_2$ CO $_3$). After removal of the ether, the residual solid was first extracted with hot light petroleum (b. p. 60—80°) to remove unchanged chloro-compound, and then recrystallised from acetone. The 2-aminoquinazoline was obtained as colourless crystals, m. p. 144° (Found: C, 65.3; H, 8.2; N, 26.8. $C_{14}H_{19}N_5$ requires C, 64.9; H, 8.1; N, 27.0%).

When this reaction was carried out at higher temperatures, e.g., 170°, intractable gummy mixtures were produced, from which the only pure constituent isolated was 2:4-dihydroxyquinazoline.

2-Chloro-4- δ -diethylamino- α -methylbutylaminoquinazoline (XI; R = NH·CHMe·[CH $_2$] $_3$ ·NEt $_2$).—A mixture of 2:4-dichloroquinazoline (10 g.), δ -diethylamino- α -methylbutylamine (8 g., 1.1 mols.), and alcohol (50 c.c.) was refluxed for 1 hour, and the alcohol then evaporated. The residual syrup was treated with 30% aqueous sodium hydroxide, and the liberated base extracted with ether and dried. Evaporation of the ether gave an oily residue which solidified when vigorously stirred with chilled light petroleum (b. p. 40—60°); recrystallisation from light petroleum then furnished the 2-chloro-compound as colourless crystals, m. p. 98° (Found: C, 63.7; H, 8.0; N, 17.8. Calc. for $C_{17}H_{25}N_4Cl$: C, 63.7; H, 7.8; N, 17.5%) (yield, 37%).

2:4-Dihydroxy-7-methoxyquinazoline and its Derivatives.—Sodium cyanate (2.5 g.) was added rapidly to a suspension of pure 4-methoxyanthranilic acid (5 g.) in acetic acid (15 c.c.) at 60°. The mixture was heated on the steam-bath until effervescence ceased, diluted with water, and the 2-carbamido-4-methoxy-

benzoic acid collected, washed with boiling alcohol to remove any traces of unchanged amino-acid, and further purified by dissolution in ammonia and reprecipitation with acetic acid; m. p. 185–186° (decomp.) (Found: N, 13.1. $C_9H_{10}O_4N_2$ requires N, 13.3%). The carbamido-acid was then boiled for 1 minute with 20% sodium hydroxide (30 c.c.), cooled, and the sodium salt of the dihydroxyquinazoline collected. The salt was dissolved in boiling water, dilute sulphuric acid followed by ammonia added, and the precipitated 2:4-dihydroxy-7-methoxyquinazoline collected and washed with alcohol (yield, 4.3 g.); m. p. 299–301° (Found: N, 14.4. $C_9H_8O_3N_2$ requires N, 14.6%).

The dihydroxyquinazoline (10 g.), phosphorus pentachloride (22 g.), and pure phosphorus oxychloride (32 c.c.) were boiled until the liquid was clear (10 minutes), the solvent distilled off under reduced pressure, and the residue extracted with boiling light petroleum (b. p. 60–80°) in a dry atmosphere. 2:4-Dichloro-7-methoxyquinazoline (7 g.) crystallised from the extract on cooling; m. p. 121–121.5° after recrystallisation from light petroleum (b. p. 60–80°) (Found: N, 12.2; Cl, 30.9. $C_9H_6ON_2Cl_2$ requires N, 12.2; Cl, 31.0%).

The dichloroquinazoline (5 g.) and β -diethylaminoethylamine (3.1 g., 1.2 mols.) were refluxed in alcohol (25 c.c.) for 10 minutes, the solvent was removed, the crystalline residue dissolved in water, aqueous sodium hydroxide added, and the liberated 2-chloro-4- β -diethylaminoethylamino-7-methoxyquinazoline isolated by extraction with chloroform and recrystallised from light petroleum (b. p. 60–80°) (yield, 5.8 g.); m. p. 108–109° (Found: N, 17.9; Cl, 11.4. $C_{16}H_{21}ON_4Cl$ requires N, 18.2; Cl, 11.5%).

The above chloroalkylamino-compound (1 g.) and alcohol saturated with ammonia at 0° (9 c.c.) were heated in a sealed tube at 160° for 3 hours. The solution was then distilled to remove solvent and ammonia, and the resulting syrup dissolved in dilute hydrochloric acid, basified with sodium hydroxide, and extracted with ether. Removal of the solvent left a small amount of resinous material which could not be crystallised, and from which crystalline salts could not be obtained.

This investigation was carried out as part of a wartime programme of antimalarial research sponsored by the Medical Research Council in collaboration with Imperial Chemical Industries Ltd. We are indebted to the former for grants (N. B. C. and G. M. G.) and to the latter for materials and for carrying out the biological tests. We are also greatly indebted to the workers of Imperial Chemical Industries for many discussions on the above work.

After this paper had been prepared for publication the following papers on quinazoline derivatives of related types appeared: Endicott, Wick, Mercury, and Sherrill (*J. Amer. Chem. Soc.*, 1946, **68**, 1299); Smith, Elisberg, and Sherrill (*ibid.*, p. 1301); Endicott, Alden, and Sherrill (*ibid.*, p. 1303); Price, Leonard, and Curtin (*ibid.*, p. 1305); Christensen, Graham, and Tomisek (*ibid.*, p. 1306), and Bunnett (*ibid.*, p. 1327).

UNIVERSITY CHEMICAL LABORATORY, CAMBRIDGE.

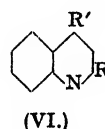

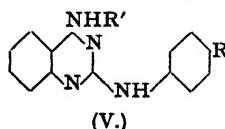

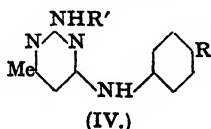

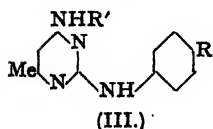

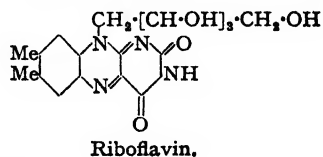

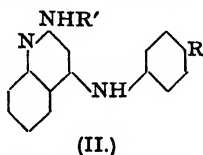

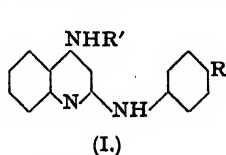

[Received, September 10th, 1946.]

167. Synthetic Antimalarials. Part XVII. Some Arylamino-aminoalkylaminoquinoline Derivatives.

By F. H. S. CURD, C. G. RAISON, and F. L. ROSE.

The differential reactivities of the substituent groups in 2:4-dihydroxy- and 2:4-dichloroquinoline have been investigated and have been utilised for the preparation of a series of 2-arylamino-4-aminoalkylaminoquinolines (I) and their isomers (II). The former show the higher degree of antimalarial activity against *P. gallinaceum* in chicks, and this is discussed in the light of recent hypotheses.

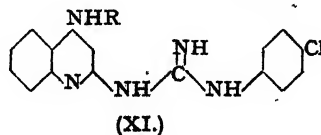

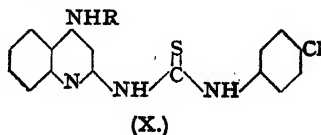

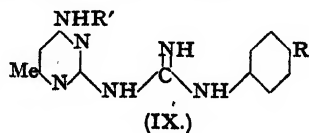

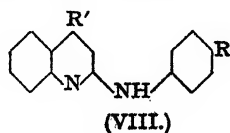

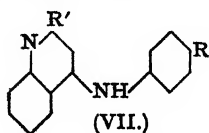

THE purpose of this communication is to report work leading to the synthesis of quinoline derivatives of types (I and II; $R' = \text{aminoalkyl}$) that have not hitherto been investigated in the search for antimalarials based on the quinoline nucleus. The new compounds have an

arylamino- and an aminoalkylamino-group attached to a heterocyclic ring system and in this respect are related to the pyrimidines of types (III) and (IV) described in Parts I, II, VI, and IX (*J.*, 1946, 343, 351, 370, 720) and the 2-arylamino-4-aminoalkylaminoquinazolines (V) (Part XIV, this vol., p. 775), all of which are actively plasmodicidal.

To achieve the synthesis of compounds of types (I) and (II) the possibility of a stepwise replacement of the groups R and R' in a quinoline derivative of type (VI; R = R' = OH or halogen) was first considered because the simplest of such compounds, namely 2:4-dihydroxyquinoline, was available as a dye intermediate. Further, literature methods were available for the preparation of a considerable number of nuclear substituted derivatives. Very little information was available, however, on the feasibility of carrying out the desired stepwise replacements. The reaction of 2:4-dihydroxyquinoline with a number of primary and secondary aliphatic amines at temperatures of 150—250° to give exclusively 4-amino- or 4-alkylamino-quinolines in high yields has been described (G.P. 681980). A similar reaction has now been found to occur with dialkylaminoalkylamines such as γ -diethylaminopropylamine giving 4- γ -diethylaminopropylamino-2-hydroxyquinoline (VI; R = OH, R' = NH·[CH₂]₃·NEt₂). This compound reacted slowly with boiling phosphoryl chloride to give 2-chloro-4- γ -diethylaminopropylaminoquinoline (VI; R = Cl, R' = NH·[CH₂]₃·NEt₂) which was then condensed with *p*-chloroaniline by heating the reactants at ca. 200° for several hours, the product being 2-*p*-chloroanilino-4- γ -diethylaminopropylaminoquinoline (I; R = Cl, R' = [CH₂]₃·NEt₂). The condensation was also possible using an equimolecular proportion of *p*-chloroaniline in aqueous suspension in presence of hydrochloric acid (1·1 mols.), but a reaction time of 48 hours was needed to achieve a good yield. The orientation of these derivatives was demonstrated by the smooth reduction of the intermediate 2-chloro-4- γ -diethylaminopropylaminoquinoline with hydrogen and Raney nickel (cf. Whitmore and Revukas, *J. Amer. Chem. Soc.*, 1940, 62, 1691; Krahler and Burger, *ibid.*, 1941, 63, 2367) to give 4- γ -diethylaminopropylaminoquinoline, identical with a specimen prepared by the condensation of γ -diethylaminopropylamine with 4-chloroquinoline.

G.P. 681980 makes no mention of the condensation of 2:4-dihydroxyquinoline with arylamines, and we have found that the former is recovered completely unchanged after being heated with excess of aniline at 180—200° for 48 hours. In the presence of aniline hydrochloride, however, a smooth reaction occurred with the elimination of water and the formation (in 90% yield) of 4-anilino-2-hydroxyquinoline (VII; R = H, R' = OH). Even so weak an acid as boric acid catalysed the condensation but less efficiently than hydrochloric acid. This compound has been described previously by v. Niementowski (*Ber.*, 1907, 40, 4285) and by Dziewonski and Dymek (*Chem. Zentr.*, 1937, I, 1153). The former obtained it as one product of the reaction of benzoylacetic ester with anthranilic acid, noted its insolubility in alkali, and obtained 4-anilinoquinoline in poor yield from it on distillation with zinc dust. The latter authors heated 2:4-dianilinoquinoline with potassium hydroxide, obtained 4-anilino-2-hydroxyquinoline, and in addition the isomeric 2-anilino-4-hydroxyquinoline which is alkali soluble. They apparently used v. Niementowski's work as a basis for the orientation of the two isomers. We have found that 4-anilino-2-hydroxyquinoline reacts readily with phosphoryl chloride to yield 2-chloro-4-anilinoquinoline, and this compound, on reduction with hydrogen and Raney nickel, gave 4-anilinoquinoline, m. p. 196—198°, identical with an authentic specimen prepared from 4-chloroquinoline (cf. Ephraim, *Ber.*, 1893, 26, 2229; Backeberg, *J.*, 1933, 618). The corresponding *p*-chloroanilino-compound (VII; R = R' = Cl) was similarly obtained by first bringing 2:4-dihydroxyquinoline into reaction with *p*-chloroaniline in presence of its

hydrochloride to give 4-*p*-chloroanilino-2-hydroxyquinoline (VII; R = Cl, R' = OH) and then treating this with phosphoryl chloride. The 2-chloro-4-*p*-chloroanilinoquinoline thus obtained reacted readily with β -diethylaminoethylamine at 130—140° to give 4-*p*-chloroanilino-2- β -diethylaminoethylaminoquinoline and with γ -di-*n*-butylaminopropylamine to give 4-*p*-chloroanilino-2- γ -di-*n*-butylaminopropylaminoquinoline which were most readily isolated as their dihydriodides.

The reactions described above sufficed for the preparation of the two isomeric types of quinoline derivatives (I) and (II) of undoubted orientation, but before they were fully worked out a number of compounds of type (I) had been prepared starting from 2 : 4-dichloroquinoline. As far as we are aware the relative reactivities of the halogen atoms in this compound have been investigated previously only by Buchmann and Hamilton (*J. Amer. Chem. Soc.*, 1942, **64**, 1357) who heated it with potassium hydroxide in alcohol. Besides a small amount of 4-chlorocarbostyryl they obtained approximately equal amounts of 4-chloro-2-ethoxy- and 2-chloro-4-ethoxy-quinoline. The reaction of (VI; $R = R' = Cl$) with arylamines has now been investigated. When heated with an equimolecular amount of aniline, in alcohol or benzene in presence of anhydrous potassium carbonate, no reaction took place. This failure was understandable when it was found that the reaction of 2 : 4-dichloroquinoline and arylamines was catalysed by acid, so that in view of the formation of hydrochloric acid by the reaction the process was normally autocatalytic and indeed, in the absence of solvent, often violently exothermic. These general observations were later given confirmation by the work of Banks (*ibid.*, 1944, **66**, 1127). When equimolecular amounts of 2 : 4-dichloroquinoline and aniline, in acetic acid solution, were warmed together on the steam-bath, only a mildly exothermic reaction took place. The product was a mixture, but the only pure compound that could be isolated (in 53% yield) was 4-chloro-2-anilinoquinoline. This gave a considerable depression in melting point with 2-chloro-4-anilinoquinoline, whilst on reduction with hydrogen and Raney nickel it gave a substance, m. p. 102—103°, conforming to the description of 2-anilinoquinoline recorded in the literature (Friedländer and Weinberg, *Ber.*, 1885, **18**, 1532; Goldschmidt and Meissler, *ibid.*, 1890, **23**, 277). A number of other arylamines were then condensed with 2 : 4-dichloroquinoline to give products of type (VIII; $R' = Cl$) which on heating with aminoalkylamines afforded compounds of type (I). Thus (VI; $R = R' = Cl$) and *p*-chloroaniline led to 4-chloro-2-*p*-chloroanilinoquinoline which when condensed with γ -diethylaminopropylamine gave (I; $R = Cl$, $R' = [CH_2]_3 \cdot NEt_3$) identical with that made from 2-chloro-4- γ -diethylaminopropylaminoquinoline and *p*-chloroaniline.

When tested against *P. gallinaceum* in chicks, 2-*p*-chloroanilino-4- β -diethylaminoethylamino- and 4- γ -diethylaminopropylamino-quinoline showed activity comparable with that of the analogous pyrimidines of type (III) but a certain lack of parallelism between the two series was observed when further variations in the arylamino- and aminoalkylamino-groups were investigated. An even greater divergence was noticeable between the quinoline derivatives of type (II) and the pyrimidine derivatives of type (IV), for the high activity of (IV; $R = Cl$, $R' = [CH_2]_3 \cdot NBu_3^a$) (Part VI, *loc. cit.*) contrasted most markedly with the very low order of activity shown by (II; $R = Cl$, $R' = [CH_2]_3 \cdot NBu_3^a$). This led us to examine the possibility that the activity of compounds of type (I) might be unconnected with their relationship to type (III), and this appeared to be a likely possibility since quinolines of types (I) and (II) do not allow conjugation between the pendant aryl and aminoalkyl groups *via* alternate carbon and nitrogen atoms as a result of either prototropy or resonance which, from our earlier work, we had come to believe might be a significant factor in the activity of our pyrimidine and diguanide types (Part XII, this vol., p. 154).

Schönhöfer (*Z. physiol. Chem.*, 1942, **274**, 1) has reported that 4- δ -diethylamino- α -methylbutylamino-6-methoxyquinoline possesses antimalarial properties, and other work carried out in these laboratories (to be published) had shown that 4-dialkylaminoalkylaminoquinolines in general possessed such properties. It therefore seemed conceivable that the activity of quinolines of type (I) might be due to their being 4-dialkylaminoalkylaminoquinolines carrying a grouping in the 2-position which made no direct contribution to the antimalarial activity and at the same time was not markedly deactivating. This possibility was further illustrated by the antimalarial results obtained with some of the intermediates, containing a dialkylaminoalkylamino-group in the 4-position, used in the synthetic work described in this paper. Thus whereas 4- γ -diethylaminopropylamino-2-hydroxy- and 2-chloro-4- γ -diethylaminopropylamino-quinoline were without activity at high doses, 2-amino-4- β -diethylaminoethylaminoquinoline and the corresponding γ -diethylaminopropylamino-derivative (VI; $R = NH_2$, $R' = NH \cdot [CH_2]_3 \cdot NEt_3$) (see later) showed considerable antimalarial activity. In this connection the work of Gilman and Spatz (*Iowa State College J. Sci.*, 1942, **17**, 129; *J. Amer. Chem. Soc.*, 1944, **66**, 621), knowledge of which only reached us when our own work was largely completed, is perhaps relevant. They have reported activity in certain 4-dialkylaminoalkylamino-2-arylquinolines prepared as "open chain models" of mepacrine, but do not provide any substantial proof that the activity of the compounds is in fact due to their relationship to mepacrine. They can equally well be regarded simply as modified 4-dialkylaminoalkylaminoquinolines.

This point was examined further in respect of our own compounds by observing the effect on antimalarial activity of introducing substituents into type (I) with and without the presence of the 2-arylamino-group. Compounds of the latter type are described in G.P. 683692 and E.P. 481874, and we were ourselves at the time collecting information on such compounds. For this purpose we prepared 2-*p*-chloroanilino-4- γ -diethylaminopropylamino-7:8-benzo-, 7-chloro-2-*p*-chloroanilino-4- γ -diethylaminopropylamino-, and 2-*p*-chloroanilino-4- γ -diethylaminopropylamino-3-methyl-quinoline. 2:4-Dichloro-7:8-benzoquinoline did not react with *p*-chloroaniline in acetic acid solution on the steam-bath, but from the product obtained by heating the two reactants together in 2-ethoxyethanol at 160°, 4-chloro-2-*p*-chloroanilino-7:8-benzoquinoline, was obtained, in rather poor yield, and condensed with γ -diethylaminopropylamine. Methyl 4-chloroanthranilate was condensed with ethyl malonate in the presence of sodium methoxide and the product hydrolysed and decarboxylated to give 7-chloro-2:4-dihydroxyquinoline which was successively condensed with γ -diethylaminopropylamine and treated with phosphoryl chloride to yield 2:7-dichloro-4- γ -diethylaminopropylaminoquinoline; this reacted with *p*-chloroaniline to give 7-chloro-2-*p*-chloroanilino-4- γ -diethylaminopropylaminoquinoline. In attempting to prepare compounds of type (I) containing an additional 3-methyl or 3-ethyl substituent, difficulties were encountered which were probably due to steric hindrance. Both 2:4-dihydroxy-3-methyl- and -3-ethyl-quinoline condensed with γ -diethylaminopropylamine to give the expected 4- γ -diethylaminopropylamino-2-hydroxy-derivatives which when treated with phosphoryl chloride gave respectively 2-chloro-4- γ -diethylaminopropylamino-3-methyl- and -3-ethyl-quinoline; but whereas the former on heating with *p*-chloroaniline gave a product from which the desired 2-*p*-chloroanilino-4- γ -diethylaminopropylamino-3-methylquinoline could be isolated, the latter gave an intractable mixture. Further, both 2:4-dichloro-3-methyl- and -3-ethyl-quinoline condensed with *p*-chloroaniline in acetic acid solution at 100° to give respectively 4-chloro-2-*p*-chloroanilino-3-methyl- and -3-ethyl-quinoline, but, although the former condensed slowly with γ -diethylaminopropylamine at 190–200°, the latter hardly reacted with this amine or with β -diethylaminoethylamine at this temperature and at higher temperatures (up to 250° in sealed tubes) gave intractable products.

The antimalarial activities obtained with these compounds (see Table I) did not support the view that they functioned simply as modified 4-dialkylaminoalkylaminoquinolines, and the possibility, mentioned earlier, that they might then be related biologically to the pyrimidines of type (III) was re-examined.

In a previous paper in this series (Curd and Rose, *J.*, 1946, 362) it was shown that the antimalarial activity of compounds of type (III) was retained and in certain instances enhanced if the arylamino- was replaced by an arylguanidino-group to give type (IX). A similar modification was accordingly made in the quinolines of type (I) utilising a synthetic method originally worked out as an alternative procedure for the synthesis of compounds of type (IX) and related compounds, which we shall report in detail later. A 2-chloro-4-dialkylaminoalkylaminoquinoline was treated with ammonia in hot phenol to give the corresponding 2-amino-4-dialkylaminoalkylaminoquinoline (VI; R = NH₂, R' = dialkylaminoalkylamino) which was then condensed with *p*-chlorophenyl isothiocyanate. The 2-*p*-chlorophenylthioureido-compound (X) thus obtained was desulphurised in the presence of alcoholic ammonia by means of mercuric oxide to give the 2-*p*-chlorophenylguanidino-derivative (XI). 2-*p*-Chlorophenylguanidino-4- β -diethylaminoethylamino- and -4- γ -diethylaminopropylamino-quinoline were prepared in this way, but both failed to show antimalarial activity at tolerated doses. The corresponding thioureido-compounds of type (X) were likewise without demonstrable activity.

Attempts to prepare compounds of type (XI) by condensation of the appropriate 2-chloro-4-dialkylaminoalkylaminoquinoline with *p*-chlorophenylguanidine were unsuccessful. The chloroquinoline was recovered unchanged from trial condensations at temperatures at which ammonia was copiously evolved by breakdown of the guanidine.

Reviewing the results obtained with these compounds it is not possible to draw any very definite conclusion concerning the chemotherapeutic relationship of the quinolines of types (I) and (II) with the pyrimidines of types (III) and (IV) respectively. So far, we have considered this relationship only from the point of view of the chemical hypotheses followed in developing the discovery of antimalarial activity in the pyrimidine of types (III) and (IV). In earlier papers, however, we have discussed the possibility that antiplasmodial activity of these latter types may be associated with a growth antagonism arising from their formal structural similarity to the riboflavin molecule. Examination of the formulæ of (I) and (II) on this basis shows the former to bear the closer structural resemblance to the growth factor. This holds whether the pyrimidine ring of (I) is considered to correspond to the pyrimidine ring or to the benzene ring of

TABLE I.

Antimalarial activities.

The activities are the results of tests against *P. gallinaceum* in chicks and are expressed in the same way as in Part I (*J.*, 1946, 343). The full biological results will be published elsewhere.

riboflavin (in the latter case the fused benzene ring of the quinoline nucleus will correspond to the 6 : 7-dimethyl grouping in riboflavin, and examples of such a biological equivalence are provided among the polycyclic carcinogenic substances). This view affords some explanation of the variations in biological activity which occur on further substitution or modification of type (I). For instance, while type (IX) retains the property of being able to function as a riboflavin antagonist, the conversion of type (I) into type (XI) probably increases the total dimensions of the molecule to such an extent that a relationship with riboflavin is no longer discernible.

EXPERIMENTAL.

4- γ -Diethylaminopropylamino-2-hydroxyquinoline (VI; R = OH, R' = NH·[CH₂]₂·NEt₃).—2 : 4-Dihydroxyquinoline (32.2 g., 1 mol.) and γ -diethylaminopropylamine (52 g., 2 mols.) were heated under reflux by means of an oil-bath at 170–180° for 18 hours. The cooled mixture was lixiviated

with water, and the product collected and washed with water. It was then extracted with dilute acetic acid and the filtered extract made alkaline with ammonia to reprecipitate the compound as an oil which rapidly solidified (yield, 68%). It formed colourless needles from aqueous alcohol, m. p. 174—175° (Found: C, 70.9; H, 8.6; N, 15.3. $C_{18}H_{22}ON_2$ requires C, 70.3; H, 8.4; N, 15.4%). It is insoluble in alkalis.

4- β -Diethylaminoethylamino-2-hydroxyquinoline (VI; R = OH, R' = NH \cdot [CH $_2$] $_2$ ·NEt $_2$).—2:4-Dihydroxyquinoline (80 g.) and β -diethylaminoethylamine (84 g., 1.45 mols.) were heated under reflux with stirring at 170—180° for 27 hours. After cooling, the mixture was extracted with dilute acetic acid and filtered from insoluble material (unchanged 2:4-dihydroxyquinoline, 32.6 g.). The acetic acid extract was made alkaline with ammonia which precipitated the product as an oil. This gradually solidified (yield, 56.8 g.), and subsequent purification by crystallisation from aqueous acetone gave 4- β -diethylaminoethylamino-2-hydroxyquinoline, m. p. 61—63° (Found: C, 61.1; H, 8.4; N, 13.8. $C_{18}H_{22}ON_2 \cdot 2H_2O$ requires C, 61.0; H, 8.5; N, 14.2%).

2-Chloro-4- γ -diethylaminopropylaminoquinoline (VI; R = Cl, R' = NH \cdot [CH $_2$] $_3$ ·NEt $_2$).—4- γ -Diethylaminopropylamino-2-hydroxyquinoline (134 g.) and phosphoryl chloride (268 c.c.) were boiled under reflux for 20 hours and the solution cooled and poured on ice. The oil liberated on basification with 40% potassium hydroxide solution was extracted with ether and the ethereal extract filtered, dried (Na $_2$ SO $_4$), and evaporated. The residual chloro-compound, purified by vacuum distillation, had b. p. 193—194°/0.2 mm., 180—182°/0.08 mm., and crystallised on standing (yield, 68%). It then separated from light petroleum (b. p. 40—80°) as colourless prisms, m. p. 51—52° (Found: C, 66.0; H, 7.4; N, 14.4; Cl, 12.1. $C_{18}H_{22}N_2Cl$ requires C, 65.9; H, 7.55; N, 14.4; Cl, 12.2%). The dipicrate crystallised from 2-ethoxyethanol in fine yellow needles, m. p. 193—194° (Found: N, 16.5; Cl, 4.8. $C_{18}H_{22}N_2Cl \cdot 2C_2H_5O_2N_2$ requires N, 16.8; Cl, 4.75%).

4- γ -Diethylaminopropylaminoquinoline (VI; R = H, R' = NH \cdot [CH $_2$] $_3$ ·NEt $_2$).—(a) 2-Chloro-4- γ -diethylaminopropylaminoquinoline in alcohol solution was shaken with hydrogen, Raney nickel, and potassium hydroxide (1 mol.), absorption of hydrogen ceasing when 1 mol. of hydrogen had been taken up. After filtration and evaporation to dryness the residue was treated with water and sodium hydroxide, and extracted with chloroform. Evaporation of the dried (K $_2$ CO $_3$) extract left an oil, purified by vacuum distillation, b. p. 171—172°/0.15 mm. (yield, 65%) (Found: N, 15.8. $C_{18}H_{22}N_2$ requires N, 16.3%), which crystallised on adding water to form a hydrate, m. p. 57° not depressed by an authentic specimen prepared according to method (b) (Found: C, 69.5; H, 8.6. $C_{18}H_{22}N_2 \cdot H_2O$ requires C, 69.8; H, 9.1%).

(b) 4-Chloroquinoline (1.95 g.), γ -diethylaminopropylamine (3 c.c.), and potassium iodide (0.05 g.) were stirred and heated at 180° for 8 hours. The resulting mixture after being cooled was extracted with 10% acetic acid containing sodium acetate (0.5 g.), and the extract treated with decolorising carbon, filtered, and made alkaline with sodium hydroxide. The product, isolated with ether, had b. p. 173—174°/0.15 mm. and gave the hydrate, m. p. 56°. It gave a dipicrate which crystallised from 2-ethoxyethanol-alcohol as pale yellow needles, m. p. 180—182° (Found: C, 47.2; H, 4.1; N, 18.0. $C_{18}H_{22}N_2 \cdot 2C_2H_5O_2N_2$ requires C, 47.0; H, 4.1; N, 17.6%).

2-Chloro-4- β -diethylaminoethylaminoquinoline (VI; R = Cl, R' = NH \cdot [CH $_2$] $_2$ ·NEt $_2$).—Prepared by careful addition of phosphoryl chloride to the dihydrate of the corresponding hydroxy-compound, followed by boiling for 18 hours and working up in the manner described for the corresponding γ -diethylaminopropylamino-derivative, this was obtained as a faintly yellow viscous oil, b. p. 183—184°/0.07 mm., which crystallised on addition of water to give the hydrate (yield, 36.6 g.) which crystallised from light petroleum (b. p. 60—80°) in colourless plates, m. p. 80—82° (Found: C, 60.9; H, 7.2; Cl, 11.6. $C_{18}H_{20}N_2Cl \cdot H_2O$ requires C, 60.9; H, 7.45; Cl, 12.0%).

4-Anilino-2-hydroxyquinoline (VII; R = H, R' = OH).—2:4-Dihydroxyquinoline (8.05 g.), aniline (23.3 g., 5 mols.), and aniline hydrochloride (6.5 g., 1 mol.) were stirred and heated at 180—190° for 12 hours. After removal of excess of aniline by steam distillation, the crystalline residue was collected and extracted with hot dilute sodium hydroxide and then washed, first with water, and then with hot methanol to remove a violet-coloured impurity. 4-Anilino-2-hydroxyquinoline remained as slightly bluish-grey prisms, m. p. 319—321° unchanged on crystallisation from 2-ethoxyethanol (v. Niementowski, *loc. cit.*, gives m. p. 318°; Dziewoński and Dymek, *loc. cit.*, give m. p. 316°) (Found: N, 12.1. Calc. for $C_{18}H_{13}ON_2$: N, 11.9%).

The same product was obtained in 87% yield by using boric acid in place of aniline hydrochloride and heating for 40 hours, but without an acid catalyst no product was formed.

4- p -Chloroanilino-2-hydroxyquinoline (VII; R = Cl, R' = OH).—2:4-Dihydroxyquinoline (40.25 g.), p -chloroaniline (160 g.), and p -chloroaniline hydrochloride (41.0 g.) were heated with stirring for 4 hours at 180—190°. While still warm, the mixture was stirred with warm methanol (150 c.c.), and the residue filtered off and washed with methanol until free from blue colour, to leave a colourless crystalline product. This was ground with hot water and then with dilute sodium hydroxide, filtered, washed with water, and dried (yield, 89%). It formed colourless crystals from 2-ethoxyethanol, m. p. 296—298° (Found: N, 10.6; Cl, 13.8. $C_{18}H_{11}ON_2Cl$ requires N, 10.35; Cl, 13.1%).

2-Chloro-4-anilinoquinoline (VII; R = H, R' = Cl).—4-Anilino-2-hydroxyquinoline (10.6 g.) and phosphoryl chloride (25 c.c.) were heated at 110—120° for 1½ hours and the solution was then evaporated under reduced pressure at 50—60°. The remaining greenish-yellow solid was ground under alcohol, and the mixture made alkaline with ammonia, diluted with water, filtered, washed, and dried. The chloro-compound (yield, 98%) had m. p. 162—164° unchanged after crystallisation from methanol from which it separated as thick colourless prisms (Found: N, 11.4; Cl, 13.9. Calc. for $C_{18}H_{11}N_2Cl$: N, 11.0; Cl, 13.9%). v. Niementowski (*loc. cit.*) gives m. p. 156°.

When the chloro-compound (1.28 g.) in alcohol (50 c.c.) was shaken with hydrogen in presence of Raney nickel and potassium hydroxide (0.3 g.), absorption of 1 mol. of hydrogen took place fairly rapidly. The mixture was then filtered and the solvent evaporated. Digestion of the solid residue with water gave a product which after crystallisation from methanol had m. p. 196—198° undepressed by an authentic specimen prepared from 4-chloroquinoline and aniline (Found: C, 81.5; H, 5.2; N, 12.8. Calc. for $C_{18}H_{11}N_2$: C, 81.8; H, 5.5; N, 12.7%).

2-Chloro-4-*p*-chloroanilinoquinoline (VII; $R = R' = Cl$), prepared in theoretical yield from 4-*p*-chloroanilino-2-hydroxyquinoline (58 g.) and phosphoryl chloride (150 c.c.) followed by working up in the manner described above for (VII; $R = H$, $R' = Cl$), had m. p. 174—175° unchanged by crystallisation from alcohol (Found: N, 9.4. $C_{15}H_{10}N_2Cl_2$ requires N, 9.7%).

4-*p*-Chloroanilino-2- β -diethylaminoethylaminoquinoline (II'; $R = Cl$, $R' = [CH_2]_2 \cdot NEt_2$).—2-Chloro-4-*p*-chloroanilinoquinoline (14.5 g.) and β -diethylaminoethylamine (9.0 g.) were heated at 130—140° for 14 hours. The mixture was dissolved in warm dilute hydrochloric acid, and the solution made alkaline with sodium hydroxide and extracted with chloroform. The extract was shaken with 5% acetic acid, the acetic acid extract made alkaline, and the product again extracted with chloroform. After drying (K_2CO_3), evaporation of the solvent left the base as an uncrystallisable oil which gave a gelatinous hydrochloride but a crystalline *dihydriodide* by evaporation of an alcoholic hydriodic acid solution of the base. This salt crystallised from alcohol in stout colourless prisms, softening from 240° and decomposing at 248° (Found: C, 39.8; H, 3.9. $C_{21}H_{25}N_4Cl \cdot 2HI$ requires C, 40.3; H, 4.3%) (3627).

4-*p*-Chloroanilino-2- γ -di-*n*-butylaminopropylaminoquinoline (II; $R = Cl$, $R' = [CH_2]_3 \cdot NBut_2$).—2-Chloro-4-*p*-chloroanilinoquinoline (9.35 g.), γ -di-*n*-butylaminopropylamine (10 g.), and powdered potassium iodide (0.1 g.) were heated and stirred at 150—160° for 6 hours. The resulting mixture was treated with warm sodium hydroxide, cooled, and extracted with chloroform. The residue left after evaporation of the chloroform was extracted with 5% acetic acid (200 c.c.), decanted from a little undissolved oil, and extracted with ether. The aqueous layer was made alkaline and extracted with chloroform. After removal of the chloroform from the dried extract, excess of amine was removed by heating to 200°/0.1 mm. and the residual base converted into its *dihydriodide* which was induced to crystallise by trituration with dilute alcohol and then recrystallised from methanol-ethyl acetate; m. p. 200—202° (Found: C, 45.1; H, 5.7; 1 mg. = 0.76 mg. AgX. $C_{26}H_{36}N_4Cl \cdot 2HI$ requires C, 45.0; H, 5.3; 1 mg. = 0.88 mg. AgX).

4-Chloro-2-arylaminoquinolines (VIII; $R' = Cl$).—A mixture of 2:4-dichloroquinoline (0.1 g.-mol.), the appropriate arylamine (0.1 g.-mol.), and acetic acid (40 c.c.) was stirred and heated on the steam-bath for times varying from $\frac{1}{2}$ hour to 2 hours. In some experiments (procedure *a*) fused sodium acetate was then added to neutralise the liberated hydrochloric acid and the mixture poured into water. In others (procedure *b*) the mixture was diluted with water to precipitate the hydrochloride which was then collected and boiled with methanolic ammonia followed by dilution with water. In either case, the precipitated base was collected when solid, dried, and crystallised to constant m. p. Table II gives details of the compounds prepared.

TABLE II.

* Dziewoński and Dymek, *Chem. Zentr.*, 1938, II, 1953, give m. p. 161°.

Reductive Dehalogenation of 4-Chloro-2-anilinoquinoline.—4-Chloro-2-anilinoquinoline (1.28 g.) and potassium hydroxide (0.3 g.) in alcohol (50 c.c.) were shaken with hydrogen and Raney nickel. Absorption of hydrogen was rapid and ceased after the theoretical uptake had occurred. The solution was filtered from catalyst and evaporated and water was added. The resulting oil soon solidified and was filtered off and dried. Crystallisation from dilute methanol and then from light petroleum (b. p. 60—80°) gave 2-anilinoquinoline as glistening colourless plates, m. p. 102—103° (Found: C, 81.4; H, 5.3; N, 13.0. Calc. for $C_{15}H_{11}N_2$: C, 81.8; H, 5.5; N, 12.7%).

2-*p*-Chloroanilino-4- γ -diethylaminopropylaminoquinoline (I; $R = Cl$, $R' = [CH_2]_3 \cdot NEt_2$).—(a) 2-Chloro-4- γ -diethylaminopropylaminoquinoline (8.1 g.), *p*-chloroaniline (10.65 g.), and powdered potassium iodide (0.1 g.) were heated at 200° for 6 hours with stirring. The mixture was dissolved in hot dilute hydrochloric acid and the filtered solution cooled and made alkaline with sodium hydroxide. The precipitated product was isolated with chloroform and partitioned between 5% acetic acid (100 c.c.) and ether. The aqueous layer was made alkaline with sodium hydroxide and the product again extracted

with chloroform. After drying (K_2CO_3), removal of the chloroform left an oil which rapidly solidified and then crystallised from benzene-light petroleum and finally from benzene giving the base as colourless fine needles, m. p. 154—156° (Found: C, 69.2; H, 7.0; N, 14.9; Cl, 9.3. $C_{22}H_{17}N_4Cl$ requires C, 69.0; H, 7.05; N, 14.6; Cl, 9.35%). It was converted into the *dihydrochloride* by dissolving in alcohol, adding hydrochloric acid until the solution was acid to Congo-red, evaporating to dryness under reduced pressure at 50—60°, and then evaporating with benzene-alcohol to remove the last traces of hydrochloric acid. The solid residue then crystallised from alcohol-ethyl acetate in colourless fine needles, which were hydrated and decomposed above 110° (Found: C, 54.0; H, 6.7; N, 11.4; Cl', 15.0. $C_{22}H_{17}N_4Cl \cdot 2HCl \cdot 2H_2O$ requires C, 53.7; H, 6.7; N, 11.4; Cl', 14.5%). This salt is readily soluble in water.

(b) 2-Chloro-4- γ -diethylaminopropylaminoquinoline (5.15 g.), *p*-chloroaniline (2.25 g.), water (20 c.c.), ethanol (5 c.c.), and 10N-hydrochloric acid (1.7 c.c.) were refluxed together for 48 hours. After cooling and addition of sodium acetate, a little unreacted *p*-chloroaniline was removed by ether extraction. Basification of the aqueous layer precipitated a solid which was filtered off, dried, and crystallised from benzene giving the same product as in (a), m. p. and mixed m. p. 155—156° (yield, 4.3 g.).

(c) 4-Chloro-2-*p*-chloroanilinoquinoline (20 g.), γ -diethylaminopropylamine (18.0 g.), and powdered potassium iodide (0.3 g.) were heated with stirring in an oil-bath at 180—190° for 16 hours. A solution of the mixture in warm dilute hydrochloric acid was made alkaline with sodium hydroxide and extracted with chloroform. The solvent was removed, the residue digested with warm 50% acetic acid (250 c.c.), and the filtered solution basified and extracted with chloroform. After drying (K_2CO_3) and removal of the chloroform an oil was obtained which quickly solidified and was then crystallised from benzene (yield, 17.6 g.); it had m. p. 153—155°, and was identical with the compound made by methods (a) and (b) (Found: C, 68.6; H, 7.1%).

Using method (c) a number of other 2-arylamino-4-dialkylaminoalkylaminoquinolines were prepared. Details are given in Table III.

2 : 4-Dichloro-7 : 8-benzoquinoline.—2 : 4-Dihydroxy-7 : 8-benzoquinoline (78 g.) (prepared from α -naphthylamine and ethyl malonate, cf. E.P. 332911 and Baumgarten and Kärger, *Ber.*, 1927, 60, 832) and phosphoryl chloride (200 c.c.) were heated at 90—100° for $\frac{1}{2}$ hour during which time hydrogen chloride was copiously evolved. The temperature was then raised to 120—125° and maintained for 3 $\frac{1}{2}$ hours. The resulting clear solution was cooled and added to crushed ice with stirring. The precipitated product was filtered off, washed free from acid, dried, and refluxed with acetone (1 l.). After filtration from insoluble matter, the acetone was distilled off and the residue crystallised from ethyl acetate (yield, 48.5 g.). 2 : 4-Dichloro-7 : 8-benzoquinoline formed long colourless needles from acetone, m. p. 134—135° (Found: C, 63.0; H, 3.5; Cl, 28.3. $C_{18}H_7NCl_2$ requires C, 62.9; H, 2.8; Cl, 28.6%).

4-Chloro-2-*p*-chloroanilino-7 : 8-benzoquinoline.—2 : 4-Dichloro-7 : 8-benzoquinoline (24.8 g.), *p*-chloroaniline (12.7 g.), *p*-chloroaniline hydrochloride (0.1 g.), and 2-ethoxyethanol (30 c.c.) were heated in an oil-bath at 160° for 3.5 hours. The mixture was then cooled and diluted with water, and the precipitated product filtered off and dissolved in boiling alcohol (350 c.c.) with the addition of sufficient ammonia to give an alkaline reaction. The resulting solution was treated with an equal volume of water. The product, when solid, was collected, dried, and crystallised first from benzene and then from butanol (yield, 40%) giving needles, m. p. 160—162° (Found: Cl, 20.4. $C_{21}H_{15}N_2Cl_2$ requires Cl, 20.4%).

2-*p*-Chloroanilino-4- γ -diethylaminopropylamino-7 : 8-benzoquinoline.—The preceding chloro-compound (17.6 g.), γ -diethylaminopropylamine (13.5 g.), and powdered potassium iodide (0.3 g.) were heated at 175—185° with stirring for 24 hours. Worked up in the usual way for this type of compound the base was obtained as a glass which could not be induced to crystallise. It was therefore dissolved in hot acetone (100 c.c.), and hydrochloric acid added until the solution showed acidity to Congo-red. On cooling, the *dihydrochloride* crystallised out as a hydrate and was recrystallised from acetone-water, m. p. 108—110° (Found: C, 55.3; H, 6.4; N, 10.0; Cl', 13.6. $C_{22}H_{17}N_4Cl \cdot 2HCl \cdot 3H_2O$ requires C, 55.8; H, 6.3; N, 10.0; Cl', 12.7%).

7-Chloro-2 : 4-dihydroxyquinoline.*—This was prepared by a modification of a method for 2 : 4-dihydroxyquinoline described by Koller (*Ber.*, 1927, 60, 1108). Methyl 4-chloroanthranilate (100 g.) (Hunn, *J. Amer. Chem. Soc.*, 1923, 45, 1028), ethyl malonate (86.2 g.), and sodium methoxide (29 g.) were mixed in a flask fitted with a condenser arranged for distillation. After the mixture had been stirred at 70° until homogeneous (ca. 1 hour), the temperature was raised slowly to 140—150° and then maintained for 6 hours. Alcohol distilled and the mixture thickened, eventually becoming quite solid. After cooling, the mixture was repeatedly extracted with cold dilute sodium hydroxide and the extracts were acidified to precipitate what was probably methyl 7-chloro-2 : 4-dihydroxyquinoline-3-carboxylate (89 g.). This ester (35 g.) was hydrolysed and decarboxylated by heating on the steam-bath overnight with sodium hydroxide (13 g. in 350 c.c. water); after being filtered from a little insoluble material the filtrate was acidified. The precipitate was collected, washed, and boiled with dilute sodium carbonate solution, and the solution cooled, filtered, and acidified. 7-Chloro-2 : 4-dihydroxyquinoline was precipitated as an almost colourless powder, m. p. 332—340° (decomp.) (Found: N, 6.7; Cl, 18.5. Calc. for $C_9H_4O_2NCl$: N, 7.2; Cl, 18.2%). This substance has been prepared very recently by another modification of Koller's method by Lutz *et al.* (*J. Amer. Chem. Soc.*, 1946, 68, 1285).

7-Chloro-4- γ -diethylaminopropylamino-2-hydroxyquinoline.*—7-Chloro-2 : 4-dihydroxyquinoline (30 g.) and γ -diethylaminopropylamine (41.2 g.) were heated at 170—180° for 20 hours and then worked up as described for 4- γ -diethylaminopropylamino-2-hydroxyquinoline to give the compound as practically colourless needles, m. p. 228—229° (Found: C, 62.2; H, 6.9; N, 13.9; Cl, 12.0. $C_{18}H_{12}ON_2Cl$ requires C, 62.4; H, 7.1; N, 13.7; Cl, 11.55%).

2 : 7-Dichloro-4- γ -diethylaminopropylaminoquinoline.*—The above hydroxy-compound (12 g.) and phosphoryl chloride (24 c.c.) were heated by means of an oil-bath at 130—140° for 16 hours followed by working up in the usual way for this type of compound to give the product, m. p. 82—87°, characterised as

* Experiments by Mrs. J. M. Wilson.

TABLE III.
2-Arylamino-4-aminoalkylaminoquinolines.

Substituent at 2.	Substituent at 4.	Derivative.	M. p. mm.	Solvent; crystalline form.	Formula.	Analysis.

¹ For biological test the picrate was dissolved in pyridine, the solution added to aqueous sodium hydroxide, and the base extracted with ether which was then thoroughly washed with sodium hydroxide and water, dried, and evaporated, giving the base as an oil. This was made soluble with lactic acid.

its *dipicrate* which crystallised from aqueous 2-ethoxyethanol and had m. p. 194—195° (Found : N, 15.8; Cl, 9.5. $C_{18}H_{21}N_3Cl_2 \cdot 2C_6H_5O_2N_3$ requires N, 16.1; Cl, 9.1%).

7-Chloro-2-p-chloroanilino-4-γ-diethylaminopropylaminoquinoline.—2 : 7-Dichloro-4-γ-diethylaminopropylaminoquinoline (8.96 g.), *p*-chloroaniline (10.6 g.), and potassium iodide (0.1 g.) were heated for 8 hours at 200°. The mixture was treated with hot dilute hydrochloric acid, made alkaline with sodium hydroxide, and steam distilled to remove unchanged *p*-chloroaniline. The residual oil was separated and dissolved in 5% acetic acid, and the solution extracted with ether. Basification followed by isolation with chloroform then gave the *product* which crystallised from benzene-light petroleum as colourless laminae, m. p. 144—145° (Found : C, 63.0; H, 6.1; N, 13.7; Cl, 17.1. $C_{23}H_{28}N_4Cl_2$ requires C, 63.3; H, 6.2; N, 13.4; Cl, 17.1%).

2 : 4-Dihydroxy-3-methylquinoline.—Aniline (46.5 g.) and ethyl methylmalonate (87 g.), contained in a flask fitted with a long condenser allowing only the liberated alcohol to escape, were heated at 230—240° for $\frac{1}{2}$ hour, then at 290—300° for $1\frac{1}{2}$ hours, and finally raised to 340° during $\frac{1}{2}$ hour. The cooled mass was boiled with acetone (100 c.c.) for 10 hours and the insoluble material filtered off after cooling. It was then boiled with sodium carbonate solution (700 c.c. of 10%) for 10 minutes and cooled, and the solution was filtered and the product precipitated with hydrochloric acid (yield, 53%). Crystallised from 2-ethoxyethanol and then from butanol it formed almost colourless prisms, m. p. 265—268° (decomp.) (Found : C, 68.3; H, 4.9; N, 8.4. Calc. for $C_{10}H_9O_2N$: C, 68.6; H, 5.1; N, 8.0%) (Gabriel and Gerhard, *Ber.*, 1921, 54, 1067, give m. p. > 270°).

2 : 4-Dichloro-3-methylquinoline.—2 : 4-Dihydroxy-3-methylquinoline (25 g.) and phosphoryl chloride (75 c.c.) were heated at 100—110° for $\frac{1}{2}$ hour and then at 120—125° for 5 hours. The mixture was then cooled and poured on ice. The precipitated product was filtered off, washed free from acid with water, dried (yield, 29.7 g.), and crystallised from 80% alcohol, m. p. 90—91° (Found : Cl, 33.1. Calc. for $C_{10}H_7NCl_2$: Cl, 33.5%) (Gabriel and Gerhard, *loc. cit.*, give m. p. 83—84°).

4-γ-Diethylaminopropylamino-2-hydroxy-3-methylquinoline.—2 : 4-Dihydroxy-3-methylquinoline (20 g.) and γ-diethylaminopropylamine (30 g.) were heated at 180—190° for 22.5 hours and the mixture was cooled and poured into water. The *product*, precipitated as an oil, soon solidified. It was collected, dissolved in 5% acetic acid, precipitated with ammonia, and dried at 60° (yield, 47.5%). It crystallised from aqueous alcohol as pale yellow stout prisms, m. p. 105—106° (Found : N, 14.7. $C_{17}H_{25}ON_3$ requires N, 14.6%).

4-γ-Diethylaminopropylamino-2-hydroxy-3-ethylquinoline, prepared in exactly the same manner from 2 : 4-dihydroxy-3-ethylquinoline (Baumgarten and Kargel, *loc. cit.*) and γ-diethylaminopropylamine, crystallised from aqueous alcohol; m. p. 100—101° (Found : N, 14.2. $C_{18}H_{27}ON_3$ requires N, 14.0%).

2-Chloro-4-γ-diethylaminopropylamino-3-methylquinoline.—4-γ-Diethylaminopropylamino-2-hydroxy-3-methylquinoline (13.35 g.) and phosphoryl chloride (30 c.c.) were heated at 115—125° for 18 hours. Most of the excess of phosphoryl chloride was then removed under diminished pressure and the residue dissolved in water, made alkaline with potassium hydroxide, and extracted with ether. The dried ethereal extract was evaporated and the residual oil extracted with cold light petroleum (b. p. 40—60°) (100 c.c.), filtered, and evaporated. 2-Chloro-4-γ-diethylaminopropylamino-3-methylquinoline remained as an oil which could not be crystallised. It gave a *dipicrate* which crystallised from 2-ethoxyethanol-alcohol as fine yellow needles of indefinite melting point (ca. 160°) (Found : N, 16.6; Cl, 4.7. $C_{17}H_{24}N_3Cl \cdot 2C_6H_5O_2N_3$ requires N, 16.5; Cl, 4.65%).

4-Chloro-2-p-chloroanilino-3-methylquinoline.—2 : 4-Dichloro-3-methylquinoline (21.2 g.) and *p*-chloroaniline (12.75 g.) in acetic acid (40 c.c.) were heated on the steam-bath for 2 hours with stirring. Crystalline material was deposited during the reaction. This was collected after dilution with water, washed, and stirred overnight with methanol containing excess of ammonia. Water was then added, and the product collected, washed, and dried. This crude material was ground and extracted with cold dioxan leaving undissolved 2 : 4-di-*p*-chloroanilino-3-methylquinoline (3.1 g.), m. p. 266—268° (Found : Cl, 18.0. $C_{22}H_{17}N_3Cl_2$ requires Cl, 18.0%). The dioxan filtrate from this di-condensation product was diluted with water and the precipitated material, initially an oil which gradually solidified, filtered off and crystallised from alcohol, giving 4-chloro-2-p-chloroanilino-3-methylquinoline as colourless fine needles, m. p. 120—121° (Found : N, 9.3; Cl, 22.9. $C_{16}H_{12}N_3Cl_2$ requires N, 9.25; Cl, 23.4%) (yield, 15.85 g.).

2-p-Chloroanilino-4-γ-diethylaminopropylamino-3-methylquinoline.—(a) Crude 2-chloro-4-γ-diethylaminopropylamino-3-methylquinoline (9.65 g.), *p*-chloroaniline (12.1 g.), and potassium iodide (0.1 g.) were heated at 200° for 12 hours. The mass was dissolved in alcohol, and the solution made alkaline with sodium hydroxide and steam distilled. The residual oil was isolated with chloroform and shaken with 5% acetic acid (150 c.c.) and ether. The aqueous layer was separated and re-extracted with ether, and then made alkaline with sodium hydroxide and extracted with chloroform. Evaporation of the dried (K_2CO_3) extract left the base as an oil which could not be induced to crystallise. The picrate and hydrochloride likewise failed to crystallise. A solution of the base in dilute hydrochloric acid on treatment with perchloric acid gave the *perchlorate* which crystallised from alcohol in rosettes of colourless needles, m. p. 216—218° (Found : C, 46.1; H, 4.9; N, 9.7. $C_{23}H_{28}N_4Cl_2 \cdot 2HClO_4$ requires C, 46.2; H, 5.2; N, 9.4%).

(b) 4-Chloro-2-p-chloroanilino-3-methylquinoline (10 g.), γ-diethylaminopropylamine (8.6 g.), and potassium iodide (0.15 g.) were heated under reflux in an oil-bath at 190—200° for 22 hours. When cool, the semi-solid mass was treated with aqueous sodium hydroxide and extracted with chloroform. After evaporation of the solvent the residue was stirred with 5% acetic acid (150 c.c.), filtered and extracted with ether. The acetic solution was then basified and extracted with chloroform. Evaporation of the dried chloroform extract left an oily base contaminated with γ-diethylaminopropylamine. This was removed by heating overnight at 120—130°/15 mm. and the residue dissolved in dilute hydrochloric acid and treated with perchloric acid to give the same perchlorate as in (a), m. p. and mixed m. p. 215—217° (Found : C, 45.7; H, 5.2%).

For biological testing the perchlorates from (a) and (b) were combined and treated with aqueous sodium hydroxide, and the liberated base was isolated with chloroform.

2-Chloro-4- γ -diethylaminopropylamino-3-ethylquinoline.—4- γ -Diethylaminopropylamino-2-hydroxy-3-ethylquinoline (15 g.) and phosphoryl chloride (35 c.c.) were heated at 115–125° for 16 hours followed by working up as described for the corresponding 3-methyl compound to give the product as an oil which could not be crystallised. It gave a *dipicrate* which crystallised from 2-ethoxyethanol–alcohol as yellow plates, m. p. 144–146° (Found: N, 16.3; Cl, 4.6. $C_{18}H_{22}N_2Cl_2 \cdot 2C_4H_8O_2 \cdot N_2$ requires N, 16.2; Cl, 4.6%).

2:4-Dichloro-3-ethylquinoline.—2:4-Dihydroxy-3-ethylquinoline (50 g.) and phosphoryl chloride (150 c.c.) were heated with stirring at 100–110° for $\frac{1}{2}$ hour and then at 120–125° for 4 hours. The cooled mixture was poured on ice and after being stirred for several hours the product was extracted with ether. Evaporation of the washed and dried ethereal extract gave an oil which was purified by vacuum distillation, b. p. 182–184°/21 mm. (yield, 88%) (Found: Cl, 31.0. $C_{11}H_8NCl_2$ requires Cl, 31.4%).

4-Chloro-2-p-chloroanilino-3-ethylquinoline.—2:4-Dichloro-3-ethylquinoline (22.6 g.), *p*-chloroaniline (12.75 g.), and acetic acid (40 c.c.) were heated on the steam-bath for 2 hours with stirring and then refluxed for 10 minutes. When cold, the mixture was diluted with water and made strongly acid to Congo-red with hydrochloric acid. The practically colourless crystalline powder thereby obtained was filtered off, washed with water, and heated on the steam-bath for 10 minutes with methanol (100 c.c.) and sufficient ammonia to give an alkaline reaction. Dilution with water gave a product which was filtered off, dried, and crystallised from alcohol; it was obviously a mixture (18.4 g.). Crystallisation from dioxan (40 c.c.) gave fine needles of 2:4-di-*p*-chloroanilino-3-ethylquinoline (3.6 g.), m. p. 224–226° (Found: Cl, 17.3. $C_{22}H_{18}N_2Cl_2$ requires Cl, 17.4%), and dilution with water the required 4-chloro-2-p-chloroanilino-3-ethylquinoline which crystallised from alcohol in stout prisms, m. p. 132–133° (Found: N, 9.0; Cl, 22.4. $C_{11}H_8N_2Cl_2$ requires N, 8.8; Cl, 22.4%).

2-Amino-4- γ -diethylaminopropylaminoquinoline (VI; R = NH₂, R' = NH·[CH₂]₃·NET₂).—Ammonia was passed through a solution of 2-chloro-4- γ -diethylaminopropylaminoquinoline (5.2 g.) in phenol (20 g.) at 170–180° for 18 hours. The cooled mixture was treated with aqueous sodium hydroxide and ether, and the ether layer washed thoroughly with dilute sodium hydroxide and then with water and dried (Na₂SO₄). Removal of the solvent left a syrup which solidified on trituration with light petroleum (b. p. 60–80°). By crystallisation from benzene–light petroleum the amino-compound was obtained as colourless stout prisms, m. p. 125–126° (Found: N, 20.0. $C_{16}H_{22}N_4$ requires N, 20.6%).

2-p-Chlorophenylthioureido-4- γ -diethylaminopropylaminoquinoline (X; R = [CH₂]₃·NET₂).—2-Amino-4- γ -diethylaminopropylaminoquinoline (13.5 g.), *p*-chlorophenyl isothiocyanate (9.0 g.), and dry xylene (30 c.c.) were refluxed for 1 hour. On cooling, the clear solution deposited crystals which were filtered off, washed with benzene, and dried. Crystallisation from xylene gave pale yellow stout prisms (yield, 72%), m. p. 188–189° (Found: N, 15.4; S, 6.9. $C_{22}H_{22}N_4ClS$ requires N, 15.9; S, 7.25%).

2-p-Chlorophenylguanidino-4- γ -diethylaminopropylaminoquinoline (XI; R = [CH₂]₃·NET₂).—The above thioureido-compound (6.5 g.) was stirred with saturated alcoholic ammonia (100 c.c.) and mercuric oxide (7 g.) for 24 hours at 30–35° with the continuous passage of ammonia into the solution. After cooling, the mixture was filtered and the dried residue extracted with hot xylene from which the product separated on cooling (yield, 78%). It formed colourless needles from xylene, m. p. 208° (Found: C, 65.3; H, 6.5; N, 19.8. $C_{23}H_{26}N_6Cl$ requires C, 65.0; H, 6.8; N, 19.8%). 2-p-Chlorophenylguanidino-4- γ -diethylaminopropylaminoquinoline is only very sparingly soluble in alcohol.

2-Amino-4- β -diethylaminoethylaminoquinoline (VI; R = NH₂, R' = NH·[CH₂]₂·NET₂).—Ammonia was passed for 22 hours into a solution of 2-chloro-4- β -diethylaminoethylaminoquinoline (21.9 g.) in phenol (50 g.) at 170–180°. The mixture was cooled, treated with sodium hydroxide solution, and shaken with ether. The ether solution after being washed with sodium hydroxide and then with water was extracted with 5% acetic acid. Addition of ammonia to this extract to render it alkaline to Brilliant-yellow precipitated 4- β -diethylaminoethylamino-2-phenoxyquinoline (VI; R = OPh, R' = NH·[CH₂]₂·NET₂) as an oil which rapidly solidified. After being collected and dried, it crystallised from cyclohexane in large irregular prisms, m. p. 104–105° (Found: N, 12.9. $C_{21}H_{25}ON_3$ requires N, 12.5%). Addition of sodium hydroxide to the aqueous filtrate precipitated 2-amino-4- β -diethylaminoethylaminoquinoline as an oil which gradually solidified (yield, 13 g.). After drying, it crystallised from cyclohexane with the addition of a little water as practically colourless laminae, m. p. 114–115° (Found: C, 69.8; H, 8.7; N, 21.8. $C_{15}H_{22}N_4$ requires C, 69.75; H, 8.5; N, 21.75%). Under the above conditions of crystallisation it was sometimes obtained as a *hydrate*, m. p. 75–77° (Found: C, 63.2; H, 8.8; N, 18.9. $C_{15}H_{22}N_4 \cdot 1.5H_2O$ requires C, 63.2; H, 8.8; N, 19.6%).

2-p-Chlorophenylthioureido-4- β -diethylaminoethylaminoquinoline (X; R = [CH₂]₂·NET₂).—The preceding thiourea (6 g.) and mercuric oxide (6 g.) were added to saturated alcoholic ammonia (100 c.c.) at 0°. With stirring, the mixture was allowed to regain room temperature, then warmed to 30–35° and ammonia passed in for 2 hours. After being stirred at this temperature for 19 hours the mixture was filtered and the insoluble residue dried and extracted with benzene to give the *product* as colourless needles, m. p. 202–203° (Found: N, 20.2. $C_{22}H_{27}N_6Cl$ requires N, 20.5%).

2-p-Chlorophenylguanidino-4- β -diethylaminoethylaminoquinoline (XI; R = [CH₂]₂·NET₂).—The preceding thiourea (6 g.) and mercuric oxide (6 g.) were added to saturated alcoholic ammonia (100 c.c.) at 0°. With stirring, the mixture was allowed to regain room temperature, then warmed to 30–35° and ammonia passed in for 2 hours. After being stirred at this temperature for 19 hours the mixture was filtered and the insoluble residue dried and extracted with benzene to give the *product* as colourless needles, m. p. 202–203° (Found: N, 20.2. $C_{22}H_{27}N_6Cl$ requires N, 20.5%).

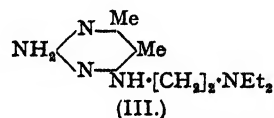

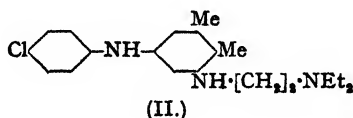

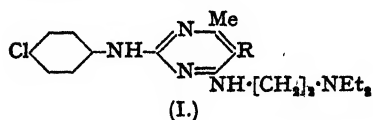

168. Synthetic Antimalarials. Part XVIII. 3-Dialkylaminoalkyl-aminodiphenylamines.

By FREDERICK G. MANN and J. W. GEOFFREY PORTER.

In order to determine whether the antimalarial activity of certain 2-anilino-4-dialkylamino-alkylaminopyrimidines of type (I) was determined primarily by their general structure, the corresponding compounds in which the pyrimidine ring has been replaced by a benzene ring, *i.e.*, diphenylamines of type (II), have been synthesised. The similar benzene analogues of the active 2-amino-4-dialkylaminoalkylaminopyrimidines of type (III) have also been synthesised.

All these benzene analogues proved to be devoid of antimalarial activity, however, and the activity of both the above types of pyrimidine compound must therefore be intimately associated either with the pyrimidine ring itself or with the tautomerism which this ring allows.

When this investigation was started, it was known that 2-*p*-chloroanilino-4- β -diethylamino-ethylamino-6-methylpyrimidine (I, R = H) showed marked antimalarial activity against avian malaria; the corresponding *p*-methoxyanilino-compound showed lower activity, but the 5:6-dimethyl homologue (I, R = Me) an activity slightly greater than that of (I, R = H) (Curd and Rose, *J.*, 1945, 343; Curd, Richardson, and Rose, *ibid.*, p. 378). Many other homologues, having similar 4-dialkylaminoalkylamino-substituents, also showed varying degrees of activity.

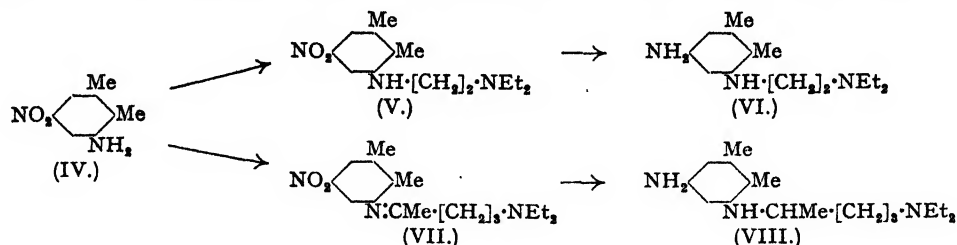

It had been suggested (Curd, Davey, and Rose, *Ann. Trop. Med. Parasit.*, 1945, 39, 157; Curd, Davis, and Rose, *J.*, 1946, 351) that these various anilino-pyrimidines might owe their antimalarial activity to their interference with some essential metabolic process involving riboflavin, due to the structural similarity which not only exists between riboflavin and the pyrimidines themselves, but might also exist between riboflavin and the most probable degradation products of these pyrimidines, for example, the corresponding 4-hydroxy-pyrimidines which could be formed by hydrolytic removal of the alkylamino-group from the drug. It was shown later by Madinaveitia (*Biochem. J.*, in the press) that the growth-inhibitory action of the above pyrimidines, as well as that of mepacrine and quinine, for *Lactobacillus casei* was actually antagonised by riboflavin.

It became of interest therefore to prepare diphenylamine compounds of type (II), which differed from compounds of type (I) only in that the pyrimidine ring of the latter had now been replaced by a benzene ring. If antimalarial activity is due primarily to a general structural similarity between riboflavin and the drug, compounds of type (II) should have an activity of the same order as that of their analogues of type (I); if, however, it is due primarily to a structural similarity between riboflavin and the main degradation products of the drug, then compounds of type (II), by virtue of their greater stability, might well prove inactive.

It should be noted, however, that a further factor enters here which might itself largely offset the result of any general structural similarity between the two classes of drugs. Pyrimidines of type (I) can clearly exist in several tautomeric forms (formulated in Part VIII, *J.*, 1946, 713), whereas in the benzene analogues of type (II) no such tautomerism can occur. It is noteworthy that a similar tautomerism can occur in mepacrine, and Schönhöfer (*Z. physiol. Chem.*, 1942, 274, 1) has suggested that the antimalarial activity of mepacrine is closely associated with this tautomerism.

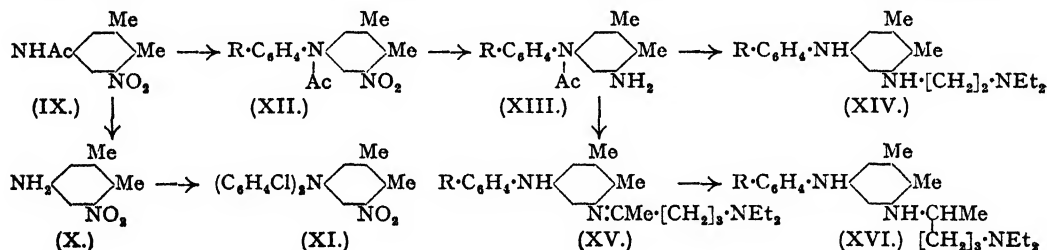

It is clear, however, that even if this structural-similarity factor is the underlying cause of the antimalarial activity of certain types of drug, it cannot apply to all types. For example, Hull, Lovell, Openshaw, Payman, and Todd (*J.*, 1945, 357) have shown that 2-amino-4- β -diethylaminoethylamino-5:6-dimethylpyrimidine (III), which does not show this structural similarity with riboflavin, has an activity of approximately the same value as that of (I, R = Me). It is significant that Madinaveitia (*loc. cit.*) has found that the action of pyrimidines of type (III) is not antagonised by riboflavin. The additional object of the present investigation therefore was to prepare the benzene analogues of (III), in order to determine whether in this class of drug also the pyrimidine ring, with its accompanying tautomerism, was essential for antimalarial activity. The synthesis of these simpler monocyclic compounds is conveniently described before that of the more complex diphenylamine derivatives.

Condensation of 5-nitro-3-amino-*o*-xylene (IV) with β -diethylaminoethyl chloride furnished the hydrochloride of 5-nitro-3- β -diethylaminoethylamino-*o*-xylene (V). Catalytic reduction followed by basification then gave 5-amino-3- β -diethylaminoethylamino-*o*-xylene (VI). Many

attempts were then made to condense the amine (IV) with δ -bromo- α -diethylamino-*n*-pentane, $\text{CHMeBr} \cdot [\text{CH}_2]_3 \cdot \text{NEt}_2$, in order ultimately to make (VIII), *i.e.*, the analogue of (VI) containing the basic side chain of mepacrine. All such attempts failed, however, in spite of a variety of conditions employed. Ultimately success was achieved by utilising the method developed by Ashley and Grove (*J.*, 1945, 768) for introducing this side chain into the aminopyridines. For this purpose, methyl 3-diethylamino-*n*-propyl ketone was converted into the diethyl ketal, $\text{CMe}(\text{OEt})_2 \cdot [\text{CH}_2]_3 \cdot \text{NEt}_2$, which was readily condensed with the amine (IV) to give the anil (VII). This compound on catalytic reduction furnished 5-amino-3- δ -diethylamino- α -methyl-*n*-butylamino-*o*-xylene (VIII).

For the preparation of the corresponding diphenylamines, 4-amino-*o*-xylene was acetylated and then nitrated to furnish 3-nitro-5-acetamido-*o*-xylene (IX) (*cf.* Crossley and Morrell, *J.*, 1911, 99, 2350), hydrolysis then giving 3-nitro-5-amino-*o*-xylene (X). This amine was subjected to an Ullmann condensation with *p*-chloriodobenzene in the presence of copper, but

in spite of a wide variety of conditions the main product isolated was always 4':4''-dichloro-3-nitro-4:5-dimethyltriphenylamine (XI), and it was clear that the initial production of the diphenylamine must have been a slow process compared with its conversion into the triphenylamine derivative. It should be noted that this preferential formation of a tertiary amine by the Ullmann reaction is rare but not unique: Wibaut and La Bastide (*Rec. Trav. chim.*, 1933, 52, 493) have shown that 2-iodopyridine and 2-aminopyridine, when heated with potassium carbonate and copper, furnish the tri-2-pyridylamine.

This difficulty was overcome by employing the acetamido-compound (IX), which in the presence of copper bronze and potassium iodide readily combined with *p*-chloriodobenzene to form 4'-chloro-3-nitro-*N*-aceto-4:5-dimethyldiphenylamine (XII, $\text{R} = \text{p-Cl}$). The latter was then reduced to the 3-amino-derivative (XIII, $\text{R} = \text{Cl}$) which, after condensation with β -2-diethylaminoethyl chloride and subsequent hydrolysis, furnished 4'-chloro-3- β -diethylaminoethylamino-4:5-dimethyldiphenylamine (XIV, $\text{R} = \text{Cl}$).

When the acetyl group in (XIII) was removed, the resulting amine readily condensed with the above diethyl ketal to give the anil (XV, $\text{R} = \text{Cl}$), which on catalytic reduction gave 4'-chloro-3-(δ -diethylaminoethylamino)-4:5-dimethyldiphenylamine (XVI, $\text{R} = \text{Cl}$).

Attempts were then made to prepare compounds of type (XIV) and (XVI) in which $\text{R} = \text{p-MeO}$, as this group has considerable significance in many antimalarial compounds. *p*-Bromoanisole was successfully condensed with the acetamido-compound (IX), but the acetodiphenylamide could not readily be isolated: consequently the crude product was hydrolysed and the pure 3-nitro-4'-methoxy-4:5-dimethyldiphenylamine thus obtained. This compound was reduced to the 3-amino-derivative, which condensed with β -diethylaminoethyl chloride to give 3- β -diethylaminoethylamino-4'-methoxy-4:5-dimethyldiphenylamine (XIV,

R = MeO). The 3-amino-derivative also gave the anil (XV, R = MeO) which on hydrogenation furnished 3-*β*-diethylamino- α -methyl-*n*-butylamino-4'-methoxy-4 : 5-dimethyldiphenylamine (XVI, R = MeO). It should be noted that, whereas the constitution of the last compound is beyond doubt, that of (XIV, R = MeO) is not absolutely certain, since the ethyl chloride might conceivably condense with the secondary amino-group : the reactivity of the 3-amino-group is so very much greater, however, that this possibility can be ignored.

The two xylene derivatives (VI) and (VIII) and the four diphenylamine derivatives (XIV, R = Cl and MeO) and (XVI, R = Cl and MeO) have been tested against *P. gallinaceum* in chicks and found to be inactive not only against the blood forms but also prophylactically. It is clear, therefore, that the marked antimalarial activity of the two types of pyrimidine derivative (I) and (III) must be intimately associated either with the pyrimidine ring as such, or with the tautomerism which this ring allows, and that a superficial structural similarity with riboflavin which ignores this tautomerism, as in the diphenylamine derivatives, is insufficient to produce activity.

EXPERIMENTAL.

5-Nitro-3-amino-*o*-xylene (IV). This compound, prepared according to Noeltling, Braun, and Thesmar (*Ber.*, 1901, 34, 2242), was obtained in 35% yield as yellow needles, m. p. 111–112°.

5-Nitro-3- β -diethylaminoethylamino-*o*-xylene (V).—A solution of 5-nitro-3-amino-*o*-xylene (12 g.) in xylene (50 c.c.) was refluxed with 2-diethylaminoethyl chloride (45 c.c. of a 30% xylene solution; 1.1 mols.) for 4 hours. On cooling, the product, which had separated during the heating, solidified; it was collected, and recrystallised from ethyl alcohol-petrol (equal vols., 400 c.c.), furnishing pale yellow plates of the hydrochloride of the diethylamino-compound (V), m. p. 182–183° (Found : C, 55.8; H, 8.1. $C_{14}H_{20}O_2N_3 \cdot HCl$ requires C, 55.7; H, 8.0%) (15 g., 70%). This compound formed a *picrate*, yellow needles from aqueous acetone containing a slight excess of picric acid, m. p. 164–165° (Found : C, 48.3; H, 5.5. $C_{14}H_{20}O_2N_3 \cdot C_6H_3O_7N_3$ requires C, 48.5; H, 5.3%).

5-Amino-3- β -diethylaminoethylamino-*o*-xylene (VI) (6048).—A solution of the above hydrochloride (9 g.) in 95% ethyl alcohol (150 c.c.) was rapidly hydrogenated in the presence of Adams's platinum catalyst (0.2 g.) at room temperature and pressure. The filtered solution was evaporated to dryness under reduced pressure, and the deliquescent crystalline residue dissolved in water and basified with aqueous sodium carbonate. The crude 5-amino-compound (VI) which separated was collected, dried, and crystallised from petrol (b. p. 40–60°); colourless needles, m. p. 75–76° (Found : C, 71.5; H, 10.4; N, 18.0. $C_{14}H_{22}N_3$ requires C, 71.5; H, 10.6; N, 17.9%).

When dry hydrogen chloride was passed into a solution of the amine in warm petrol, the deliquescent trihydrochloride rapidly crystallised, m. p. 170° (decomp.) (Found : N, 12.25. $C_{14}H_{22}N_3 \cdot 3HCl$ requires N, 12.2%). When the amine was refluxed with acetic acid-acetic anhydride, and the product poured into water and basified with sodium carbonate, the diacetyl derivative slowly crystallised; needles from very dilute aqueous alcohol, m. p. 140–141° (Found : C, 67.2; H, 9.4; N, 13.0. $C_{14}H_{20}O_2N_3$ requires C, 67.6; H, 9.1; N, 13.1%).

α -Diethylamino-*n*-pentan-3-one Diethyl Ketal (cf. van Schelven, B.P. 388,087).—A solution of the amino-ketone (90 g.) in a slight excess of dilute hydrochloric acid was evaporated to dryness under reduced pressure, the residual hydrochloride dissolved in alcohol (100 c.c.) containing dry hydrogen chloride (1 g.), ethyl orthoformate (100 g., 1.2 mols.) added, and the mixture set aside for 8 days. The solution was then partly neutralised by addition of sodium ethoxide (from 12 g. of sodium), filtered from sodium chloride, and shaken with an excess of silver oxide. The filtered solution was fractionally distilled, and the ketal obtained as a colourless liquid, b. p. 116–118°/14 mm. (110 g., 85%).

5-Amino-3-(β -diethylamino- α -methyl-*n*-butylamino)-*o*-xylene (VIII) (6049).—A mixture of the 5-nitro-compound (IV) (10 g.), the diethyl ketal (15.5 g., 1.1 mols.), and ammonium chloride (0.05 g.) was heated in a small distilling flask by means of a metal-bath. As the temperature reached 160° a brisk reaction set in with evolution of ethyl alcohol; when this subsided the temperature was increased to 210° and maintained there for 0.5 hour. The excess of ketal was removed under reduced pressure, and the residual anil dissolved in ethyl alcohol (100 c.c.) and hydrogenated in the presence of Adams's catalyst (0.2 g.) at 60° under a pressure of 90 atm., the almost theoretical absorption of hydrogen (4 mols.) taking 4 hours. The alcohol was then evaporated from the filtered solution, the residue refluxed with 15% hydrochloric acid (60 c.c.) for 1 hour to hydrolyse any traces of unchanged anil, and the solution cooled, basified with sodium carbonate, and extracted with ether, dried, and distilled. A small initial fraction of 3 : 5-diamino-*o*-xylene, b. p. 130°/0.05 mm., was followed by the main fraction, b. p. 170–175°/0.05 mm. This on redistillation gave the amine (VIII) as a pale brown syrup, b. p. 172–174°/0.01 mm. (Found : C, 73.3; H, 11.6; N, 15.3. $C_{14}H_{22}N_3$ requires C, 73.6; H, 11.2; N, 15.2%). The amine slowly darkens on exposure to light. No crystalline salts could be obtained; those prepared were all intractable gums which rapidly darkened when exposed to light.

4-Acetamido-*o*-xylene.—A solution of 4-amino-*o*-xylene (50 g.) in cold acetic acid (50 c.c.) was diluted with water (200 c.c.) and continuously agitated whilst acetic anhydride (50 g., 1.1 mols.) was slowly added. The acetamido-compound readily crystallised and, after the product had been poured into water (2 l.), was collected, washed and dried; m. p. 94–95° (65 g., 97%). Jacobsen (*Ber.*, 1884, 17, 161) acetylated the amine both with acetic acid alone and with acetic acid-acetyl chloride; we find that the use of acetic acid-acetic anhydride gives a syrupy product containing much diacetyl derivative.

3-Nitro-5-acetamido-*o*-xylene (IX).—Crossley and Morrell (*loc. cit.*) give no detailed directions for this preparation. The previous compound (100 g.) was added with stirring to concentrated sulphuric acid (500 c.c.) maintained at –10°, and the resulting solution continuously stirred and kept below –7° whilst a solution of nitric acid (40 c.c., *d* 1.42, 1.05 mols.) in concentrated sulphuric acid (100 c.c.) was

slowly added. The product was poured on crushed ice (ca. 10 kg.), and the solid nitro-compound collected, washed with water, and dried. Recrystallisation from alcohol gave colourless needles, m. p. 207—208° (Found : C, 58.0; H, 6.1. Calc. for $C_{10}H_{12}O_2N_2$: C, 57.7; H, 5.8%).

3-Nitro-5-amino-o-xylene (X).—The acetyl compound was refluxed with 70% sulphuric acid (5 parts) for 30 minutes, and the solution poured on ice and made alkaline with ammonia. The precipitated 5-amino-compound, collected and recrystallised from aqueous alcohol, gave deep orange needles, m. p. 74—75° (Found : C, 57.8; H, 5.9. Calc. for $C_8H_{10}O_2N_2$: C, 57.9; H, 6.0%). This compound has previously been prepared only by the reduction of the 3 : 5-dinitro-derivative (Noelting *et al.*, *loc. cit.*).

4' : 4''-Dichloro-3-nitro-4 : 5-dimethyltriphenylamine (XI).—A mixture of 3-nitro-5-amino-o-xylene (X) (10.5 g.), *p*-chloriodobenzene (16 g., 1.1 mols.), anhydrous potassium carbonate (5 g., 1.2 mols.), copper powder (0.2 g.), potassium iodide (0.05 g.), and dry nitrobenzene (50 c.c.) was gently refluxed with occasional shaking for 7 hours. The product was steam-distilled to remove nitrobenzene and *p*-chloriodobenzene, and the tarry residue dried and extracted (Soxhlet) with petrol (b. p. 40—60°; 250 c.c.). The extract on cooling deposited a reddish-yellow solid, which on crystallisation from alcohol furnished the triphenylamine (XI), pale yellow crystals, m. p. 146—147° (Found : N, 7.3; Cl, 18.1. $C_{30}H_{18}O_2N_2Cl_2$ requires N, 7.2; Cl, 18.3%) (5 g., 20%).

Aqueous dilution of the alcoholic mother-liquor precipitated a red solid, which, crystallised from methyl alcohol, furnished 4'-chloro-3-nitro-4 : 5-dimethyldiphenylamine (see later); m. p. 120—121°. Similar dilution of the methyl-alcoholic mother-liquor gave unchanged (X) (1.5 g.).

4'-Chloro-3-nitro-N-aceto-4 : 5-dimethyldiphenylamide (XII, R = Cl).—A mixture of (IX) (30 g.), *p*-chloriodobenzene (170 g.), anhydrous potassium carbonate (15 g.), copper powder (1 g.), and potassium iodide (0.5 g.) was heated with continuous stirring in a metal-bath at 240° for 4 hours. The cool product was poured into petrol (b. p. 60—80°, 1 l.), and the mixture boiled, filtered, and cooled. The acetodiphenylamide (XII, R = Cl) which separated was once recrystallised from petrol; pale yellow needles, m. p. 121—122° (Found : C, 60.7; H, 4.8; N, 8.9. $C_{18}H_{14}O_2N_2Cl$ requires C, 60.3; H, 4.7; N, 8.8%) (30 g., 70%).

4'-Chloro-3-nitro-4 : 5-dimethyldiphenylamine.—The previous compound was refluxed with 70% sulphuric acid (10 parts) for 30 minutes, and the solution cooled, poured into water, and basified with ammonia. The precipitated diphenylamine was collected and recrystallised from methyl alcohol; orange-red needles, m. p. 121—122° (Found : C, 61.2; H, 4.7; N, 10.3. $C_{14}H_{12}O_2N_2Cl$ requires C, 60.8; H, 4.7; N, 10.1%).

4'-Chloro-3-amino-N-aceto-4 : 5-dimethyldiphenylamide (XIII, R = Cl).—A solution of (XII, R = Cl) (15.5 g.) in alcohol (250 c.c.) was hydrogenated (Adams's catalyst, 0.2 g.) at 50° and 50 atm., theoretical absorption occurring in 3 hours. The filtered solution was evaporated under reduced pressure, and the crystalline residue extracted (Soxhlet) with petrol (b. p. 60—80°, 1 l.). The acetamide (XIII, R = Cl) separated from the extract as colourless crystals, m. p. 118—119° (Found : C, 66.4; H, 6.2. $C_{16}H_{14}ON_2Cl$ requires C, 66.5; H, 5.9%). When hydrogen chloride was passed into an ethereal solution of this amine, the hydrochloride readily crystallised, m. p. 210—212° (decomp.) (Found : C, 58.6; H, 5.7; N, 8.3. $C_{16}H_{14}ON_2Cl \cdot HCl$ requires C, 59.0; H, 5.7; N, 8.6%). The amine also readily afforded a picrate, yellow needles from aqueous alcohol, m. p. 198—199° (decomp.) (Found : C, 51.2; H, 4.2. $C_{16}H_{14}ON_2Cl \cdot C_6H_3O_7N_3$ requires C, 51.0; H, 3.9%).

When the amine was refluxed with dilute hydrochloric acid, the hydrochloride of 4'-chloro-3-amino-4 : 5-dimethyldiphenylamine (6050) separated during the heating in almost theoretical yield; pale pink needles from aqueous alcohol, m. p. 236—237° (decomp.) (Found : C, 59.5; H, 5.8; N, 9.8. $C_{14}H_{12}N_2Cl \cdot HCl$ requires C, 59.3; H, 5.6; N, 9.9%). Addition of aqueous ammonia to a warm aqueous-alcoholic solution of the hydrochloride precipitated the free amine, colourless needles from petrol, m. p. 98—99° (Found : C, 67.6; H, 6.1; N, 11.4. $C_{14}H_{12}N_2Cl$ requires C, 68.1; H, 6.1; N, 11.3%).

When the acetyl derivative (XIII) was hydrolysed with 70% sulphuric acid and the resulting solution poured into water, the sulphate monohydrate separated; colourless needles from alcohol, m. p. 173—174° (Found : C, 55.1; H, 5.6; N, 9.2. $(C_{14}H_{12}N_2Cl)_2 \cdot H_2SO_4 \cdot H_2O$ requires C, 55.1; H, 5.9; N, 8.8%). The yield, however, was now only 40%.

4'-Chloro-3- β -diethylaminoethylamino-4 : 5-dimethyldiphenylamine (XIV, R = Cl) (6051).—A solution of (XIII, R = Cl) (6 g.) in xylene and a solution of β -diethylaminoethyl chloride (1.1 mols.) in xylene (14 c.c., of 30% concentration) were refluxed together for 12 hours, the condensation product separating meanwhile as a heavy oil. The cold mixture was then extracted with 10% aqueous hydrochloric acid (50 c.c.), and the extract refluxed for 1 hour to hydrolyse the acetamido-group. The cold extract was basified with ammonia, the oily deposit extracted with ether, and the dried ethereal extract then distilled. The diphenylamine (XIV, R = Cl) was obtained as a viscous syrup, b. p. 222—223°/0.002 mm. (Found : C, 70.0; H, 8.4; N, 12.4. $C_{30}H_{28}N_3Cl$ requires C, 69.5; H, 8.1; N, 12.15%) (5 g., 70%).

When acetone solutions of this amine and of *p*-toluenesulphonic acid were mixed, the di-*p*-toluenesulphonate crystallised, m. p. 201° (preliminary softening and darkening) (Found : C, 58.9; H, 6.5; N, 6.1. $C_{30}H_{28}N_3Cl_2 \cdot 2C_6H_4SO_3$ requires C, 59.2; H, 6.4; N, 6.1%). This was the only crystalline salt of the base isolated.

4'-Chloro-3-(β -diethylamino- α -methyl-*n*-butylamino)-4 : 5-dimethyldiphenylamine (XVI, R = Cl) (6052).—4'-Chloro-3-amino-4 : 5-dimethyldiphenylamine (11 g.), the diethyl ketal (12 g., 1.1 mols.), and ammonium chloride (0.05 g.) were heated together for 2 hours, initially at 170° and later at 210°. The excess of ketal was removed under reduced pressure, and the residual anil dissolved in alcohol (70 c.c.) and hydrogenated (Adams's catalyst, 0.2 g.) at 60° and 100 atm. for 3 hours. The alcohol was then evaporated from the cold filtered solution, and the residue refluxed with 15% hydrochloric acid (60 c.c.) for 1 hour. The cold solution was basified (sodium hydroxide), extracted with ether, and the dried extract then distilled; the diphenylamine (XVI, R = Cl) was obtained as a pale yellow oil, b. p. 240—242°/0.07 mm. (Found : C, 71.4; H, 8.8; N, 11.0; Cl, 9.2. $C_{25}H_{34}N_3Cl$ requires C, 71.2; H, 8.8; N, 10.8; Cl, 9.2%). No crystalline salts of this amine could be isolated.

3-Nitro-4'-methoxy-4 : 5-dimethyldiphenylamine.—A mixture of (IX) (35 g.), *p*-bromoanisole (180 g.), potassium carbonate (17 g.), copper powder (1 g.), and potassium iodide (0.7 g.) was heated with stirring at 240° for 6 hours in an apparatus so arranged that water formed by slight decomposition could distil away. The cool product was then poured into hot petrol (b. p. 60–80°, 800 c.c.), and the mixture boiled, filtered, evaporated to *ca.* 250 c.c., and then steam-distilled until free from *p*-bromoanisole. The oily residue was then refluxed with 12% hydrochloric acid (120 c.c.) for 1 hour, cooled, and repeatedly extracted with ether until the extracts were colourless. The united, dried extracts on distillation gave the above *diphenylamine* as a viscous red syrup, b. p. 238–240°/0.01 mm. (30 g., 64%); trituration with methyl alcohol induced crystallisation, and the compound then crystallised from *cyclohexane* in orange-yellow plates, m. p. 122–123° (Found: C, 66.5; H, 6.3; N, 10.1. $C_{18}H_{18}O_2N_2$ requires C, 66.2; H, 5.9; N, 10.3%).

3-Amino-4'-methoxy-4 : 5-dimethyldiphenylamine (6053).—A solution of the above compound (30 g.) in alcohol (250 c.c.) was hydrogenated as usual at 50° and 50 atm. for 5 hours. Fractional distillation ultimately gave this *diphenylamine* as a colourless oil, b. p. 220°/0.01 mm., which set to a brittle deliquescent glass, which could not be crystallised (Found: N, 11.3. $C_{18}H_{18}ON_2$ requires N, 11.6%) (22 g., 87%). This compound formed a *picrate* which, recrystallised from very dilute aqueous picric acid, formed fine yellow needles, m. p. 183° (decomp.) (Found: C, 53.25; H, 4.7. $C_{18}H_{18}ON_2 \cdot C_6H_3O_7N_3$ requires C, 53.5; H, 4.5%).

3-β-Diethylaminoethylamino-4'-methoxy-4 : 5-dimethyldiphenylamine (XIV, R = MeO) (6054).—This was prepared precisely similarly to the 4'-chloro-analogue but by using the unacetylated diphenylamine, and obtained initially as a crude fraction, b. p. 235–240°/0.06 mm., which on refractionation gave the pure *diphenylamine* as a colourless oil, b. p. 238°/0.01 mm. (Found: N, 12.6. $C_{21}H_{21}ON_2$ requires N, 12.3%) (60%).

3-δ-Diethylamino-α-methyl-n-butylamino-4'-methoxy-4 : 5-dimethyldiphenylamine (XVI, R = MeO) (6055).—This compound was also prepared precisely similarly to the 4'-chloro-analogue and obtained as a pale green oil, b. p. 210°/0.002 mm. (Found: C, 74.8; H, 9.3; N, 11.3. $C_{26}H_{28}ON_2$ requires C, 75.2; H, 9.7; N, 11.0%): 58% of the theoretical.

No crystalline salts of the last two amines could be isolated.

This research was carried out on behalf of the Medical Research Council under a wartime collaborative agreement on antimalarial research between the Medical Research Council and Imperial Chemical Industries Ltd. We are greatly indebted to the Council for a grant (J. W. G. P.) and to Imperial Chemical Industries Ltd. both for materials and for carrying out the antimalarial tests.

169. Synthetic Antimalarials. Part XIX. Dialkylaminoalkylaminodiphenylguanidines.

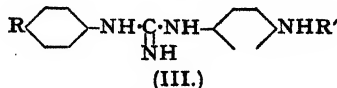

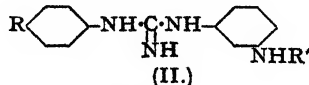

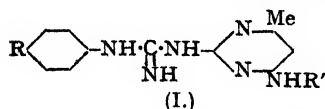

By FREDERICK G. MANN, FREDERICK T. NAYLOR, and J. W. GEOFFREY PORTER.

The study of the effect on antimalarial activity caused by replacing the pyrimidine by the benzene ring has been extended to include the diphenylguanidines of types (II) and (III), the former being the benzene analogues of the active 2-phenylguanidino-4-dialkylaminoalkylamino-6-methylpyrimidines of type (I).

The scope of the investigation was restricted by the intractable nature of many of the products.

IN Part XVIII (Mann and Porter, preceding paper) an attempt was made to ascertain whether the marked antimalarial properties of the 2-*p*-chloroanilino-4-dialkylaminoalkylamino-6-methylpyrimidines were determined primarily by their general molecular structure, or more specifically by the presence and properties of the constituent pyrimidine ring. This factor was investigated by preparing analogous compounds differing only in that the pyrimidine ring of the former compounds had now been replaced by a benzene ring. The compounds so prepared, of the general type 4'-chloro-3-dialkylaminoalkylamino-4 : 5-dimethyldiphenylamine, were found to be without antimalarial activity.

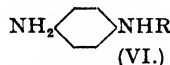

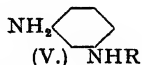

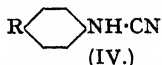

It was clearly desirable, however, that the evidence concerning this factor should not be limited to one class of pyrimidine derivative. The 2-phenylguanidino-4-dialkylaminoalkylamino-6-methylpyrimidines (Curd and Rose, *J.*, 1946, 362) (I) constitute a second class of pyrimidine derivative having high antimalarial activity, and it was considered of interest,

therefore, to prepare their benzene analogues, *i.e.*, diphenylguanidines of type (II). Furthermore, in order to determine whether the position of the dialkylaminoalkylamino-

substituent relative to that of the guanidine nucleus has any marked influence on the antimalarial activity, the preparation of the *pp'*-disubstituted diphenylguanidines of type (III) was investigated.

The most convenient method for the preparation of asymmetrically disubstituted diaryl guanidines is the interaction of an aryl cyanamide with the hydrochloride of an arylamine (Heller and Bauer, *J. pr. Chem.*, 1902, **65**, 384). Thus *p*-chlorophenylcyanamide (IV, R = Cl) condensed with *N*- β -diethylaminoethyl-*m*-phenylenediamine (V, R = CH₂·CH₂·NEt₂) in alcoholic hydrogen chloride to afford *N*-*p*-chlorophenyl-*N'*-*m*- β -diethylaminoethylaminophenylguanidine (II, R = Cl, R' = CH₂·CH₂·NEt₂) in moderate yield. A similar condensation between (IV, R = Cl) and *N*- β -diethylaminoethyl-*p*-phenylenediamine furnished *N*-*p*-chlorophenyl-*N'*-*p*- β -diethylaminoethylaminophenylguanidine (III, R = Cl, R' = CH₂·CH₂·NEt₂). Both the above guanidines were crystalline compounds.

N- β -Diethylaminoethyl-*m*-phenylenediamine has previously been prepared (U.S.P. 1,757,394) by heating *m*-phenylenediamine with β -diethylaminoethyl chloride. A more convenient preparation both of this compound and of *N*- β -diethylaminoethyl-*p*-phenylenediamine consists in the condensation of β -diethylaminoethyl chloride and the corresponding nitroaniline to give the hydrochloride of 1-nitro-3- β -diethylaminoethylamino- and of 1-nitro-4- β -diethylaminoethylamino-benzene. Catalytic reduction of these hydrochlorides afforded good yields of the phenylenediamines (V and VI, R = CH₂·CH₂·NEt₂).

With the object of preparing the analogous guanidines carrying the δ -diethylamino- α -methyl-*n*-butyl side chain, *N*- δ -diethylamino- α -methyl-*n*-butyl-*m*- and -*p*-phenylenediamine (V and VI, R = CHMe·[CH₂]₃·NEt₂) were prepared by condensing the appropriate nitroaniline with δ -diethylamino-*n*-pentan-2-one diethyl ketal and reducing the resulting anil to give the required product (cf. Mann and Porter, *loc. cit.*). Although both these substituted phenylenediamines appeared to react with (IV, R = Cl) under the usual conditions, the products proved to be intractable, deliquescent gums which could neither be crystallised nor induced to give crystalline salts. Dewar (*J.*, 1944, 534) has noted similar difficulties in attempting to crystallise *N*-dialkylaminoalkyldiarylguanidines.

Attempts were next made to prepare compounds of types (II) and (III) in which R = OMe. *p*-Methoxyphenylthiourea (Dienske, *Rec. Trav. chim.*, 1931, **50**, 407) was treated with lead hydroxide to give *p*-methoxyphenylcyanamide (IV, R = OMe). This reacted normally with each of the above four substituted phenylenediamines but no crystalline product could be isolated. Analysis of the resinous gum produced by the reaction between (IV, R = OMe) and *N*- β -diethylaminoethyl-*p*-phenylenediamine showed it to be almost certainly the required *N*-*p*-methoxyphenyl-*N'*-*p*- β -diethylaminoethylaminophenylguanidine (III, R = OMe, R' = CH₂·CH₂·NEt₂).

An alternative synthetic route was equally unproductive of crystalline products. *p*-Methoxyphenylcyanamide was heated in alcoholic solution with *m*-nitroaniline hydrochloride to form *N*-*p*-methoxyphenyl-*N'*-*m*-nitrophenylguanidine hydrochloride which was catalytically reduced to *N*-*p*-methoxyphenyl-*N'*-*m*-aminophenylguanidine hydrochloride (II, R = OMe, R' = H). The latter compound, however, did not condense normally with β -diethylaminoethyl chloride: a complex mixture of products, arising apparently from the rupture of the guanidino-linkage, being isolated.

Only the two crystalline guanidine derivatives (II and III, R = Cl, R' = CH₂·CH₂·NEt₂) have been tested. Whereas the former (5220) showed significant activity (+ to ++ at 80 mg./kg.) the latter (6180) was inactive at the same dosage (highest tested). The former is the more closely related to the active 2-arylguanidino-4-dialkylaminoalkylaminopyrimidines of type (I), and the conclusion may therefore perhaps be drawn that the replacement of a pyrimidine ring by a benzene ring in an antimalarial structure based on pyrimidine does not necessarily lead to complete loss of activity despite the results given in the previous paper. In this connection it may be noted that, whereas the diphenylamines described in the previous paper do not retain any of the tautomeric possibilities characteristic of their pyrimidine analogues, the diphenylguanidine (II, R = Cl, R' = CH₂·CH₂·NEt₂) is not devoid of all the tautomeric possibilities existent in type (I).

EXPERIMENTAL.

1-Nitro-3- β -diethylaminoethylaminobenzene.—A mixture of *m*-nitroaniline (100 g.) and β -diethylaminoethyl chloride (105 g., 1.1 mols.) in xylene (500 c.c.) was refluxed for 3 hours. The crystalline

hydrochloride was then collected and recrystallised from ethyl alcohol–light petroleum (b. p. 60–80°) (equal vols.); pale yellow needles, m. p. 177–178° (Found: N, 15.3; Cl, 13.2. $C_{12}H_{19}O_2N_2 \cdot HCl$ requires N, 15.4; Cl, 13.0%). Yield, 140 g.; 70%.

Basification of an aqueous solution of the hydrochloride furnished the oily base (Found: C, 60.35; H, 8.1; N, 17.7. $C_{12}H_{19}O_2N_2$ requires C, 60.7; H, 8.1; N, 17.7%). The base readily afforded a *picrate*, orange crystals from alcohol, m. p. 149–150° (Found: N, 18.2. $C_{12}H_{19}O_2N_2 \cdot C_6H_3O_7N_3$ requires N, 18.0%).

1-Nitro-4- β -diethylaminoethylaminobenzene hydrochloride was similarly prepared and recrystallised; yellow needles, m. p. 159–160° (Found: C, 52.35; H, 7.6; N, 15.3. $C_{12}H_{19}O_2N_2 \cdot Cl$ requires C, 52.6; H, 7.6; N, 15.4%). Yield, 72%. The *picrate*, yellow needles from ethyl alcohol, had m. p. 168–169° (Found: N, 18.5. $C_{12}H_{19}O_2N_2 \cdot C_6H_3O_7N_3$ requires N, 18.0%).

N- β -Diethylaminoethyl-*m*-phenylenediamine (V, $R = CH_2 \cdot CH_2 \cdot NEt_2$).—A solution of 1-nitro-3- β -diethylaminoethylaminobenzene hydrochloride (140 g.) in 90% aqueous ethyl alcohol (350 c.c.) was hydrogenated (Adams's catalyst, 0.3 g.) at room temperature and atmospheric pressure. The filtered solution was evaporated and then basified with aqueous sodium hydroxide. The product was extracted with ether and the dried extract fractionally distilled. The pure *amine* had b. p. 154°/0.05 mm. (Found: C, 69.2; H, 10.4; N, 19.9. $C_{12}H_{19}N_3$ requires C, 69.5; H, 10.3; N, 20.3%). Yield, 106 g.; 85%.

N- β -Diethylaminoethyl-*p*-phenylenediamine (VI, $R = CH_2 \cdot CH_2 \cdot NEt_2$) was similarly prepared as a hygroscopic oil, b. p. 156°/0.02 mm. (Found: C, 69.1; H, 10.8; N, 21.0%).

p-Chlorophenylcyanamide (IV, $R = Cl$).—This compound was prepared from *p*-chlorophenylthiourea and obtained as colourless needles, m. p. 103° (Found: N, 18.4. Calc. for $C_7H_5N_2Cl$: N, 18.3%).

N-*p*-Chlorophenyl-*N'*-*m*- β -diethylaminoethylaminophenylguanidine (II, $R = Cl$, $R' = CH_2 \cdot CH_2 \cdot NEt_2$).—A solution of (IV, $R = Cl$) (10 g.) and *N*- β -diethylamino-*m*-phenylenediamine (13 g., 1 mol.) in ethyl alcohol (50 c.c.) containing hydrogen chloride (2.5 g., 2 mols.) was refluxed for 20 hours. The whole was then poured into 5% acetic acid (300 c.c.) and filtered, and the filtrate was slowly run into an excess of ice-cold 10% aqueous sodium hydroxide. The sticky white solid which separated was collected and dried. Prolonged extraction (Soxhlet) with light petroleum (b. p. 60–80°) afforded the crude product, which readily separated from the hot solution. Recrystallisation from light petroleum gave the pure *guanidine*, m. p. 112–113° (Found: C, 63.8; H, 6.9; N, 19.5. $C_{19}H_{28}N_6$ requires C, 63.4; H, 7.3; N, 19.5%). Yield, 3.8 g.; 17%.

N-*p*-Chlorophenyl-*N'*-*p*- β -diethylaminoethylaminophenylguanidine (III, $R = Cl$, $R' = CH_2 \cdot CH_2 \cdot NEt_2$).—A solution of (IV, $R = Cl$) (11.8 g.) and *N*- β -diethylamino-*p*-phenylenediamine (16.4 g., 1 mol.) in ethyl alcohol (55 c.c.) containing hydrogen chloride (2.85 g., 2 mols.) was refluxed for 24 hours. The solution was then evaporated and the residue was triturated with a slight excess of 5% aqueous ammonia. The resulting gum was washed by stirring with water and dried. Repeated extraction with light petroleum (b. p. 40–60°) afforded the *guanidine* which was once recrystallised from light petroleum; colourless plates, m. p. 102–103° (Found: C, 63.5; H, 7.5; N, 19.0%). Yield, 5 g.; 18%.

N- δ -Diethylamino- α -methyl-*n*-butyl-*m*-phenylenediamine (V, $R = CHMe \cdot [CH_2]_3 \cdot NEt_2$).—*m*-Nitroaniline (50 g.), δ -diethylamino-*n*-pentan-2-one diethyl ketal (88 g.), and ammonium chloride (0.05 g.) were heated together for 2 hours, initially at 170° and later at 210°. The excess of ketal was removed under reduced pressure and the residual anil was dissolved in alcohol (200 c.c.) and hydrogenated (Adams's catalyst, 0.2 g.) at 60° and 100 atmospheres during 3 hours. The filtered solution was evaporated and the residue refluxed with 15% hydrochloric acid (400 c.c.) for $\frac{1}{2}$ hour. The cold solution was basified (sodium hydroxide) and extracted with ether, and the dried extract was distilled. The *amine* was obtained as a colourless oil, b. p. 168°/0.01 mm. (Found: C, 72.1; H, 11.1; N, 17.0. $C_{18}H_{27}N_3$ requires C, 72.3; H, 10.8; N, 16.9%). Yield, 50 g.; 55%.

N- δ -Diethylamino- α -methyl-*n*-butyl-*p*-phenylenediamine (VI, $R = CHMe \cdot [CH_2]_3 \cdot NEt_2$) was similarly prepared, except that the temperature during anil formation was not raised above 180°, since a higher temperature caused spontaneous decomposition. This *amine*, a colourless oil, had b. p. 174°/0.05 mm. (Found: C, 71.9; H, 10.7; N, 16.9%). Yield, 20 g.; 23%.

p-Methoxyphenylcyanamide (IV, $R = OMe$).—*p*-Methoxyphenylthiourea (30 g.), potassium hydroxide (43 g.), lead acetate (85 g.), and water (430 c.c.) were stirred during heating on a steam-bath for 15 minutes. The lead sulphide was then collected, and the filtrate acidified with 10% acetic acid and cooled. The crude product was filtered off, dissolved in 5% sodium hydroxide (150 c.c.), and cautiously reprecipitated by the addition of 5% acetic acid. Careful neutralisation resulted in the almost complete separation of a pale yellow amorphous material (ca. 1 g.) which was collected; acidification of the filtrate then caused the required product to separate in short needles. A second similar purification gave the *cyanamide* as colourless needles, m. p. 86–87° (Found: C, 64.8; H, 5.6. $C_8H_9ON_2$ requires C, 64.8; H, 5.4%). 10 g., 40%.

N-*p*-Methoxyphenyl-*N'*-*m*-nitrophenylguanidine.—*p*-Methoxyphenylcyanamide (7 g.) and *m*-nitroaniline hydrochloride (8.5 g., 1 mol.) were dissolved in alcohol (35 c.c.) and heated under reflux for 24 hours. The whole was then poured into 2% acetic acid (1 l.) and filtered. The filtrate was basified (sodium hydroxide) and the crude product collected. Two recrystallisations from 50% aqueous alcohol gave the pure *guanidine*, orange-red needles, m. p. 142° (Found: C, 58.3; H, 5.2; N, 19.6. $C_{14}H_{14}O_3N_4$ requires C, 58.7; H, 4.9; N, 19.6%). 8 g., 55%. The hydrochloride formed colourless needles, m. p. 128–136° (Found: C, 52.5; H, 4.6; N, 17.2. $C_{14}H_{14}O_3N_4 \cdot HCl$ requires C, 52.1; H, 4.7; N, 17.4%).

N-*p*-Methoxyphenyl-*N'*-*m*-aminophenylguanidine Hydrochloride (II, $R = OMe$, $R' = H$).—A solution of the above hydrochloride (8 g.) in alcohol (200 c.c.) was hydrogenated (Adams's catalyst, 0.2 g.) at room temperature and atmospheric pressure. The filtered solution was evaporated to ca. 50 c.c. and, on cooling, the *amino-guanidine* hydrochloride crystallised. Recrystallisation from alcohol gave small crystals, m. p. 212° (Found: C, 57.8; H, 6.0; N, 20.1. $C_{14}H_{14}ON_4 \cdot HCl$ requires C, 57.4; H, 5.9; N, 20.05%). Yield, 5 g.; 70%.

N-*p*-Methoxyphenyl-*N'*-*p*- β -diethylaminoethylaminophenylguanidine (III, $R = OMe$, $R' = CH_2 \cdot CH_2 \cdot NEt_2$).—*p*-Methoxyphenylcyanamide (7.5 g.) and *N*- β -diethylaminoethyl-*p*-phenylenediamine

(10.5 g.) were dissolved together in ethyl alcohol (35 c.c.) containing hydrogen chloride (2.9 g.) and refluxed for 36 hours. Evaporation followed by trituration of the residue with 5% aqueous ammonia gave a brown gum which was washed and dried. Repeated extraction with hot light petroleum (b. p. 40–60°) afforded, on cooling, a pale brown gum (1 g.). This was shaken with ether (20 c.c.), the ethereal solution evaporated, and the residue re-extracted with hot light petroleum. On cooling, the *guanidine* separated as a pale brown gum which was almost pure (Found: C, 68.3; H, 8.7; N, 19.1. $C_{20}H_{22}ON_5$ requires C, 67.6; H, 8.2; N, 19.7%). Yield, 0.7 g.; 4%. Neither the base nor any salts could be obtained crystalline.

This research was carried out on behalf of the Medical Research Council under a wartime collaborative agreement on antimalarial research between the Medical Research Council and Imperial Chemical Industries Ltd. We are greatly indebted to the Council for grants (F. T. N., J. W. G. P.) and to Imperial Chemical Industries Ltd., both for materials and for carrying out the antimalarial tests.

UNIVERSITY CHEMICAL LABORATORY, CAMBRIDGE.

[Received, September 30th, 1946.]

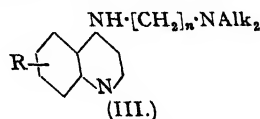

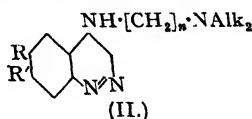

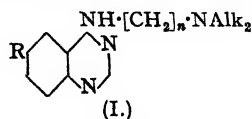

170. Synthetic Antimalarials. Part XX. Cinnolines. Part XIII. Synthesis and Antimalarial Action of 4-Aminoalkylaminocinnolines.

By J. R. KENEFORD and J. C. E. SIMPSON.

The preparation of a series of 6- and 7-substituted 4-aminoalkylaminocinnolines is described, and their antimalarial activities are recorded.

THE cinnoline ring-system is one which has obvious potentialities as a vehicle for the production of chemotherapeutic agents. As a result of earlier work (*J.*, 1942, 353; 1943, 447; 1945, 512, 520; 1946, 673; this vol., pp. 227, 232) having as its objective the consolidation of routes leading to different types of 4-substituted cinnolines, we were in a position to investigate the chemotherapeutic possibilities which this field appeared to offer, and we decided first to attempt to prepare compounds having antimalarial activity. Our interest in this problem was given additional stimulus by the fact that, when the work was begun, the bulk of the published synthetic work relating to the chemotherapy of malaria was restricted to derivatives of acridine and quinoline, although a few aminoalkylaminoquinazolines of type (I; R = Cl or NO₂) had been synthesised by Magidson and Golovchinskaya (*J. Gen. Chem. Russia*, 1938, 8, 1797; *Chem. Abs.*, 1939, 33, 4993); these compounds, however, were stated to be devoid of antimalarial activity.

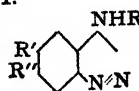

Preliminary results with cinnoline derivatives of type (II; R = H or OMe; R' = H) (Simpson and Schofield, *Nature*, 1946, 157, 439) suggested that activity might be expected in suitably substituted compounds, and in this paper we describe the preparation of a series of derivatives of type (II) substituted at C₆ and C₇. In choosing these positions of nuclear substitution we were guided partly by the accessibility of intermediates and partly by the fact that antimalarial activity is recorded for 4-aminoalkylaminoquinolines substituted in the same positions (III; R at C₆ or C₇) (Schönhöfer, *Z. physiol. Chem.*, 1942, 274, 1; B.P. Appl. 27673/38).

The compounds listed in Table III were prepared by conversion of the requisite 4-hydroxycinnoline (*J.*, 1945, 520; this vol., pp. 227, 232) into the 4-chloro- and thence into the 4-phenoxy-derivative, followed by condensation of the latter with the appropriate amine; the use of phenoxy- instead of chloro-compounds for this reaction was more convenient, as most 4-chlorocinnolines decompose on storage, whereas the phenoxy-compounds can be kept indefinitely. The yield of 7-chloro-4-hydroxycinnoline was raised from 30% (this vol., p. 232) to 90% by the use of concentrated hydrochloric acid for the final stage, and we have found that this modification is of general applicability to the preparation in high yield of 4-hydroxycinnolines which do not contain an electron-attractive group in positions 6 or 8.

The compounds (I) were tested against *P. gallinaceum* in chicks at the Blackley laboratories of Imperial Chemical Industries Limited by the method of Curd, Davey, and Rose (*Ann. Trop. Med. Parasit.*, 1945, 39, 139), and the results [including, for purposes of comparison, those of Simpson and Schofield (*loc. cit.*)] are shown in Table I. Inspection of these results leads to the following conclusions: (a) Combination of the side-chain characteristic of mepacrine and

* Activity is shown as marked (++), slight (+), doubtful (±), or inactive (—).

pamaquin with a suitably substituted nucleus results in considerably greater activity than does the combination of other side-chains with the same nuclei (compare, *e.g.*, 3309, 6022, 5656 with 3602, 6024, 5853); (b) substitution at C₇, *ceteris paribus*, increases the antimalarial activity; (c) substitution at C₈ exerts a pronounced dystherapeutic effect. These conclusions are meant to apply only to the range of compounds studied; a discussion of their possible significance is held over pending the accumulation of further data.

The following compounds were tested for prophylactic activity against *P. gallinaceum* in chicks by the method of Davey (*Ann. Trop. Med. Parasit.*, 1946, 40, 52) but found to be inactive; 5654, 5659, 6022, 6023, and 6024 at 80 mg./kg., and 6024, 6025, and 6026 at 160 mg./kg.

A paper by Leonard and Boyd (*J. Org. Chem.*, 1946, 11, 419), which appeared after completion of this work, describes the preparation of 6023 and of 6-bromo-4-γ-diethylaminopropyl-

aminocinnoline; these compounds, for which no antimalarial results are yet recorded, were made directly from the chlorocinnolines and the amine.

EXPERIMENTAL.

M. ps. are uncorrected Derivatives of 4-hydroxy- and 4-hydroxy-6-methoxy-cinnoline were prepared by Dr. K. Schofield. All the reactions could apparently be carried out on any desired scale without loss of yield.

Improved Preparation of 7-Chloro-4-hydroxycinnoline.—Diazotisation was effected in hydrochloric acid, followed by heating on the steam-bath at 60° (cf. this vol., p. 232). It was found that the yield of cinnoline increased with an increase in concentration of acid up to ca. 8.5N; the yield was then 90–95%, and no significant increase resulted with higher concentrations. The ratio amino-ketone : acid medium varied between 1 : 60 and 1 : 100.

Similar results were obtained in the preparation of 4-hydroxycinnoline (70–75% yield in 9–9.5N-hydrochloric acid; contrast *J.*, 1945 520); amino-ketone : acid medium = ca. 1 : 100.

In each set of experiments the acid concentrations were calculated after addition of the nitrite solution, and the time of reaction was 4–5 hours. The products were isolated by evaporation under reduced pressure (this gave 4-hydroxycinnoline as hydrochloride, but in the case of the 7-chloro-compound much free base crystallised from the reaction mixture).

Preparation of 4-Chlorocinnolines.—The appropriate 4-hydroxycinnoline (1 mol.), phosphorus pentachloride (ca. 2 mols.), and phosphorus oxychloride (ca. 6 mols.) were heated on the steam-bath for 1 hour. The reaction was usually rapid; the hydroxycinnoline dissolved, and the chlorocinnoline crystallised from the hot solution. The mixture was poured on ice, made just alkaline with aqueous sodium hydroxide, and extracted with ether. The extract was washed with very dilute sodium hydroxide and water, dried, and concentrated (in the case of 4-hydroxycinnoline this was done under reduced pressure); yields of crude products were 80–90%. 4-Anilino-cinnolines, by which the chlorocinnolines were occasionally characterised, were made by warming the reactants on the steam-bath for a few minutes, followed by crystallisation of the products from alcohol or ammoniacal alcohol.

4-Chlorocinnoline formed very pale yellow needles, m. p. 78–79°, from ether-ligroin (b. p. 40–60°); Busch and Klett (*Ber.*, 1892, 25, 2847) and Leonard and Boyd (*loc. cit.*) give m. p. 79° and 76–77° respectively. The compound is unstable and decomposes very rapidly when warmed either alone or with acids. 4-Anilino-cinnoline formed pale yellow silky needles, m. p. 229.5–230.5° (Busch and Klett, *loc. cit.*, give m. p. 232°) (Found : N, 19.0. Calc. for $C_{14}H_{11}N_3$: N, 19.0%). 4-Chloro-6-bromocinnoline, pale yellow needles, had m. p. 136–138° [Leonard and Boyd, *loc. cit.*, give 136–137° and 127–128° (interconvertible)]. 4 : 7-Dichlorocinnoline formed colourless polyhedra, m. p. 143–144° (Found : C, 48.3; H, 2.1; Cl, 35.4. Calc. for $C_8H_4N_2Cl_2$: C, 48.2; H, 2.0; Cl, 35.7%). Leonard and Boyd give m. p. 143–143.5°. The 4 : 6-isomer, soft pale yellow needles, had m. p. 111–112°, and 4 : 6-dichloro-7-methylcinnoline crystallised in small cream-coloured needles, m. p. 176–177°. 4-Chloro-6-methoxycinnoline formed colourless hair-like needles, m. p. 149–151°, from ether (Found : Cl, 18.4. $C_9H_7ON_2Cl$ requires Cl, 18.25%), and yielded 4-anilino-6-methoxycinnoline (pale yellow needles, m. p. 235.5–236°) (Found : C, 71.6; H, 5.25. $C_{14}H_{13}ON_3$ requires C, 71.7; H, 5.2%).

Preparation of 4-Phenoxycinnolines.—The chloro-compound (1 mol.) was added to a solution of powdered potassium hydroxide (1.2 mols.) in phenol (ca. 7.5 mols.), and the whole was heated on the steam-bath for 1 hour (the reaction with 4-chloro-6-methoxycinnoline was sluggish, and a reaction time of 6 hours was used). The mixture was poured into excess of aqueous sodium hydroxide and extracted with ether, after which the extract was repeatedly washed with sodium hydroxide solution and water, dried, and concentrated, giving the phenoxy-compounds (see Table II) in yields of 80–95%.

Preparation of 4-Aminoalkylaminocinnolines.—The phenoxy-compound (1 mol.) and aliphatic amine (ca. 2 mols.) were heated in an oil-bath, completion of the reaction being ascertained by examination of a sample of the material which (except in the reactions with δ -diethylamino- α -methylbutylamine) crystallised on cooling. The cold mixtures were filtered after addition of ether and the solid bases crystallised from the appropriate solvent (yields, 90–95%). The reactions in which δ -diethylamino- α -methylbutylamine was used were more sluggish than those with other amines, and the products from them were worked up by basification with aqueous sodium hydroxide and extraction with ether; the ethereal solutions were extracted with 33% aqueous acetic acid, the latter basified, and the products again taken into ether, which was washed, dried, and evaporated; excess of fatty amine was then removed at 90–110°/0.2–0.5 mm., and the residues recrystallised (yields were 65–75%). Distillation of the aminoalkylaminocinnolines was unsuccessful in the few cases tried owing to decomposition. 4404 was prepared by heating the chloro-compound and amine in phenol at 170°; 3602 was formed when 4-chlorocinnoline and the amine were heated at 130° without solvent under nitrogen, but was best prepared *via* the phenoxy-compound.

This investigation was carried out as part of a wartime programme of antimalarial research sponsored by the Medical Research Council in collaboration with Imperial Chemical Industries Limited. We are indebted to the former for a Research Studentship (J. R. K.) and to the latter for materials and for carrying out the biological tests. We are also greatly indebted to the workers of Imperial Chemical Industries for many discussions on the above work.

171. *The Effect of Temperature on the Proportions of Isomers formed in the Mononitration of Toluene.*

By W. W. JONES and M. RUSSELL.

Toluene has been nitrated with mixtures of nitric and sulphuric acids at various temperatures from -30° to 60° . The proportion of *m*-nitrotoluene formed in each instance has been calculated from the setting point of the derived TNT. The results afford evidence that in applying the Arrhenius equation $k = nAe^{-E/RT}$ to the mononitration of toluene, $A_p = 2.90 A_m$, $A_p = 2.70 A_m$, $E_m - E_o = 917$ and $E_m - E_p = 1103$ cal. deg. $^{-1}$ mol. $^{-1}$.

THE manufacture of trinitrotoluene is complicated by the undesirable formation of *m*-nitrotoluene in the mononitration stage. Several workers have published data on the proportions of isomers formed in the mononitration of toluene at various temperatures and in several media. Their results, for percentage *m*-nitrotoluene, are collected in Table I. Generally

the proportions of isomers were determined by thermal analysis, but Ingold *et al.* (*loc. cit.*) also determined the meta-content by solubility measurements on the derived nitrobenzoic acids.

The figures recorded in Table I show rather wide variations and, in particular, they indicate that change in meta-nitration with temperature is much less for nitration in mixed acid than in other media. Because of its technical importance, nitration in mixed acid has been reinvestigated, using a new method of analysis which is simpler and considered to be less liable to error than thermal analysis.

2:4-Dinitrotoluene, *p*-nitrotoluene, and known mixtures of *m*- and *p*-nitrotoluene were trinitrated by the standard method described in the experimental part, and the setting points of

TABLE II.

Concn. of <i>m</i> -nitrotoluene (%)	2:4-DNT.	Mixtures of <i>m</i> - and <i>p</i> -nitrotoluene.				
		0	2.11	3.22	4.58	5.75
Setting point of TNT, found	80.80°	80.78°	79.87°	79.26°	78.70°	78.13°
" " " , calc.	—	80.80°	79.82°	79.30°	78.67°	78.13°

the products were determined. The results are recorded in Table II, the setting points being corrected. Setting points have been calculated from the equation:

$$\text{Setting point} = 80.80 - 0.465 (\text{concn. of } m\text{-nitrotoluene}) \quad (1)$$

which was derived from the data by the method of least differences. That trinitration in these experiments was substantially complete is shown by the close agreement between the setting points of products derived from *p*-nitrotoluene and 2:4-dinitrotoluene with that recorded by Rintoul (*J. Soc. Chem. Ind.*, 1916, **34**, 80).

Toluene was nitrated at various temperatures with 1.2 mols. of nitric acid in the form of a mixed acid. The nitrotoluenes, after removal of unchanged toluene, were trinitrated by the

standard method. The setting points of the trinitrotoluenes were determined and the proportions of *m*-nitrotoluene in the original nitrotoluenes were calculated from equation (1). The results,

TABLE III.

Temperature of mononitration	-30°	0°	30°	60°
Setting point of TNT	79.42°	79.09°	78.76°	78.52°
Concn. of <i>m</i> -nitrotoluene (%)	2.97	3.68	4.39	4.90

collected in Table III, show that the proportion of *m*-nitrotoluene changes almost linearly with temperature and there is no evidence that the rate of change is less for mixed acid nitrations than for nitrations in other media.

DISCUSSION.

Bradfield and Jones (*J.*, 1928, 1006) calculated, for several substitutions, the proportions of isomers formed at one temperature from the experimentally determined proportions at a second temperature by means of the Arrhenius equation, $k = nAe^{-E/RT}$, in which, for each isomer, k is the rate of formation, n is the number of equivalent substitution positions, A is a temperature-independent factor, E is the energy of activation, and T is the absolute temperature. They obtained fair agreement with experiment on the assumption that A was the same for each isomer formed in a particular reaction. The close agreement, for the proportion of *m*-nitrotoluene formed at 0° and 30°, between our results and those of Ingold *et al.*, determined by entirely different techniques, is strong evidence for the essential reliability of the experimental data. The values for *m*-nitrotoluene, calculated for other temperatures by the method of Bradfield and Jones from the data of Ingold *et al.* at 30°, are given in the left side of Table IV. They show increasing divergence from our experimental values as the temperatures depart from 30°. As these deviations are considerable and show a systematic trend they cannot be attributed to experimental error.

Better agreement between calculated and experimental results can be obtained only by assuming that the temperature-independent factors are different for the three isomers. Appropriate values for these factors can be calculated from the proportions of isomers at two temperatures, thus:

$$\text{Let } k_o = 2A_o e^{-E_o/RT}; \quad k_m = 2A_m e^{-E_m/RT}; \quad k_p = A_p e^{-E_p/RT}$$

$$\text{Then } k_o/k_m = (A_o/A_m)e^{(E_m - E_o)/RT}$$

If r_1 and r_2 are the ratios of *o*- to *m*-nitrotoluene formed at two temperatures T_1 and T_2 , then

$$2.303 \{ \log_{10} r_1 - \log_{10} (A_o/A_m) \} = (E_m - E_o)/RT_1 \quad . \quad . \quad . \quad (2)$$

$$\text{and } 2.303 \{ \log_{10} r_2 - \log_{10} (A_o/A_m) \} = (E_m - E_o)/RT_2$$

Dividing and transposing we obtain

$$\log_{10} (A_o/A_m) = (T_2 \log_{10} r_2 - T_1 \log_{10} r_1)/(T_2 - T_1) \quad . \quad . \quad . \quad (3)$$

Similarly, if s_1 and s_2 are the ratios of *p*- to *m*-nitrotoluene at T_1 and T_2 ,

$$\log_{10} (A_p/2A_m) = (T_2 \log_{10} s_2 - T_1 \log_{10} s_1)/(T_2 - T_1) \quad . \quad . \quad . \quad (4)$$

By substituting in equations (3) and (4) the ratios of isomers given by Ingold *et al.* for 0° and 30° it was found that

$$A_o = 2.90A_m \text{ and } A_p = 2.70A_m.$$

and by further calculation the proportions of isomers formed at -30° and 60°, shown in the right side of Table IV, were obtained. It is evident that much better agreement with experiment is given by the new equations.

TABLE IV.

Temp.	$A_o = A_m = A_p.$			$A_o = 2.90A_m; A_p = 2.70A_m.$		
	<i>o</i> (%).	<i>m</i> (%).	<i>p</i> (%).	<i>o</i> (%).	<i>m</i> (%).	<i>p</i> (%).
-30°	58.33	2.32	39.35	57.55	2.98	39.47
0	58.49	3.31	38.20	(58.10)	(3.70)	(38.20)
30	(58.45)	(4.40)	(37.15)	(58.45)	(4.40)	(37.15)
60	58.21	5.54	36.25	58.66	5.07	36.27

The numbers in parentheses are the experimental values on which the calculations are based.

The values of A_o and A_p are nearly equal and only small changes in the proportions of *o*- and *p*-nitrotoluene, but none in the proportions of *m*-nitrotoluene, are caused by adopting the mean value, 2.80, for both. There does not, however, appear to be any reason why, in the general case, A_o should be equal to A_p and so the separate values have been used in the calculations of Table IV.

From equation (2) and the corresponding equation for the ratio of *p*- to *m*-nitrotoluene we have obtained the following values, in cal. deg.⁻¹ mol.⁻¹, for activation energy differences :

$$E_m - E_o = 917$$

$$E_m - E_p = 1103$$

EXPERIMENTAL.

Materials.—"Nitration" toluene (National Benzole Specification No. 7, 1938) was distilled through a short column. The middle fraction, having d_{4}^{20} : 0.8710, n_{D}^{20} : 1.4963, was used. Commercial *m*-nitrotoluene was purified by fractional freezing until the maximum setting point, 16.0° (corr.), was reached. Commercial *p*-nitrotoluene and 2:4-dinitrotoluene were recrystallised from alcohol until the setting points remained unchanged at 51.6° (corr.) and 69.8° (corr.).

A stock of mononitration mixed acid was made from sulphuric acid (d 1.84, 18.8 kg.), nitric acid (d 1.42, 1.1 kg.), liquid nitrogen tetroxide (0.9 kg.), and water (4.7 kg.). Analysis of the mixture gave 71.4% H_2SO_4 , 6.35% HNO_3 , 1.75% HNO_2 , and 21.5% H_2O . Nitrous acid was added because it catalyses the nitration and prevents undue temperature fluctuations in the early stages. Dinitration and trinitration acids were made up as required for each nitration from concentrated sulphuric and nitric acids and 20% oleum that had been titrated.

Mononitration.—The all-glass apparatus was a 2-l., 3-necked, bolt-head flask fitted with paddle stirrer, reflux condenser, dropping funnel, and thermometer, the last two reaching to near the bottom. The flask was immersed in a suitable cooling bath: solid carbon dioxide and trichloroethylene for -30° and 0°, ice-water for 30°, and water at the ordinary temperature for 60°. Mixed acid (2300 g.) was placed in the nitrator and cooled to just below the reaction temperature, and toluene (150 g.) was run in, fairly rapidly at first till the intended temperature was reached and then more slowly to keep the temperature constant. After the initial warming up, the maximum variation in temperature was $\pm 1^\circ$. The addition of toluene took about 30 minutes, and the reaction was continued for a further 75 minutes except for the -30° nitration which was run for a total time of 4.5 hours. During the later stages of the reaction the bath temperature was raised gradually to keep the reaction temperature constant until, finally, outside and inside temperatures were almost equal. The reaction mixture was poured into ice-water (4 kg.), the aqueous layer was removed, and more water was added followed by ether until the organic layer was the lighter. The ethereal layer was washed with water till acid-free and dried (Na_2SO_4), and the ether was distilled off. Traces of ether and any un-nitrated toluene were removed by passing a current of air through the residue heated to 100° under reduced pressure. The nitrotoluenes were tested colorimetrically for toluene by shaking with an equal volume of a solution of sodium nitrite (2.5 g.) in 88% sulphuric acid (100 c.c.). Absence of a red colour indicates less than 0.2% of toluene (Dr. J. K. N. Jones, private communication).

Dinitration.—The apparatus was similar to that used for mononitration, except that the flask was of 1 l. capacity. It was immersed in a stirred oil-bath provided with means for heating and cooling. Mononitrotoluene (50 g.) was dissolved in 90% sulphuric acid (120 g.) in the nitrator at 50°. Mixed acid (125 g.), containing 70.0% of sulphuric acid, 21.5% of nitric acid, and 8.5% of water, was added cautiously from the dropping funnel. As soon as reaction had started the bath was cooled to about 30° and the rate of addition controlled so that all the mixed acid was added at about 50° in 30 minutes. The mixture was then rapidly heated to 70° and this temperature maintained for 1.5 hours. The product was washed thrice at 100°, each time by stirring vigorously for 15 minutes with an equal volume of water, allowing to settle for 5 minutes, and separating the aqueous layer. Solid which separated from the washings on cooling was collected and added to the main product, and the whole was dried at 100° for 3 hours.

Trinitration.—The same apparatus was used as for dinitration. The whole of the dinitration product (or 65 g. in the case of 2:4-dinitrotoluene) was dissolved in 100% sulphuric acid (220 g.) in the nitrator at 100°, the oil-bath was cooled to about 97°, and the addition of mixed acid (125 g.), containing 60% of sulphuric acid, 40% of nitric acid, and 0% of water, was started. Reaction did not begin immediately, and the addition of mixed acid was stopped after a few g. had been added until there was a noticeable rise in temperature. The bath was then cooled to about 80° and the rate of addition controlled to keep the temperature at 100°. The addition was complete in 30 to 45 minutes. Towards the end of the addition of mixed acid the bath temperature was gradually raised so that it was 95° at the end of the addition, and it was further raised to about 98° during the additional reaction time of 3.5 hours. Finally, the reaction mixture was poured on ice and kept overnight, and the solid was then collected. The trinitrotoluene was washed with water at 100°, in the same manner as the dinitrotoluene, till the acidity of the last wash, titrated to phenolphthalein, was equivalent to not more than 0.002 g. of sulphuric acid. The washed trinitrotoluene was dried for 6 hours at 100° and its setting point determined. The observed value was corrected for exposed stem.

We thank the Director-General of Scientific Research (Defence), Ministry of Supply, for permission to publish this work.

172. The Reaction of 1-Nitropropane with Formaldehyde and Ammonia.

By E. L. HIRST, J. K. N. JONES, (MRS.) S. MINAHAN, F. W. OCHYNSKI, A. T. THOMAS, and T. URBANSKI.

Products of both high and low molecular weight are formed by the interaction of 1-nitropropane, formaldehyde, and ammonia. The reaction is shown to be essentially one of the type described by Mannich, in which the nitropropane provides the necessary active hydrogen atom. Amongst the products are ring compounds of the 1:3-tetrahydro-oxazine and 1-oxa-3-azacyclooctane type.

CONSIDERABLE interest has been shown recently in the chemistry of the nitro-paraffins (see, for example, Johnson and Degenry, *J. Amer. Chem. Soc.*, 1939, **61**, 3194; Spring and Degenry, *ibid.*, 1942, **64**, 1063; Senkus, *ibid.*, 1946, **68**, 11; Johnson, *ibid.*, pp. 12, 14) and it is opportune to summarise work carried out during the past few years, but hitherto withheld from publication by reason of war-time secrecy regulations. One of the authors has previously shown that the large-scale preparation of nitro-paraffins was practicable (Urbanski, *Rocz. Chem.*, 1936, **16**, 466; 1937, **17**, 161; *Compt. rend.*, 1936, **203**, 620; 1937, **204**, 870) and has indicated their use for the production of combustible resins (Urbanski, B.P. Appln. 7681, 5th June, 1942; U.S.P. Appln. 488,456, 25th May, 1943). These resinous materials were made by the interaction of nitropropane, formaldehyde, and ammonia, and it was therefore of interest to investigate the nature of the reactions responsible for their formation. The present paper records some of the results obtained in a study of reactions which had not at that time been reported in the literature, despite the interest displayed by earlier workers (*e.g.*, Henry; Mousset; Duden, Bock, and Reid; Cerf de Mauny; Zief and Mason) in the condensation of formaldehyde, nitro-paraffins, and amines. The resins obtained from 1-nitropropane, formaldehyde, and ammonia are basic. The precise nature of the portion of high molecular weight is still uncertain, but the types of linkage are indicated by the structures of the accompanying materials of low molecular weight and by the nature of the decomposition products of the resinous materials.

The first stage in the series of reactions is the formation of 2-nitrobutanol (I) and 2-nitro-2-ethylpropane-1:3-diol (II). Since ammonia is present, together with formaldehyde, hexamethylenetetramine is also produced and this yields with (II) a molecular complex. When warmed in water this complex gives a resin similar to those obtained by the interaction of the three components. The mechanism of the reaction appears to resemble that of the Mannich reaction. From (II) and ammonia a base (III) is produced, and this then reacts with formaldehyde, giving the *N*-hydroxymethyl derivative (IV), which on cyclisation gives the *oxazine* (V). No evidence for the formation of *N*-methyl derivatives was obtained. Since only one of the hydrogen atoms in (V) can react with formaldehyde it follows that (V) cannot yield a polymer on further condensation, and its production in reactions designed to lead to resin formation is to be avoided. Under appropriate conditions, however, there may be as much as 30% of (V) present in the crude resin. It is an oil which can be separated by distillation or by precipitation of the crystalline *hydrochloride*, and yields with methyl iodide a crystalline *methiodide* (VI). The corresponding hydroxide decomposes when heated yielding nitrobutene and other decomposition products.

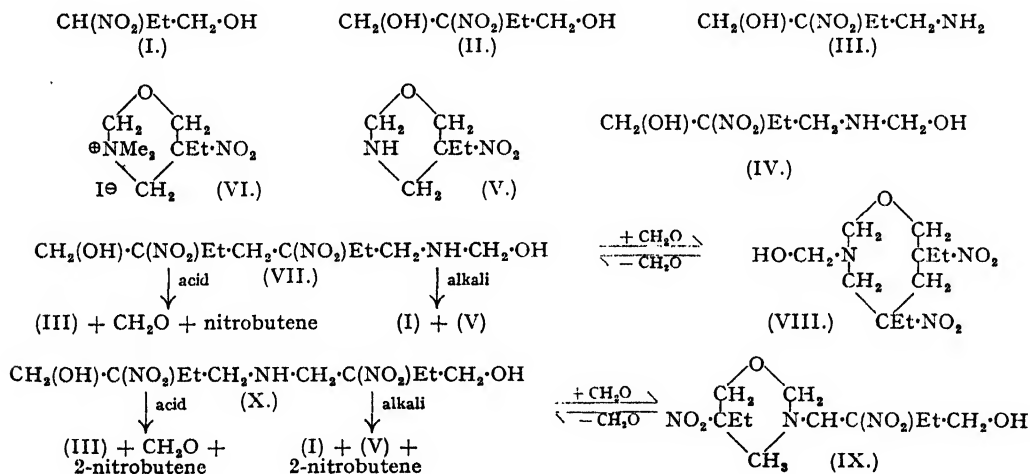

If the reaction between nitropropane, formaldehyde, and ammonia was interrupted shortly after the nitropropane had dissolved, an oily product was precipitated on cooling. It crystallised slowly, and either (VIII) or (X) was formed according to the conditions of the reaction, (VIII) being found when 1 mol. of ammonia was used per mol. of nitropropane, and (X) when 0.5 mol. of ammonia was used. (VIII) lost formaldehyde on being warmed with concentrated hydrochloric acid and gave the crystalline *hydrochloride* of (VII), and when the latter was warmed with formaldehyde it passed back into (VIII). The *hydrochloride* of (VII) gave a *picrate*; with sodium nitrite it gave an oily nitroso-compound which was reconverted into (VII) on being heated with concentrated hydrochloric acid, the presence of an imino-group being thus proved. The *hydrochloride* of (VII) when boiled in aqueous solution decomposed with the formation of the *hydrochloride* of (III), 2-nitrobutene, and formaldehyde. With aqueous sodium hydrogen carbonate it gave the crystalline base (VII) which decomposed on distillation in a vacuum giving (V) and (I). The formation of (VII) and (VIII) can be represented as an example of the Mannich reaction, and the formulæ suggested for these substances serve to explain their mode of origin and their chemical properties.

The base (IX) gives a series of reactions similar to those of (VIII). It dissolves in cold

concentrated hydrochloric acid giving a *hydrochloride* which hydrolyses in water, regenerating (IX). If (IX) is heated with dilute hydrochloric acid, 1 mol. of formaldehyde is eliminated and the *hydrochloride* of the secondary base (X) is formed. The hydrochloride of (X) when heated with aqueous formaldehyde regenerates the tertiary base (IX). The hydrochloride of (X) gave a well-defined *picrate* and an oily nitroso-compound which regenerated the hydrochloride of (X) when heated with concentrated hydrochloric acid, indicating the presence of an imino-group. The hydrochloride of (X) on treatment with aqueous sodium carbonate gave the corresponding crystalline base which decomposed when boiled with water or on distillation under reduced pressure with formation of (I), 2-nitrobutene, and (V). The hydrochloride of (X), on prolonged boiling with water, gave ammonium chloride, formaldehyde, 2-nitrobutene, and the hydrochloride of (III). The formation of (IX) and (X) and their chemical properties can most easily be explained by the mechanism shown in the accompanying scheme.

Substance (V) can be obtained from the resin by distillation under reduced pressure or by the action of hydrochloric acid, as well as by the decomposition of the bases (VII) and (X). It forms a picrate and hydrochloride and an oily nitroso-derivative. The hydrochloride when boiled with water eliminates 1 mol. of formaldehyde with formation of the hydrochloride of (III). This reaction is reversible, the hydrochloride of (III) regenerating the hydrochloride of (V) on crystallisation from propyl alcohol containing formaldehyde.

The base (III), which was unstable even at room temperature, is a primary amine, since it gives nitrogen with aqueous sodium nitrite. The action is, however, complex since the initial gentle evolution of nitrogen was followed by a violent reaction in which nitrous oxide, as well as nitrogen, was evolved and a greenish water-insoluble oil was produced.

EXPERIMENTAL.

Additive Compound $[(\text{C}_6\text{H}_{11}\text{O}_4\text{N})_3, \text{C}_6\text{H}_{12}\text{N}_4]$ of 2-Nitro-2-ethylpropane-1:3-diol and Hexamethylenetetramine.—1-Nitropropane (1 mol., 89 g.) was added to a cold mixture of 40% formaldehyde (3 mols., 225 c.c.) and 33% ammonia (1 mol., 59 c.c.). The mixture was stirred at room temperature until the nitropropane disappeared (12–15 hours). After some time the aqueous solution was separated from an oily precipitate (containing 2-nitrobutanol). The addition of sodium chloride to the aqueous solution salted out an oil, which solidified in fine needles (100 g.). It was the additive compound of 2-nitro-2-ethylpropane-1:3-diol (3 mols.) and hexamethylenetetramine (1 mol.); white needles from chloroform, m. p. 117°. The additive compound is very readily soluble in water, soluble in alcohol, very slightly soluble in ether. It gave hexamethylenetetramine picrate, m. p. 179°, with picric acid, and hexamethylenetetramine hydrochloride with hydrochloric acid. It was dissociated in solution. For example, ebullimetric determination in chloroform gave M , 158 [calc. for hexamethylenetetramine, 140; for 2-nitro-2-ethylpropane-1:3-diol, 149. $(\text{C}_6\text{H}_{11}\text{O}_4\text{N})_3, \text{C}_6\text{H}_{12}\text{N}_4$ requires M , 587]. When heated it was converted into a resin.

Another method for the preparation of the additive compound consisted in mixing concentrated aqueous solutions of 2-nitro-2-ethylpropane-1:3-diol (4.47 g.) with hexamethylenetetramine (1.40 g.). The crystalline additive product (4.2 g.) was precipitated on standing [Found: CH_2O , determined by the 2:4-dinitrophenylformylhydrazine method, 30.5. $(\text{C}_6\text{H}_{11}\text{O}_4\text{N})_3, \text{C}_6\text{H}_{12}\text{N}_4$ requires CH_2O , 30.8%].

Resin A.—1-Nitropropane (1 mol., 89 g.) was heated with 40% formaldehyde (3 mols., 225 c.c.) and 33% ammonia (1 mol., 59 c.c.) with stirring at 90–95° for 15–30 minutes. The reaction was then stopped by rapid cooling (pouring on ice). An oily layer containing nitro-olefins was separated

by decantation. The liquor was reheated and the temperature maintained at 90–95° for 8 hours with efficient stirring.

The resin formed a separate phase which was isolated by decantation. It was washed with hot water and dried in a partial vacuum. By evaporation of the liquor an additional quantity was obtained (yield, 110–125 g.).

Resin B.—2-Nitro-2-ethylpropane-1:3-diol (1 mol., 149 g.) was mixed with 40% formaldehyde (1 mol., 75 c.c.) and 33% ammonia ($\frac{1}{2}$ mol., 295 c.c.). The temperature was kept between 90° and 95° for 10 hours with stirring. The oily product was precipitated and, after cooling, was separated from the liquor, washed, and dried in partial vacuum (yield, 110 g.). The resin was a colourless and odourless viscid liquid.

Isolation of (V) from resins A and B. Fractionation of the resin under reduced pressure gave two fractions: (a) b. p. 140° (bath temp.)/0.01 mm., n_D^{20} 1.4720; (b) b. p. 160–180° (bath temp.)/0.01 mm., n_D^{20} 1.4880. Both fractions with methyl iodide gave a derivative, m. p. 218° (decomp.), identical with the methiodide of 5-nitro-3-methyl-5-ethyltetrahydro-1:3-oxazine (VI) described below. The liquid air trap of the distillation apparatus contained 2-nitrobutene and a blue nitroso-derivative of unknown constitution.

Isolation of (IX) by steam distillation of the resin A or B. The resin A or B (9.3 g.) was distilled in steam giving an oil (6 g.) which was mainly the base (V), since with methyl iodide it gave the crystalline methiodide (VI). The aqueous distillate was extracted with ether and then with benzene, and the combined extracts were dried (Na_2SO_4) and evaporated to a syrup (4 g.) under reduced pressure. The syrup crystallised on standing and, after tilting and recrystallising from benzene, 5-nitro-5-ethyl-3-(2-nitro-2-hydroxymethylbutyl)tetrahydro-1:3-oxazine (IX), m. p. 101°, was isolated (Found: C, 45.4; H, 7.2; N, 13.9. $\text{C}_{11}\text{H}_{21}\text{O}_6\text{N}_3$ requires C, 45.4; H, 7.2; N, 14.4%).

Preparation of the Bases (VIII) and (IX).—1-Nitropropane (1 mol., 89 g.) was mixed with 40% formaldehyde (3 mols., 225 c.c.) and 33% ammonia (1 mol., 59 c.c.) and heated with stirring during 1½ hours at 90–95°. The hot solution was then poured into ice-water. The oily precipitate crystallised on standing (after ca. 2 weeks), yielding crystals of 5:7-dinitro-3-hydroxymethyl-5:7-diethyl-1-oxa-3-azacyclooctane (VIII). Recrystallised from ether and then from chloroform or from benzene-light petroleum, it gave white needles, m. p. 97° (yield, 15–20 g.). It was soluble in hot water, cold ether, alcohol, acetone, and benzene, insoluble in light petroleum. It was less soluble in chloroform than (IX). Mixed with (IX) it gave considerable depression of m. p. (70–73°) [Found: C, 45.3; H, 7.0; M (ebulliometrically in benzene), 280. $\text{C}_{11}\text{H}_{21}\text{O}_6\text{N}_3$ requires C, 45.4; H, 7.2%; M, 291].

The base (VIII) gave with cold concentrated hydrochloric acid the *hydrochloride*, m. p. 174° (Found: C, 40.1; H, 6.7; N, 12.1; Cl, 10.9. $\text{C}_{11}\text{H}_{21}\text{O}_6\text{N}_3\text{HCl}$ requires C, 40.3; H, 6.5; N, 12.8; Cl, 10.8%). This hydrochloride hydrolysed in cold water yielding the free base (VIII). On being warmed with concentrated hydrochloric acid the hydrochloride lost one molecule of formaldehyde and was converted into the *hydrochloride* of hydroxymethyl-2:4-dinitro-4-hydroxymethyl-2-ethyl-hexamylamine (VII), m. p. 179° (Found: CH_2O , 10.9. Loss of 1 mol. of CH_2O requires 10.3%). It depressed the m. p. of the hydrochloride of (VIII). This hydrochloride of (VII) was insoluble in ether, benzene, and chloroform, readily soluble in water and hot alcohol, sparingly soluble in cold alcohol. It recrystallised from alcohol in the form of small plates, m. p. 179° (decomp.) (Found: C, 38.4; H, 7.1; N, 12.4; Cl, 11.2. $\text{C}_{10}\text{H}_{21}\text{O}_6\text{N}_3\text{HCl}$ requires C, 38.0; H, 6.7; N, 13.3; Cl, 11.3%). On being heated with concentrated aqueous formaldehyde it gave an oil, which was extracted with ether; the dried extracts were evaporated in partial vacuum to a syrup, which crystallised slowly. After standing the crystals were triturated with ether and filtered. Recrystallisation from benzene gave the pure base (VIII), m. p. and mixed m. p. 97°. The hydrochloride of (VII) reacted with sodium nitrite and gave an oily nitroso-derivative soluble in ether. The latter regenerated the hydrochloride of (VII) on treatment with concentrated alcoholic hydrogen chloride.

The hydrochloride of (VII) was dissolved in alcohol and aqueous picric acid was added. The pale yellow *picrate* of (VII) was precipitated, m. p. 154° (Found: C, 38.2; H, 4.8; N, 16.4. $\text{C}_{10}\text{H}_{20}\text{O}_{13}\text{N}_3$ requires C, 37.8; H, 4.7; N, 16.5%). The picrate was unstable and could not be recrystallised from water.

The hydrochloride of (VII) (1.45 g.) was dissolved in water, and sodium hydrogen carbonate and ether were added. The syrupy base (1.33 g.) was isolated on evaporation of the solvent. The base (VII) (1.33 g.) on distillation under reduced pressure gave a fraction (0.74 g.), n_D^{20} 1.4670, b. p. 140° (bath temp.)/0.01 mm., and a still residue (0.35 g.). The volatile fraction consisted of the base (V) and 2-nitrobutanol. These were separated by dissolving the base in the calculated quantity of hydrochloric acid. The 2-nitrobutanol (I) was then extracted with ether. The base (V) was characterised by its hydrochloride, m. p. 203° (decomp.), and picrate, m. p. 153°, not depressed on admixture with an authentic specimen.

The hydrochloride of (VII) (888 mg.) was dissolved in water and the solution boiled. Decomposition occurred and formaldehyde and 2-nitrobutene distilled. The aqueous solution remaining in the flask was evaporated to dryness under reduced pressure and the residue (516 mg.) was triturated with acetone and filtered. The residue (68 mg.) was ammonium chloride. The acetone solution was evaporated to a syrup and triturated with ether; the hydrochloride of the base (III), m. p. 126° (see below), then crystallised. The aqueous distillate contained formaldehyde (Found: 9%; 1 mol. requires 9.5%) and 2-nitrobutene (characteristic odour, absorption of bromine, polymerises with alkali).

Preparation of (IX).—2-Nitro-2-ethylpropane-1:3-diol (1 mol., 149 g.) was heated with 40% formaldehyde (1 mol., 75 c.c.) and 33% ammonia ($\frac{1}{2}$ mol., 26 c.c.) at 95–96° for ca. 1½ hours. The product (IX) was isolated by pouring into ice-water. It recrystallised from ether, chloroform, or benzene-light petroleum in long needles, m. p. 101°. Yield, 50 g. [Found: C, 45.6; H, 7.0; N, 14.5; M (ebulliometrically in benzene), 285. Calc. for $\text{C}_{11}\text{H}_{21}\text{O}_6\text{N}_3$: C, 45.4; H, 7.2; N, 14.4%; M, 291].

A simple method of isolating the base (IX) from the resin B consisted in dissolving the resin in cold hydrochloric acid. The solution was poured on ice. The resinous substance precipitated was extracted

with ether, the extracts were dried and the ether was evaporated. The residue solidified into crystals of (IX), m. p. and mixed m. p. 98°.

The base (IX) reacted with cold concentrated hydrochloric acid, yielding the *hydrochloride*, m. p. 156° (Found: C, 40.4; H, 6.8; N, 12.6; Cl, 10.6. $C_{11}H_{21}O_4N_3.HCl$ requires C, 40.3; H, 6.5; N, 12.8; Cl, 10.8%). The same product was obtained by passing hydrogen chloride through a solution of the base (IX) in chloroform or carbon tetrachloride. It is insoluble in ether or chloroform, soluble in alcohol. On dissolving in water it hydrolyses giving the free base (IX), m. p. 101° (Found: C, 45.1; H, 7.3; N, 13.3%).

Hydrochloride of (X).—The base (IX) or its hydrochloride, when heated with concentrated hydrochloric acid, lost a molecule of formaldehyde and was converted into the hydrochloride of bis-2-nitro-2-hydroxymethylbutylamine (X) (Found: CH_2O , 10.3. Loss of one mol. of CH_2O requires 10.3%). The *hydrochloride* separated in plates or needles from absolute alcohol, m. p. 186° (Found: C, 38.0; H, 6.8; N, 12.7; Cl, 11.2. $C_{10}H_{19}O_4N_3.HCl$ requires C, 38.0; H, 6.7; N, 13.3; Cl, 11.3%). On warming an aqueous solution of the hydrochloride with formaldehyde solution (40%) an oil separated and was extracted with ether. The extract was dried (Na_2SO_4) and the ether removed; the base (IX) then crystallised. M. p. and mixed m. p. [with base (IX)] 99°.

The hydrochloride reacted with sodium nitrite solution giving the nitroso-derivative which separated as an oil. It was extracted with ether and the dried extracts were evaporated under reduced pressure. Concentrated hydrochloric acid reconverted it into the parent hydrochloride of (X), m. p. and mixed m. p. 186°.

Isolation of the Base (X).—The hydrochloride of (X) was dissolved in a minimum amount of water, and ether and excess of sodium hydrogen carbonate solution were added. The ethereal layer was separated and the aqueous solution extracted twice with ether. The combined extracts were dried (Na_2SO_4) and evaporated under reduced pressure to a syrup, which crystallised on trituration with a little ether. The compound separated in a good yield as a white crystalline solid, and was recrystallised from ether–light petroleum, m. p. 54° [Found: C, 43.1; H, 7.5; (OH), 11.8. $C_{10}H_{19}O_4N_3(OH)_2$ requires C, 42.9; H, 7.5; (OH), 11.3%]. The *picrate*, after recrystallisation from water, had m. p. 148° (Found: C, 37.8; H, 5.1; N, 16.7. $C_{10}H_{19}O_4N_3$ requires C, 37.8; H, 4.7; N, 16.5%).

On boiling an aqueous solution of the base (X) two molecules of formaldehyde were liberated (Found: CH_2O , 19%. Two mols. of CH_2O require 21.5%). On distillation under reduced pressure, the base (X) (1.4 g.) gave a fraction (0.9 g.), b. p. 140° (bath temp.)/0.01 mm., n_D^{20} 1.4665, containing basic material, and a still residue (unchanged material). With alcoholic hydrogen chloride the distillate gave the crystalline hydrochloride (V), m. p. 202°. Titration with dilute hydrochloric acid showed that some of the distillate was neutral and not soluble in acid. After neutralisation the solution was therefore extracted with ether and the extracts were distilled under reduced pressure giving a fraction (0.3 g.), b. p. 120° (bath temp.)/0.01 mm., n_D^{20} 1.4438. This was 2-nitrobutanol, n_D^{20} 1.4430.

The hydrochloride of (X) (385 mg.) was dissolved in water and heated at 93° for 12 hours. The solution was then evaporated under reduced pressure and the residue (202 mg.) was triturated with acetone. The insoluble material (18 mg.) was identified as ammonium chloride. The acetone solution on evaporation gave a crystalline solid, m. p. 126°. This was the hydrochloride of (III). The aqueous distillate was extracted with ether and the formaldehyde estimated in the aqueous solution (Found: CH_2O , 7. One mol. requires 9.3%). The ethereal extract on evaporation left an oil (10 mg.) which had the reactions of 2-nitrobutene. On heating the hydrochloride of (X) with sodium hydroxide solution and then adding acid and distilling, two molecules of formaldehyde were eliminated (Found: CH_2O , 18.0. 2 mols. of CH_2O require 19.0%).

Action of Concentrated Hydrochloric Acid on Resin A.—(a) The resin dissolved in concentrated hydrochloric acid with evolution of heat. The solution was then evaporated under reduced pressure to a syrup. On standing, crystals separated. They were fractionated into hydrochlorides of (V), (VII), (X), and (IV) by the differences of their solubilities in alcohol and ether. The hydrochloride of (V) is less soluble than that of (X), which in turn is less soluble than that of (VII). The most soluble is the hydrochloride of (IV). The yields varied, (IV) being obtained in the greatest proportion (up to 30% by weight of the resin). (VII) was not obtained from Resin B.

(b) The resin was dissolved in chloroform (or alcohol) and hydrogen chloride bubbled through the solution. The gas was strongly absorbed, the colour of the solution changed from light yellow to deep orange, heat was evolved, and an evolution of formaldehyde occurred. At first a thick emulsion appeared, which then crystallised. The crystals were separated and washed with chloroform and ether. Hydrogen chloride was again passed through the filtrate and a second crop of crystals was formed and separated. This was repeated several times and finally several fractions were collected, representing the hydrochlorides of the four bases mentioned above. Yield, 80 g. from 100 g. of Resin A.

The *hydrochloride of 5-nitro-5-ethyltetrahydro-1:3-oxazine* (V) was isolated in the form of white crystals, insoluble in ether, benzene, and chloroform, readily soluble in water and alcohol, m. p. 203° (decomp.) (Found: C, 36.8; H, 6.5; N, 13.9; Cl, 17.9. $C_8H_{15}O_3N_3.HCl$ requires C, 36.7; H, 6.6; N, 14.2; Cl, 18.1%). Sodium nitrite converted it into an oily, pale yellow nitroso-derivative, soluble in hot water, insoluble in cold water, and volatile with steam. It was not decomposed on boiling with water. It distilled under reduced pressure, b. p. 130° (bath temp.)/0.01 mm., n_D^{20} 1.5000. The free base (V) was prepared from the hydrochloride (2.15 g.) by the action of sodium hydrogen carbonate and extraction with ether. Yield, 1.8 g. It is an oily liquid insoluble in water, n_D^{20} 1.4873 [Found: C, 45.4; H, 7.5; M (Rast), 162. $C_8H_{15}O_3N_3$ requires C, 45.1; H, 7.5%; M, 160]. The hydrochloride with aqueous picric acid gave a pale yellow *picrate*, m. p. 156° (Found: C, 36.8; H, 4.0; N, 18.0. $C_{12}H_{15}O_{10}N_3$ requires C, 37.0; H, 3.8; N, 18.0%).

Preparation of (VI).—The base (V) (2 g.) by the action of methyl iodide gave the crystalline *methiodide* (VI), m. p. 218° (decomp.). Yield, 1.5 g. It can also be prepared directly from the resin. The resin (3.028 g.) was dissolved in methyl iodide and the solution warmed. After 12 hours the crystals, which had separated, were triturated with acetone, filtered off, and dried. Yield, 0.7 g. It was recrystallised from methyl alcohol; m. p. 218° (decomp.) (Found: C, 30.6; H, 5.3; N, 8.4; I, 39.7;

NO_2 , 15.4. $\text{C}_8\text{H}_{17}\text{O}_3\text{N}_2\text{I}$ requires C, 30.4; H, 5.4; N, 8.9; I, 40.2; NO_2 , 14.6%. With picric acid it gave the corresponding *picrate*, m. p. 210°, after recrystallisation from water (Found: C, 40.4; H, 4.5; N, 16.8. $\text{C}_{11}\text{H}_{19}\text{O}_{10}\text{N}_2$ requires C, 40.4; H, 4.1; N, 16.8%).

An aqueous suspension of silver oxide (10 g.) converted the methiodide (1.775 g.) into the hydroxide of (VI) (1.2 g.) which, on distillation, decomposed violently, giving various liquid and gaseous products. The distillate was strongly alkaline and had a pronounced odour resembling that of methylamine. Addition of picric acid to a solution of the gaseous products absorbed in dilute hydrochloric acid gave a pale yellow *picrate* soluble in water and almost insoluble in dilute hydrochloric acid; m. p. 156°. It was identified (by mixed m. p.) as dimethylamine *picrate*. The liquid distillate contained an aldehyde or ketone, which formed a 2:4-dinitrophenylhydrazone, m. p. 166° (Found: C, 49.8; H, 4.2; N, 21.6. $\text{C}_{11}\text{H}_{14}\text{O}_4\text{N}_4$ requires C, 49.6; H, 5.3; N, 21.1%), and a base, which, with methyl iodide, gave a derivative, m. p. >300°.

Decomposition of the Hydrochloride of (V).—When the hydrochloride of (V) was boiled with water, formaldehyde (1 mol.) was evolved (Found: CH_2O , 14.1. 1 mol. of CH_2O requires 15.2%). On evaporation of the aqueous solution, the *hydrochloride* of 2-nitro-2-hydroxymethylbutylamine (III) remained. It is a crystalline solid, very soluble in alcohol, acetone, and water, sparingly soluble in ether, m. p. 126°, and is the final product of decomposition of the more complex bases (VIII), (X), (V), and (VII). No crystalline *picrate* or methiodide could be prepared. It was recrystallised from propyl alcohol; m. p. 126° (Found: C, 32.6; H, 7.0; N, 14.1; Cl, 19.5. $\text{C}_8\text{H}_{14}\text{O}_3\text{N}_2\text{HCl}$ requires C, 32.7; H, 6.8; N, 15.2; Cl, 19.3%).

The hydrochloride of (III) (1 g.) reacted with the calculated quantity of sodium nitrite dissolved in water (5 c.c.). A colourless gas was evolved, briskly at first and then more slowly; the solution became slightly milky and heat was evolved. Total volume of gas at N.T.P., 145 c.c. (Found: N, 67.6; NO, 1.8; N_2O , 24.1; CO_2 , 5.5; CO, 1.0%). This reaction occurred, if only 0.25 mol. of sodium nitrite was added. Addition of urea failed to prevent the second part of the reaction from occurring, once nitrogen had been evolved. The yellow-green oil which separated had an odour resembling that of diazomethane. The oil (0.43 g.) was extracted with ether and distilled under reduced pressure. Much decomposition occurred and a yellow acidic oil (0.1 g.) passed over, n_D^{20} 1.4700, b. p. 140° (bath temp.)/0.01 mm. (Found: C, 45.6; H, 7.4; N, 8.9%). Formaldehyde was liberated on boiling the hydrochloride of (III) with sodium hydroxide (Found: CH_2O , 11. One mol. requires CH_2O , 16.2%).

The oily base (III) was obtained by ethereal extraction of a solution of the hydrochloride made alkaline. Evaporation of dried extracts under reduced pressure gave a syrup which evolved ammonia on standing with formation of crystals. The crystals were basic, m. p. 98° depressed on admixture with (VIII) or (IX) (Found: C, 39.1; H, 7.1; N, 13.1. $\text{C}_8\text{H}_{12}\text{O}_3\text{N}_2$ requires C, 40.4; H, 7.7; N, 13.5%). This crystalline substance gave no test for primary or secondary nitro-groups. It was insoluble in ether. It gave ammonia with alkalis, whilst with concentrated alcoholic hydrogen chloride it gave formaldehyde and the hydrochloride of (III), m. p. 126°.

A sample of the mother liquor, after removal of the crystalline derivative, m. p. 98°, gave with concentrated hydrochloric acid a mixture of the hydrochloride of (V), m. p. 203° (decomp.), and the hydrochloride of (III), m. p. 126°. After removal of the base (III) by ether extraction, the mother liquors, on heating, gave an oily base with a piperidine-like odour. This was extracted with ether and the dried extracts were evaporated. The strongly alkaline oil (10% yield calculated on the weight of hydrochloride) was distilled under reduced pressure; b. p. 160°/16 mm., n_D^{20} 1.4862 (Found: C, 46.8; H, 8.1; N, 20.4. $\text{C}_{10}\text{H}_{20}\text{O}_4\text{N}_4$ requires C, 46.2; H, 7.7; N, 21.6%). The oil gave no crystalline *picrate* or methiodide. The oily methiodide contained 34.8% of iodine.

Characteristic Reaction for Bases (VIII) and (IX) and their Derivatives (VII) and (X).—The substance [(VIII), (IX), (VII), or (X)] was shaken with bromine dissolved in carbon tetrachloride; alcohol was added to produce a clear solution followed by the addition of alcoholic potassium hydroxide. The solution lost its bromine colour and became pink-red. The addition of a drop of acid deepened the colour but excess changed it to yellow. Addition of potassium hydroxide brought back the red colour. The base (V), its methiodide (VI), and the base (III) did not give this reaction.

Our thanks are due to Professor J. E. Lennard-Jones, F.R.S., Chief Scientific Officer, Ministry of Supply, for permission to publish this paper.

173. Some Catalysed Gas-phase Reactions of Aromatic Hydrocarbons. Part I. The Interaction of Benzene with Methyl Ether.

By P. H. GIVEN and D. LL. HAMMICK.

Methyl ether interacts with benzene at 400–500° in the presence of metal oxide catalysts to give toluene and polymethylbenzenes. The most effective catalysts are of the synthetic aluminosilicate type. The reaction has been investigated under various conditions of temperature, contact time, etc.; the gaseous products have been determined. Under the optimum conditions for the reaction, 12–15% (moles) of toluene per pass is formed, or 35–50% calculated on the benzene consumed; the total methylation (on benzene consumed) is about 70%. Wastage of the reactants is low.

The results obtained are compared with those of previous work, and the nature of the reaction is briefly discussed.

THE various known methods for alkylating aromatic hydrocarbons in solution, *e.g.*, the Friedel-Crafts reaction and its modifications, have been thoroughly investigated (see, *e.g.*, Calloway, *Chem. Reviews*, 1935, 17, 327; Linstead, *Ann. Reports*, 1937, 34, 254); they have been very widely applied, and their mechanisms have been elucidated. In recent years, several processes for the production of certain alkylbenzenes in the gas phase have been reported, but gas-phase alkylation as a general method has not been investigated nearly so extensively as the corresponding reaction in solution, and available data on the reactions which have been studied are limited in scope.

The catalytic ethylation of benzene by means of ethanol or ethylene in the gas phase is a reaction now widely used in the United States in the manufacture of ethylbenzene (and hence styrene) for the production of plastics and synthetic rubber (Anon., *Oil and Gas J.*, 1942, 41, No. 13, 14). Kieselguhr, impregnated with phosphoric acid, and aluminium silicates are suitable catalysts (see, *e.g.*, Standard Oil Co., U.S.P.P. 2,238,594, 2,390,211, 2,067,764; Ipatieff and Schmerling, *Ind. Eng. Chem.*, 1946, 38, 400; Pardee and Dodge, *ibid.*, 1943, 36, 273). Other olefins, such as propene and the butenes, or alcohols or ethers which can give rise to them, have been used in similar processes (see Universal Oil Co., B.P. 464,752, 1935; Ipatieff, Pines, and Schaad, *J. Amer. Chem. Soc.*, 1944, 66, 816).

The particular case of methylation is of interest, since the reaction cannot proceed by way of an olefin. Methanol, methyl ether, and methyl chloride have been used as methylating agents in gas-phase reactions. For instance, Jenkins (B.Sc. Thesis, Oxford, 1940) observed that when benzene and methanol were passed over bauxite heated to 400°, about 2% of toluene was formed, together with much methyl ether and water. (Other published work is reviewed, and considered in relation to the present work, below, under "Discussion.") It is well known that methanol is rapidly converted into methyl ether and water in the presence of certain metal oxide catalysts: $2\text{CH}_3\text{OH} = (\text{CH}_3)_2\text{O} + \text{H}_2\text{O}$ (see, *e.g.*, Adkins and Perkins, *J. Physical Chem.*, 1928, 32, 221). Hence, when benzene and methanol vapours are led over a catalyst, it is uncertain whether the alcohol or the ether is the actual reactant.

Our experiments confirm that methyl ether interacts with benzene in the presence of catalysts to give methylbenzenes, and show that water is one of the reaction products. We find that, under the conditions we have employed, the ether is a more effective methylating agent than the alcohol. We obtain yields of toluene comparable with those claimed by previous workers (see p. 933), *viz.*, 15% (moles) per pass, and 35–50% on the benzene consumed, the total methylation (on benzene consumed) being about 70%. (Here and throughout the paper, all yields are given as moles %.) The wastage of methyl ether is 10–15% per pass.

In the present communication we present a study of the interaction of benzene and methyl ether. A number of catalysts have been examined, and the reaction investigated under various conditions of temperature, contact time, etc. The gaseous products of the reaction have been determined. Subsequent communications will describe the isomeric composition of the polymethyl derivatives formed in the methylation of benzene and its homologues, and also the methylation of thiophene and pyridine. Certain catalytic rearrangements and cracking reactions undergone by the aromatic compounds will also be reported later.

EXPERIMENTAL.

The vapours of benzene and methyl ether were led at known and constant rates through an electrically heated horizontal Pyrex tube containing the catalyst. The liquid products were analysed by fractional distillation in a Podbielniak still, and gaseous products were collected and also analysed.

1. *Materials.*—*Benzene.* "AnalaR" Benzene was purified by crystallisation, and distillation from phosphoric oxide; n_D^{20} 1.5007–1.5010, m. p. 5.4°.

Methyl ether. This was prepared by passing methanol over alumina at 375°, and collected in sulphuric acid. The ether was regenerated by running the sulphuric acid solution into water, and was dried, liquefied by cooling, and poured into a cylinder while cold. A needle valve was then screwed into the cylinder.

Catalysts. Three naturally-occurring materials have been used as catalysts, *viz.*, two specimens of bauxite, and a Scottish bauxitic clay. Two further catalysts were made by extraction of the bauxitic clay with acids to reduce, first, the alumina (Silica "O"), and secondly, the titania content (Silica "T"). The analyses were as shown in Table I.

Alumina A. Activated alumina, supplied by Peter Spence, Ltd.

Alumina B. "Special activated alumina", supplied by Peter Spence, Ltd.

Alumina C. Prepared by running 8% sodium hydroxide solution into 36% aluminium nitrate solution at 50–55°; 8/14 mesh.

Alumina D. Prepared by precipitation of aluminium nitrate solution with ammonia, by the method of Adkins and Krause (*J. Amer. Chem. Soc.*, 1922, 44, 385).

Alumina E. Supplied by I.C.I. Ltd.; screened 10/18 mesh.

Ferric oxide. Prepared in the same way as Alumina C.

TABLE I.

	Bauxite A. ¹	Bauxite B. ²	Natural aluminosilicate. ³	Silica- "O". ³	Silica "T". ³

¹ Traces of Cr, Mn, and SO₄²⁻; analysis made by I.C.I. Ltd.

² Trace of Mg; analysis by Dr. Hartley, Inorganic Chemistry Laboratory, Oxford.

³ The materials and their analyses were supplied by Messrs. Peter Spence Ltd.; all three had been heated to 500° before analysis.

Titania gel. Titanium tetrachloride was run slowly into excess of 10% ammonia.

Silica gel, basic aluminium phosphate, boron phosphate, and thoria gel. Supplied by I.C.I. Ltd.

Chromic oxide gel. A dilute solution of chromic nitrate was precipitated at 78—84° with 17% ammonia solution.

Zinc oxide gel. Zinc chloride solution was precipitated with sodium hydroxide solution (see Adkins and Millington, *J. Amer. Chem. Soc.*, 1929, **51**, 2452).

Nickel-alumina. A method of Balandin and Rubinstein (*Z. physikal. Chem.*, 1935, **B**, **31**, 793) was used. Sufficient 10% sodium hydroxide was run into 0.25M-aluminium nitrate solution just to redissolve the precipitate first formed. An equivalent quantity of nickel nitrate in 0.5M-solution was run in with stirring. After being washed, filtered off, and dried, the product was reduced in hydrogen at 320—340°.

Mixed oxide-silica catalysts. The following mixtures of silica with other oxides were prepared by Dr. W. Cule Davies, of Peter Spence Ltd., by precipitation of sodium silicate solution with an appropriate salt: Al₂O₃-SiO₂, 3 : 1, 1 : 1, 1 : 2, 1 : 4; Cr₂O₃-SiO₂, 1 : 2; TiO₂-SiO₂, 1 : 2; BeO-SiO₂, 1 : 1.

Except where otherwise stated, all materials were screened 4/8 mesh.

2. *Apparatus.*—The rate of flow of methyl ether was measured with a flow-meter; this was calibrated for rates of flow of 0—40 g. (0—20 l.) per hour by absorption in concentrated sulphuric acid and weighing the methyl ether passed in a known time for a known deflection of the flow-meter. The gas was freed from water, carbon dioxide, and methanol by passing through a long tube packed with soda-lime and calcium chloride.

The benzene was vaporised in a Dewar vessel by heating electrically with a small element immersed in the liquid (principle suggested by Adkins, *J. Amer. Chem. Soc.*, 1922, **44**, 2175). Since the insulation provided by a Dewar vessel is not perfect, the apparatus had to be calibrated directly. Benzene could be vaporised conveniently at rates of 15—100 g. per hour.

The vapours were mixed, preheated, and injected into the catalyst chamber, a Pyrex tube 2.9 cm. in diameter; the catalyst column in the evenly heated section of the furnace was 84 cm. long. The tube was heated in an electric furnace whose temperature could be kept constant $\pm 2^\circ$ by suitable adjustment of a rheostat. The temperature was measured with a thermocouple and millivoltmeter. The charge of catalyst was 200—450 g., depending on its bulk density.

The liquid reaction products were collected, separated from water, dried and analysed by fractional distillation.

Podbielniak still used in analysis. Analyses of the liquid products of reaction were made by means of a Podbielniak-type still (column of 0.55 cm. internal diameter); this enabled benzene and its homologues to be separated without difficulty. For instance, 1.5 c.c. of toluene in 20 c.c. of benzene could be determined with a maximum uncertainty of 0.1 c.c., and larger samples were analysed with corresponding or greater accuracy.

Gas analyses. These were performed with the standard Bone and Wheeler apparatus. As absorbents, 86% H₂SO₄, 20% KOH, 20% oleum, and alkaline pyrogallol were used for methyl ether, CO₂, C₂H₄, and O₂ respectively, H₂ and CO were determined by combustion in a copper oxide pipette, and paraffins by explosion.

3. *Method of Working.*—Before use, each catalyst was heated to 500° in a stream of nitrogen; it was then repacked in the tube to ensure that no appreciable space was left above the solid catalyst. Benzene and methyl ether were passed over the heated catalyst at known rates and for a known length of time. The liquid products (50—100 c.c.) were collected, separated from water, and analysed by fractional distillation. The gaseous products were led through a trap cooled in a freezing mixture of ice and salt (to remove benzene vapour) before collection.

It was found that the activity of the catalysts fell with continued use; hence they were re-activated as necessary by heating in a stream of oxygen for 1—2 hours at 500° (oxides such as Cr₂O₃ which are oxidizable were not so treated).

Results.—1. *Search for active catalysts.* As a primary step, methyl ether was passed with benzene over a heated sample of the specimen of bauxite used by Jenkins (*loc. cit.*) in his experiments with benzene and methanol. The yield of toluene was small (3—5% per pass), although greater than that obtained by Jenkins. Therefore a search for more active catalysts was undertaken.

(i) A preliminary survey of the effect of catalysts on the rate of production of methylbenzenes was carried out in an apparatus of the type used for studying the kinetics of gaseous reactions. Methyl ether was found to be strongly adsorbed on the catalysts examined, and to undergo faster and more complex decomposition than the homogeneous reactions in the gas phase (cf. Hinshelwood and Askey, *Proc. Roy. Soc.*, 1927, **A**, **115**, 215; Staveley and Hinshelwood, *J.*, 1937, 1568). By comparing the pressure-time curves, and the analyses of the gaseous products, obtained when pure methyl ether, and ether plus benzene, were admitted to the apparatus, a qualitative series of catalytic activities was obtained. Alumina B, C, D, and E, ferric oxide, titania, silica, thoria, chromic oxide, zinc oxide, and nickel-alumina

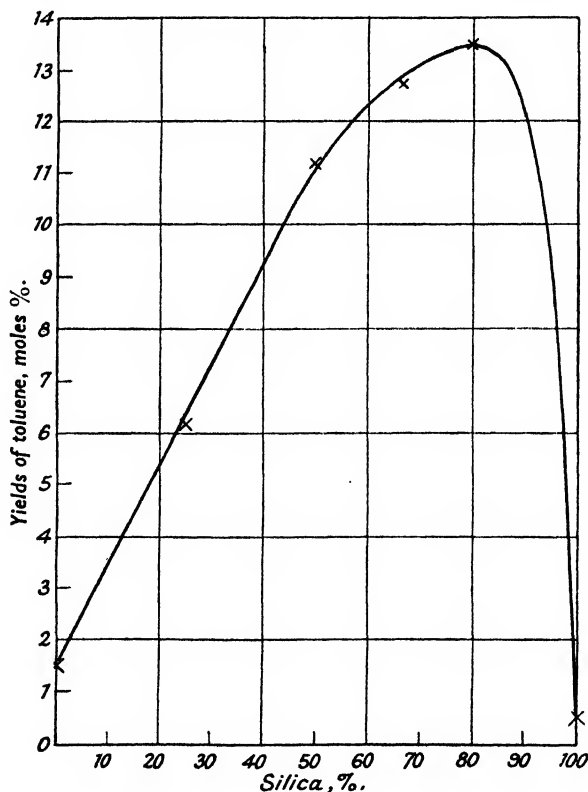

appeared to be ineffective as catalysts. Alumina A, basic aluminium phosphate, and boron phosphate were deemed worthy of further study.

(ii) The search was continued by the flow method described above. In all cases the criterion of the activity of a catalyst was the yield of toluene (moles of toluene as percentage of moles of benzene passed) under the following standard conditions: Vol. of packed catalyst space, 600 c.c.; temp. 450°; rate of flow of benzene, 42 g. per hour; of methyl ether, 12 g. per hour; molar ratio, benzene to ether, 1:8; contact time of benzene 30 secs.; space rate of flow of benzene about 0.15 c.c. of liquid per hour per volume of catalyst. It may be noted that the yield of polymethylbenzene was in all cases less than that of toluene. The average yields under the above conditions are given below in Table II.

TABLE II.

Catalyst.	Yield of toluene (moles %).	Catalyst.	Yield of toluene (moles %).
Bauxite A	4.0	Alumina-silica 1 : 1	11.3
Bauxite B	0.5	" " 1 : 2	13.0

Alumina-silica 3 : 1	6.2	Silica " T "	0.8

The plot of yield of toluene against percentage of silica for the alumina-silica mixtures is reproduced in the figure.

Yields of toluene as a function of composition of alumina-silica mixtures.

The mixtures of silica and other oxides are evidently the most effective catalysts, and the 1 : 4 mixture was adopted for all further work.

3. *More detailed investigation of the reaction on alumina-silica catalyst (1 : 4).* Some experiments were made to determine the effect on the reaction between benzene and methyl ether of varying the reaction conditions. The alumina-silica (1 : 4) catalyst was used throughout.

(i) *Rate of flow of reactants.* The yield of toluene was surprisingly insensitive to variations in the time of contact with the catalyst (see runs 179, 178, 181 in Table III),

TABLE III.

194	500	27.2	12.0	1.3	15.5	4.0	3.2

* First use of new batch of catalyst.

(ii) Ratio of benzene to ether. It is seen from Table III (runs 174, 176, 184; also 186, 187) that when the rate of flow of benzene is kept constant, an increase in the molar ratio benzene: ether causes only a slight decrease in the yield of methylated products.

(iii) Temperature. The results of experiments at 400° and 500° are given in Table III (runs 186, 187, 192—194). The yields are not markedly temperature-dependent. Experiments over a wider range of temperatures were performed with Bauxite A as catalyst (300—500°). The yield of toluene fell off from 4.0 at 450° to 2.4 at 400°, 1.6 at 350°, and 0.6 at 300°.

(iv) Wastage of reactants, and yields calculated on benzene consumed. In Table IV some representative figures for the recovery of unchanged benzene are given in col. 3; in col. 4, 5, and 6 are given the yields of methylated products calculated on the benzene consumed, *i.e.*, input of benzene less recovered benzene. The total methylation is given in col. 7, the total methylation calculated on the input of benzene in col. 8, and in col. 9 is shown the loss of benzene, *i.e.*, the defect from 100% of the sum of the total methylation (calculated on input) and the benzene recovered.

TABLE IV.

1. Run.	2. Temp.	3. C_6H_6 recovered, %.	4. Percentage yields of			7. Total methyln. on C_6H_6 recovered.	8. Total methyln. on C_6H_6 input.	9. % Loss of C_6H_6 .

192	500	65	49.6	14.0	6.2	69.8	24.4	10.6

The wastage of methyl ether per run is estimated below.

4. *Some general observations on the reaction of benzene with methyl ether.* The products of reaction were in all cases pale yellow or orange liquids with a green fluorescence, and contained water (see below). The polymethylbenzenes collected from a large number of runs were found on distillation to contain a small quantity of material boiling above hexamethylbenzene (the polymethylbenzenes will be dealt with more fully in a subsequent communication); this amounted to about 1% of the yield of methylated products, and was possibly a mixture of diphenyl derivatives. Apart from this (and water), no other products than methylbenzenes were detected, except in the methylation of benzene on the beryllia-silica catalyst when methanol was formed, in amount roughly equivalent to the toluene produced. The methanol was separated as its azeotrope with benzene, and characterised by means of its 3:5-dinitrobenzoate (m. p. 107°). A certain amount of carbon deposition was observed on all the catalysts.

As already noted, catalysts were reactivated when necessary by heating to 500° in a stream of oxygen for 1—2 hours. The activity of the most active catalyst, alumina-silica (1:4), decreased appreciably with continued use, in spite of reactivation; for instance, comparable figures for total methylation (at 500°) are: on a fresh batch of the material, 24%; on one which had been used in 20 previous runs (*i.e.*, ca. 800 g. of benzene had passed over it), 19%.

5. *Use of methanol as a methylating agent.* In view of the fact that other workers have used methanol as a methylating agent, it was thought of interest to compare its reaction with benzene with that of methyl ether with benzene, under the same conditions. It was found that methanol is a much less effective methylating agent than the ether; *e.g.*, when basic aluminium phosphate and the alumina-silica (1:4) were used as catalysts at 450°, the yields of toluene were $\frac{1}{2}$ % and 1% respectively when methanol was the reactant, and 2.7% and 13.0% with methyl ether, for corresponding rates of flow of the reactants. Water and methyl ether were by-products of the reaction of methanol and benzene.

6. *Decomposition of methyl ether.* It was of obvious interest to determine the fate in a methylation experiment of the methyl ether which does not react with benzene. The gaseous products of reaction consist mainly of hydrogen, carbon monoxide, and paraffin, but whereas in the homogeneous decomposition of the ether these products are formed in nearly equal amounts (Hinshelwood and Askey, *loc. cit.*), in

the heterogeneous reaction (in the presence or absence of benzene) they are formed in widely differing proportions in the presence of different catalysts (see Table V). Water was always found in the products of the reaction of benzene with methyl ether, and of the decomposition of the ether alone. When the alumina-silica mixtures were used as catalysts, the ratio of total weight of ether passed to water produced was more or less constant: 1 mole of ether gave about 0.8—1.0 mole of water. Water is therefore one of the products of decomposition of methyl ether on these catalysts. In no case of the surface reaction studied here has it been possible to write a simple stoichiometric equation between methyl ether and its products of decomposition. Therefore it has not been possible to calculate accurately the wastage of ether in a methylation run from the amount and composition of the gaseous products of reaction. However, from measurements of the volume of gas produced in a known time, during the course of an experiment, and its analysis, the amount of ether decomposed in passage over the catalyst was calculated, on the assumption that the decomposition is accompanied by a trebling of the initial volume. Thus, in the course of a methylation experiment with the alumina-silica (1 : 4) catalyst at 450°, about 10—15% of the ether is decomposed to permanent gases and water; if ether alone is passed over the catalyst the figure is about 20%.

In Table V are presented some representative analyses of the gaseous products resulting from experiments in which (a) methyl ether alone, (b) methanol alone, and (c) benzene plus methyl ether were passed

TABLE V.

Analysis of the gaseous products of reaction.

(All the figures are on a nitrogen-free, ether-free basis, except those for ether itself, which are on a nitrogen-free basis; the analyses are percentage volumes.)

† Decomposition of methanol.

‡ Products of reaction of benzene and methanol.

Where no sign appears, the figures refer to the decomposition of methyl ether.

over various catalysts. In addition to the observations quoted above, the following points may be noted: (1) The average carbon number, *n*, of the paraffins was nearly always greater than unity. (2) In most cases, the gases had nearly the same composition when (a) methyl ether alone or (b) methyl ether plus benzene were passed over the same catalyst. (3) A comparison of the decompositions of methanol and methyl ether is interesting: when these substances decompose on the surface of boron phosphate, the gaseous products have nearly the same composition in each case, and the same is true of several other materials which are known to catalyse the conversion of methanol into methyl ether (*e.g.*, alumina, titania, thoria, bauxite, chromic oxide; see Sabatier and Mailhe, *Ann. Chim. Phys.*, 1910, 20, 298).

DISCUSSION.

The production of toluene by reaction of methanol or methyl ether with benzene at atmospheric pressure is claimed in B.P. 574,738 (Standard Oil Development Co., application dated April 1942; complete specification accepted January 1946 *). The reactants are passed at 300—460° over a catalyst of the "solid" phosphoric acid type, which is prepared by treating a siliceous material (such as clay, kieselguhr, or a synthetic alumina-silica mixture) with a phosphoric acid. Yields of up to 50 moles of toluene per mole of benzene consumed are claimed, though it is not clear how these are calculated from the figures presented. The yields of toluene

* It appears that the work which led to this and the following patent specification was being carried out simultaneously with the work described here, which, with that to be described in subsequent papers of the series, was performed in 1940—1944 and was submitted in 1944 in a thesis for the degree of D.Phil., Oxford, by one of us (P. H. G.).

obtained by us are of comparable magnitude. Our optimum temperature range, 450—500°, is higher than that quoted for the above process (*i.e.*, 325—425°). Methanol is a more effective methylating agent in the Standard Oil Co. process than methyl ether; comparable figures are (for a reaction temperature of 354—358°): 12.2% (moles) of toluene per pass for methanol, and 7.9% for methyl ether as reactant (we obtained 1% and 11.0% respectively at 450° for approximately the same space rate of flow, using the alumina-silica catalyst).

A similar process has been patented by the Gas Light and Coke Co. (B.P. 541,534, application dated 1942), which involves bringing a (4 : 1 molecular) mixture of benzene and methanol at 250—600° (480°) and 100—300 atm. into contact with a phosphoric acid (H_3PO_4) or a metal (magnesium) phosphate alone or on an inert support, *e.g.*, coke, charcoal, siliceous material. The yield of toluene claimed is 14% by volume (12.2 moles %) on benzene passed. A further patent of the same company (B.P. 577,314, application dated March 1942, complete specification accepted May 1946) covers the use of methyl ether in a similar process, virtually the same reaction conditions being employed; the yield of toluene claimed is 18% per pass (15.5% moles), xylenes 4%, polymethylbenzenes 4%, *i.e.*, methyl ether is a more effective methylating agent than methanol in this process. The process uses roughly the same reaction temperatures as ours and gives similar yields, but requires the application of 100—300 atm. pressure.

Cullinane and Chard (*J.*, 1945, 821) have described the interaction of phenol and methanol on alumina at 200—375° to give anisole, homologues of phenol, and hexamethylbenzene.

Kutz and Corson (*J. Amer. Chem. Soc.*, 1945, 67, 1312) have described the methylation of benzene, toluene, and naphthalene with methyl chloride at 400° over alumina, alumina-silica mixtures, and other materials. In the reaction of benzene on alumina they claim yields of 8—15% (moles) of toluene, which are similar to ours obtained by the use of methyl ether. For their reaction, they find alumina a more active catalyst than the synthetic aluminosilicates.

It is noteworthy that in all these processes for the methylation of benzene, monomethylation predominates, and our work confirms this. This characteristic of the gas-phase reaction is in marked contrast to the property of the Friedel-Crafts method, *viz.*, that the monomethyl product is always accompanied by large quantities of polymethyl derivatives. In fact, the latter method is of little value for preparing monoalkylbenzenes.

Comparison of Methanol and Methyl Ether.—It is of interest to enquire whether, when toluene is produced by passing methanol and benzene over a catalyst, the methanol reacts directly, or first gives methyl ether, which then reacts with benzene. Previous workers (see above; and Cullinane and Chard, *loc. cit.*) do not appear to have envisaged the latter possibility. Our results show that, at least under the conditions we have used, methanol very probably acts as a methylating agent only by virtue of its ready conversion into methyl ether. Thus, we find that the ether gives a much better yield of toluene in reaction with benzene than does methanol. On many catalysts the decomposition products of methanol, produced under the same conditions as obtain in the course of a methylation, have very nearly the same composition as those of methyl ether on the same catalyst; this must mean that the alcohol is rapidly converted into the ether and water, and the ether then decomposes to the final products. In this connection, it may be mentioned that McKee and Burke (*Ind. Eng. Chem.*, 1923, 15, 793) have shown that the equilibrium between methanol, methyl ether, and water is rapidly achieved at 350° on alumina, and have determined the equilibrium constant at that temperature.

It may be noted that at the temperatures used in methylation experiments, the equilibrium constant of the methanol-methyl ether conversion is of the order of magnitude unity. Given (*J.*, 1943, 589) has obtained :

$$2CH_3\cdot OH (v) = (CH_3)_2O + H_2O (v) : \log_e K_p = 7300/RT - 4.8$$

The values of $\log_{10} K_p$ at various relevant temperatures, calculated from this equation, are given in Table VI. The equilibrium constant is actually unity at 761° K. (488° C.). Of course, if the

Equilibrium constants of methanol-methyl ether conversion.

Temp., ° K.	300	400	500	600	700	800	900	1000
$\log_{10} K_p$	3.21	19.8	1.09	0.56	0.19	-0.10	-0.32	-0.50

methyl ether produced decomposes, or reacts with benzene, the equilibrium will be shifted by a mass-action effect.

The Metal Oxide-Silica Catalysts.—Our experiments show that the mixed oxide catalysts are all more active than any of the pure oxides examined and that the catalytic activity of the

alumina-silica mixtures varies in an apparently rational way with composition (see Fig.). One would expect there to be some characteristic physical property which distinguishes these materials from the pure oxides, and which varies in a rational manner in a series of mixtures with composition; it is not immediately apparent what that property is. It may be noted that synthetic alumina-silica mixtures have found wide application recently in catalysing many reactions of hydrocarbons, such as polymerisation, isomerisation, and cracking (see, e.g., Nikolaeva and Frost, *Bull. Acad. Sci. U.R.S.S., Cl. Sci. Tech.*, 1944, 536; Thomas, *Ind. Eng. Chem.*, 1945, 37, 543).

Nature of the Reaction between Methyl Ether and Benzene.—The simplest equation which can be written to represent the reaction of benzene and methyl ether to give toluene is

presumably followed by

These can be combined into

As stated above, the only reaction products we have detected are methylbenzenes, water, and permanent gases. The gases have virtually the same composition as the decomposition products of methyl ether determined in separate experiments on the same catalyst. It is logical to assume, therefore, that the gases produced in the reaction of benzene and methyl ether are not primary products, but result only from secondary cracking of the ether.

With one exception (the beryllia-silica mixture), we have never found methanol in the reaction products of benzene and methyl ether; in view of the known readiness of reaction (2) this is not surprising. Thus the available analytical data are in accordance with the suggestion that reaction (1) represents the course of the interaction of benzene and methyl ether, but are not sufficient to establish this unequivocally.

Thermodynamic Considerations.—It was thought of interest to determine how nearly the yields of toluene so far obtained approach the theoretical equilibrium values. We have calculated the thermodynamic equilibria in both reactions (1) and (3) above.

The change in heat capacity in both reactions is small over the relevant range of temperatures, and so the heats of reaction were taken as independent of temperature. Considering all the reactants in the gaseous state, we obtain:

$$\begin{aligned} \text{Reaction (1): } \Delta H^\circ_{298.16} &= -10.23 \text{ kcal.}; \Delta G^\circ_{298.16} = -11.68 \text{ kcal.} \\ &\text{and } \Delta G^\circ = -10,230 - 4.86T \quad (4) \end{aligned}$$

$$\begin{aligned} \text{Reaction (3): } \Delta H^\circ_{298.16} &= -27.89 \text{ kcal.}; \Delta G^\circ_{298.16} = -29.525 \text{ kcal.} \\ &\text{and } \Delta G^\circ = -27,890 - 5.48T \quad (5) \end{aligned}$$

We see from equations (4) and (5) that the free-energy changes of both reactions are always negative. Values of the equilibrium constants are given in Table VII.

TABLE VII.

$T^\circ \text{K.}$	298.16.	500.	723.	1000.
Reaction (1) $\log_{10} K_p$	18.2	5.50	4.13	3.28
Reaction (3) $\log_{10} K_p$	21.5	13.31	9.57	6.25

We conclude from the data here presented that, thermodynamically, the conversion of benzene into toluene by reaction with methyl ether approaches 100%, and is far larger than that so far observed experimentally. (The data employed were obtained from Pitzer and Scott, *J. Amer. Chem. Soc.*, 1943, 65, 803; Prosen, Gilmont, and Rossini, *J. Res. Nat. Bur. Stand.*, 1945, 34, 65; Bichowsky and Rossini, "Thermochemistry of some Chemical Substances"; Crawford, *J. Chem. Physics*, 1943, 8, 526; Given, *loc. cit.*).

The authors wish to express their gratitude to Dr. E. H. Rodd and Dr. Green of I.C.I. (Dyestuffs) Ltd. for helpful discussions and gifts of materials for use as catalysts; Dr. W. Cule Davies and Messrs. Peter Spence Ltd. for the preparation of the metal oxide-silica catalysts, which was specially undertaken; and the Department of Scientific and Industrial Research for grants to one of them (P. H. G.).

174. Curare Alkaloids. Part VI. Alkaloids from *Chondrodendron tomentosum* R. and P.

By HAROLD KING.

d-Tubocurarine chloride is of value in anæsthesia. The discovery of its botanical origin to ensure future supplies is therefore of importance. *Chondrodendron tomentosum* Ruiz and Pavon has been examined and found to yield *l*-curine and *l*-tubocurarine chloride. Dutcher (*J. Amer. Chem. Soc.*, 1946, **68**, 419) has also examined tube-curare prepared on the Upper Amazon from *Ch. tomentosum* but found *d*-tubocurarine chloride, *l*-curine, and other non-quaternary bases. It is possible that undifferentiated species are covered by the name *Ch. tomentosum*.

IN 1935 it was shown (King, *J.*, 1931) that the active principle of tube-curare of native origin was crystalline *d*-tubocurarine chloride. The botanical origin of the poison was not known, but the view was expressed that the genus *Chondrodendron* was probably involved. It was also known, from museum specimens and from the exploratory journeys of Poeppig in the early years of the last century, that tube-curare came from the upper waters of the Amazon in Peru. Through the kind co-operation of Mr. J. W. Massey of the British Consulate at Iquitos in Peru, I received in 1939 a quantity of the liane, "amphi huasca" (amphi = poison, huasca = rope), used by the Indians near Tarapoto in the preparation of curare, which was collected by the late Guillermo Klug. At the same time I also received ample specimens of the leaves of the same liane, and these were identified by Mr. N. Y. Sandwith, M.A., of The Herbarium, Kew, as being indistinguishable from the leaves of *Ch. tomentosum* R. and P. They agreed perfectly with leaves (herbarium sheet No. 4474) collected by Spruce at Tarapoto in 1856 and identified as *Ch. tomentosum* by Moldenke (Krukoff and Moldenke, *Brittonia*, 1938, **3**, 16).

The powdered stem was extracted with dilute tartaric acid; a sample of the neutralised extract had a true curare action when tested on the frog. The extract was worked up for non-quaternary and quaternary alkaloids in the usual way; the non-quaternary fraction readily yielded *l*-curine (*l*-bebeerine) identical with the alkaloid isolated from natural tube-curare (King, *loc. cit.*). The quaternary fraction crystallised with difficulty but was eventually obtained pure and proved to be, not *d*-tubocurarine chloride as expected, but *l*-tubocurarine chloride.

Folkers and Ugna (*Arch. int. Pharmacodyn.*, 1939, **61**, 373) examined a small specimen of *Ch. tomentosum* collected by Klug and identified by Krukoff, and found evidence of definite curare-like action in the crude quaternary fraction. Wintersteiner and Dutcher (*Science*, 1943, **97**, 467; Dutcher, *J. Amer. Chem. Soc.*, 1946, **68**, 419), however, were able to examine a sample of curare, prepared by Indians of the Upper Amazon, in which only one plant species was used. This was said to have been identified as *Ch. tomentosum* by a botanist at the time of preparation and authenticated by herbarium specimens. From this curare they isolated four non-quaternary bases, one of which was identified as *l*-curine, and a quaternary crystalline alkaloid which proved to be *d*-tubocurarine chloride.

The conclusion to be drawn from these observations, provided the botanical identification of the raw materials has been correct, is that under the name *Ch. tomentosum* there must be two closely allied species which need further differentiation by systematic botanists, one of which yields *l*-curine and *l*-tubocurarine chloride and the other *l*-curine and *d*-tubocurarine chloride. The position is reminiscent of that which held for "pareira brava" until a few years ago (King, *J.*, 1940, 737). Sometimes this drug gave *d*-bebeerine and sometimes *l*-bebeerine, and this was traced to the fact that two closely allied and difficultly distinguishable *Chondrodendron* species were concerned, one of which, *Ch. microphyllum*, gave *d*-bebeerine and the other, *Ch. platyphyllum*, *l*-bebeerine. It is not without interest that *Ch. toxicoferum* (Wedd, Krukoff and Moldenke) (*Ch. polyanthum*, Diels) bears a superficial resemblance to *Ch. tomentosum* and grows like the latter in the Huallaga river valley of the Upper Amazon. Chemical examination of this species is much to be desired.

EXPERIMENTAL.

The stem of *Ch. tomentosum* (667 g.) was powdered and percolated with 1% tartaric acid (10 l.) and the solution then concentrated to 1 l. This solution when neutralised was tested for curare activity on the frog; the paralyzing dose corresponded to 1.0 g. of stem per kg. of frog (compare King, *J.*, 1937, 1478, for definition).

A preliminary assay for alkaloidal content and distribution of activity was carried out on the main solution. Of this, 10 c.c. were treated with chloroform (50 c.c.) and saturated sodium hydrogen carbonate solution (15 c.c.). An amorphous precipitate which formed was removed by filtration, and the aqueous layer was extracted with 3 further portions of chloroform. The chloroform on evaporation

left a syrup which on being moistened with methyl alcohol crystallised, yield 0.5 g. This proved to be *l*-curine, m. p. 213°. The rotation of the dried material was determined in *N*/10-hydrochloric acid; $[\alpha]_{544.1}^{20} = 313^\circ$. Pure *l*-curine under similar conditions gave $[\alpha]_{544.1}^{20} = 340^\circ$ (King, J., 1940, 742). The rotation liquor on evaporation readily crystallised giving *l*-curine hydrochloride, m. p. 282° (efferv.) not depressed by admixture with pure *l*-curine hydrochloride.

The sodium hydrogen carbonate mother liquor and the amorphous precipitate, which had been collected, were separately neutralised with sulphuric acid and assayed by the frog test. It was found that there was approximately twice as much activity in the precipitate (phenolic betaine formation) as in the mother liquor.

On this basis, the main bulk of solution was worked up in a similar way. The total yield of crystalline *l*-curine was 34.1 g. corresponding to a 5% yield on the original stems.

The combined amorphous precipitates produced by bicarbonate and insoluble in chloroform were dissolved in *N*/10-sulphuric acid, concentrated to 1150 c.c., and treated with sulphuric acid (57 g.) followed by 25% phosphotungstic acid in 5% sulphuric acid. The precipitate was converted into the hydrochloride in the usual way, and the solution concentrated to 70 c.c. and treated with saturated aqueous mercuric chloride solution (70 c.c.) followed by addition of solid mercuric chloride (15 g.). The precipitate was decomposed with hydrogen sulphide and the filtered solution evaporated to dryness, yield 5.7 g. (A).

In a similar way the sodium hydrogen carbonate mother liquor was neutralised, concentrated to 800 c.c., precipitated with phosphotungstic acid solution, converted into chloride, and precipitated with mercuric chloride. The mercury-free water soluble residue amounted to 5.6 g. (B).

These two fractions of comparable weights, containing the quaternary alkaloids, were kept as aqueous syrups at 0° for some months; that from the amorphous phenolic-betaines (A) had then crystallised partially. The solid was collected, yield 0.74 g. It was crystallised twice from water and gave *l*-tubocurarine chloride, minute needles, m. p. 275° (efferv.) (Found on hydrated material: loss at 100° (macro), 10.7; (micro), 9.6. OMe (micro), 7.0. $C_{48}H_{44}O_6N_2Cl_2 \cdot 5H_2O$ requires H_2O , 11.5; loss of $4H_2O$, 9.2; 2OMe, 7.9%. Found on dried material (micro): C, 63.5; N, 6.5. $C_{48}H_{44}O_6N_2Cl_2 \cdot H_2O$ requires C, 63.9; H, 6.5%). Partial loss of water of crystallisation on micro-drying had been observed previously for *d*-tubocurarine chloride (King, J., 1935, 1386). The anhydrous salt showed $[\alpha]_{546.1}^{20} = 258^\circ$ (c, 0.38). The rotation of *d*-tubocurarine chloride was determined afresh under comparable conditions and gave $[\alpha]_{546.1}^{20} + 256^\circ$ (c, 0.39) for the anhydrous salt.

The mother liquors of the *l*-tubocurarine chloride were fractionally precipitated with saturated aqueous mercuric chloride and seven fractions collected. Each of these was freed from metallic ions, but no further crystallisation of *l*-tubocurarine chloride could be effected. Each of these fractions was then completely methylated in methyl alcoholic solution with methyl iodide in excess and sodium methoxide, and each gave complex amorphous quaternary iodides. From fraction 6 a crystalline solid was obtained which on further crystallisation from water gave *l*-O-methyltubocurarine iodide clusters of small prisms, m. p. 268° (efferv.), yield 22 mg. (Found: Loss at 95°, 5.5. $C_{40}H_{40}O_6N_2I_2 \cdot 3H_2O$ requires H_2O , 5.6%. Found for the anhydrous salt: C, 51.7; H, 5.6; OMe, 13.8. $C_{40}H_{40}O_6N_2I_2$ requires C, 52.9; H, 5.3; 4OMe, 13.7%). The figure for carbon is low but the same figure was found in duplicate micro-analyses of the dextro-form (King, J., 1935, 1386). *d*-O-Methyltubocurarine iodide had previously been found to melt at 266–267° (efferv.).

It is probable that the *l*-O-methyltubocurarine iodide has arisen from *l*-tubocurarine chloride present in the mother liquors.

The fraction, 5.6 g. (B) above, failed to give *l*-tubocurarine chloride by direct crystallisation. It has not been examined further chemically, but biological assay showed that it contains a more powerful curarising agent than *l*-tubocurarine chloride.

I am indebted to Dr. B. D. Burns of this Institute for a biological assay of *l*-tubocurarine chloride, which, on the isolated rat's diaphragm, was 30 to 60 times weaker than *d*-tubocurarine chloride. The quaternary fraction (B) was about 3.5 times weaker than *d*-tubocurarine chloride, but the active principle contained in it cannot be *d*-tubocurarine chloride.

My thanks are also due to Mr. F. J. Pound, Agronomist to the Department of Agriculture of Trinidad, for help in securing *Ch. tomentosum* whilst in Peru.

175. *The Friedel-Crafts Reaction in the Carbazole Series. Part III.*

By S. G. P. PLANT and (MRS.) J. F. POWELL.

3:6-Dichloro- and 3:6-dibromo-9-acetylcarbazole were recovered largely unchanged in attempts to apply Friedel-Crafts reactions, but the closely related 6-chloro-9-acetyltetrahydrocarbazole readily gave its 7-acetyl derivative under similar conditions. 6-Bromo-9-acetyl- and 9-acetyl-6-methyl-tetrahydrocarbazole gave analogous products, but several unacetylated tetrahydrocarbazoles proved to be unreactive. 3:6-Dichlorocarbazole, which has been prepared synthetically from 5:4'-dichloro-1-phenylbenzotriazole, gave only *N*-acyl derivatives.

It has been established that under the usual conditions for Friedel-Crafts reactions two acyl groups can be readily introduced into carbazole and its 9-alkyl derivatives in the 3- and the

6-position, but with the 9-acylcarbazoles substitution of a single acyl group in the 2-position ensues (J., 1935, 741; 1936, 1295). It seemed possible that these reactions might be extended to the preparation of substances which would be of value as intermediates for dyes by the use of certain substituted carbazoles, e.g., 3:6-dichloro-9-acetylcarbazole (I; R = Ac). 3:6-Dichlorocarbazole was first prepared by Mazzara and Lamberti-Zanardi (*Gazzetta*, 1896, 26, 236) by heating carbazole with sulphuryl chloride in chloroform, but the constitution of the product appears never to have been rigidly established. This has now been achieved in the form of an unambiguous synthesis by heating 5:4'-dichloro-1-phenylbenzotriazole (II) (the Graebe-Ullmann reaction), which was obtained from 4:4'-dichloro-2-nitrodiphenylamine through the corresponding 2-amino-compound.

3:6-Dichloro-9-acetylcarbazole proved to be unreactive towards acetyl bromide and aluminium chloride in boiling carbon disulphide. Similar lack of reactivity was displayed towards phthalic anhydride and aluminium chloride in nitrobenzene, except that in one experiment, after prolonged standing, a very small quantity of 3:6-dichlorocarbazole-9-phthaloylic acid (I; R = CO·C₆H₄·CO₂H), formed by displacement of the acetyl group, was isolated. 3:6-Dichlorocarbazole itself reacted with phthalic anhydride, benzoyl chloride, and acetyl chloride in the presence of aluminium chloride with the introduction of the corresponding acyl radical, but the substituent was shown in each case to be attached to nitrogen by the fact that it could readily be removed by warming with alkali, and C-acylation was not observed. 3:6-Dibromo-9-acetylcarbazole also failed to react with acetyl bromide under similar conditions.

In contrast, it was found that the closely related 6-chloro-9-acetyltetrahydrocarbazole (III) could be easily converted into 6-chloro-7:9-diacetyltetrahydrocarbazole. This was hydrolysed to 6-chloro-7-acetyltetrahydrocarbazole, the constitution of which was established by reducing it with the Clemmensen reagent. The product, evidently a mixture of 6-chloro-7-ethyltetrahydrocarbazole and 6-chloro-7-ethylhexahydrocarbazole from the fact that it was only partly soluble in dilute acids, was heated with palladised charcoal in an atmosphere of hydrogen with the formation of 2-ethylcarbazole. The result is in harmony with the observations of Plant and Rogers (J., 1936, 40) who found that the 7-acetyl and 7-benzoyl derivatives were obtained when 9-acetyl- and 9-benzoyl-tetrahydrocarbazole were submitted to Friedel-Crafts reactions with acetyl bromide and benzoyl chloride. It was not, however, possible to obtain an analogous phthaloylic acid from 6-chloro-9-acetyltetrahydrocarbazole by the use of phthalic anhydride.

An acetyl group has been similarly introduced into 6-bromo-9-acetyltetrahydrocarbazole and 9-acetyl-6-methyltetrahydrocarbazole, the products being evidently 6-bromo-7:9-diacetyl- and 7:9-diacetyl-6-methyl-tetrahydrocarbazole respectively. The latter was hydrolysed to 7-acetyl-6-methyltetrahydrocarbazole.

A surprising observation is that unacetylated tetrahydrocarbazole, and its 6-chloro-, 6-bromo-, 6-methyl-, and 6-acetamido-derivatives, were recovered unchanged after treatment with acetyl bromide and aluminium chloride in carbon disulphide, even with prolonged boiling. This is remarkable in view of the ease with which carbazole undergoes substitution.

EXPERIMENTAL.

Synthesis of 3:6-Dichlorocarbazole.—After a mixture of 2:5-dichloronitrobenzene (16 g.), p-chloroaniline (12 g.), and potassium carbonate (12 g.) had been heated at 220° for an hour, unchanged materials were removed in steam and the residue crystallised from alcohol, 4:4'-dichloro-2-nitrodiphenylamine being obtained in crimson needles, m. p. 149–150° (cf. Blom, *Helv. Chim. Acta*, 1921, 4, 1038). The nitro-compound (1·2 g.) in hot glacial acetic acid (20 c.c.) was treated gradually with stannous chloride (6 g.) dissolved in hydrochloric acid (20 c.c. of 28%), and the solution boiled for 10 minutes, cooled, and made alkaline with concentrated aqueous potassium hydroxide. The precipitated amine separated from alcohol in colourless needles, m. p. 137°. Its suspension in glacial acetic acid was treated with aqueous sodium nitrite, and, after the addition of water, the precipitated 5:4'-dichloro-1-phenylbenzotriazole was crystallised from alcohol and obtained in brown needles, m. p. 175° (Found: N, 15·9. C₁₂H₈N₂Cl₂ requires N, 15·9%). When this substance was heated for an hour at 360° and the product distilled under reduced pressure, 3:6-dichlorocarbazole, colourless prisms, m. p. 202°, from glacial acetic acid, was obtained. It proved to be identical (mixed m. p.) with the material obtained by the chlorination of carbazole as described by Mazzara and Lamberti-Zanardi (*loc. cit.*).

Attempted Friedel-Crafts Reactions with 3:6-Dichlorocarbazole.—(a) A solution of 3:6-dichlorocarbazole (2 g.), phthalic anhydride (2 g.), and aluminium chloride (2 g.) in nitrobenzene (25 c.c.) was left

at room temperature for 4 days and then treated with ice-dilute hydrochloric acid, and the solvent removed in steam. After the residue had been dissolved in hot alcohol and poured into dilute ammonia, the filtered aqueous solution was acidified, and 3 : 6-dichlorocarbazole-9-phthaloylic acid, colourless needles, m. p. 185° (rapid heating), from glacial acetic acid, obtained (Found: Cl, 18.2. $C_{20}H_{11}O_3NCl_2$ requires Cl, 18.5%). When its solution in aqueous ammonia was boiled, a precipitate of 3 : 6-dichlorocarbazole, identified by mixed m. p., soon appeared. Similar results were obtained when the reaction was carried out in nitrobenzene at 60° for 6 hours.

(b) Benzoyl chloride (2.5 g.) was added to 3 : 6-dichlorocarbazole (2 g.) and aluminium chloride (2.5 g.) in carbon disulphide (25 c.c.), and the whole refluxed for an hour. After the carbon disulphide had been distilled off, the residue poured into ice-dilute hydrochloric acid, and the excess of benzoyl chloride removed in steam, 3 : 6-dichloro-9-benzoylcarbazole remained; it separated from glacial acetic acid in almost colourless needles, m. p. 204° (Found: Cl, 20.3. $C_{19}H_{11}ONCl_2$ requires Cl, 20.9%). When its solution in aqueous-alcoholic potassium hydroxide was boiled for 1½ hours and poured into water, 3 : 6-dichlorocarbazole was precipitated.

(c) After 3 : 6-dichlorocarbazole had been treated with acetyl chloride and aluminium chloride under conditions similar to those used with benzoyl chloride, 3 : 6-dichloro-9-acetylcarbazole, colourless prisms, m. p. 185°, from glacial acetic acid, was obtained. It was identical (mixed m. p.) with the substance obtained by boiling 3 : 6-dichlorocarbazole with acetic anhydride and a drop of concentrated sulphuric acid under reflux (cf. Mazzara and Lamberti-Zanardi, *loc. cit.*).

6-Chloro-7-acetyltetrahydrocarbazole.—Aluminium chloride (2 g.) was added to a mixture of 6-chloro-9-acetyltetrahydrocarbazole (2 g., prepared as described by Plant and Rosser, *J.*, 1928, 2454) and acetyl bromide (1.5 c.c.) in carbon disulphide (30 c.c.), and the whole refluxed for 10 minutes. After the solvent had been distilled off, the residue added to ice-dilute hydrochloric acid, and the solid crystallised from alcohol, 6-chloro-7 : 9-diacetyltetrahydrocarbazole was obtained in colourless needles, m. p. 118° (Found: C, 66.5; H, 5.2. $C_{16}H_{14}O_2NCl$ requires C, 66.3; H, 5.5%). The reaction proceeded less readily when acetyl chloride was used. When a solution of the diacetyl compound (1 g.) in alcohol (10 c.c.) containing potassium hydroxide (0.6 g.) and water (0.5 c.c.) was refluxed for an hour, filtered, and allowed to cool, 6-chloro-7-acetyltetrahydrocarbazole separated. It was recrystallised from alcohol and isolated in almost colourless prisms, m. p. 171° (Found: C, 68.1; H, 6.0; N, 5.9. $C_{16}H_{14}ONCl$ requires C, 67.9; H, 5.7; N, 5.7%).

Acetyl chloride (0.7 c.c. in a little acetone) was gradually added with constant shaking to the 7-acetyl compound (0.5 g.) dissolved in acetone (10 c.c.) containing aqueous potassium hydroxide (0.45 g. of 66%). Water then precipitated 6-chloro-7 : 9-diacetyltetrahydrocarbazole, which was crystallised from alcohol and found to be identical (mixed m. p.) with the substance described above.

Conversion of 6-Chloro-7-acetyltetrahydrocarbazole into 2-Ethylcarbazole.—6-Chloro-7-acetyltetrahydrocarbazole (2.6 g.) and concentrated hydrochloric acid (50 c.c.) were shaken with amalgamated granulated zinc (200 g.), and the whole was left overnight. After the addition of anisole (5 c.c.) and more concentrated hydrochloric acid (30 c.c.), the mixture was refluxed for 12 hours, the product extracted with ether, the extract evaporated, and anisole removed from the residue by distillation in steam. The less volatile material, which was only partly soluble in dilute acids, was again extracted with ether, and the extract dried (K_2CO_3) and evaporated. When the residue was mixed with 25% of its weight of palladised charcoal and heated at 300–320° for 11 hours in an atmosphere of hydrogen, hydrogen chloride was freely evolved in the early stages. The product was dissolved in warm acetone and recovered from the filtered solution by the addition of water. After it had been distilled under reduced pressure and crystallised from glacial acetic acid, 2-ethylcarbazole was obtained in colourless plates, m. p. 218–220°, identical (mixed m. p.) with the substance prepared by Plant and Williams (*J.*, 1934, 1142).

6-Bromo-7 : 9-diacetyltetrahydrocarbazole.—After a solution of 6-bromotetrahydrocarbazole (25 g., Borsche, Witte, and Bothe, *Annalen*, 1908, 359, 53) in acetic anhydride (90 c.c.) containing a few drops of concentrated sulphuric acid had been refluxed for 6 hours, 6-bromo-9-acetyltetrahydrocarbazole separated on cooling. It was recrystallised from alcohol (charcoal) and obtained in colourless plates (15 g.), m. p. 120° (Found: N, 4.7. $C_{16}H_{14}ONBr$ requires N, 4.8%). Aluminium chloride (4 g.) was added to a mixture of this acetyl compound (2 g.) and acetyl chloride (6 c.c.) in carbon disulphide (25 c.c.), and the whole refluxed for 15 minutes and treated as described for the corresponding chloro-compound. When the product was crystallised from alcohol, 6-bromo-7 : 9-diacetyltetrahydrocarbazole separated in colourless needles, m. p. 112° (Found: N, 4.2. $C_{16}H_{14}O_2NBr$ requires N, 4.2%). The use of acetyl bromide gave less satisfactory products.

When the diacetyl compound (3 g.) in hot glacial acetic acid (10 c.c.) was treated with concentrated nitric acid (1.2 g.), oxides of nitrogen were evolved, and 6-bromo-10 : 11-dihydroxy-7 : 9-diacetylhexahydrocarbazole separated on cooling. On crystallisation from alcohol, it was obtained in colourless plates, m. p. 210° (decomp.) (Found: C, 52.0; H, 4.9. $C_{16}H_{18}O_4NBr$ requires C, 52.2; H, 4.9%).

7-Acetyl-6-methyltetrahydrocarbazole.—When treated with acetyl bromide and aluminium chloride as described for the corresponding chloro-compound, 9-acetyl-6-methyltetrahydrocarbazole (Manjunath and Plant, *J.*, 1926, 2260) gave 7 : 9-diacetyl-6-methyltetrahydrocarbazole, colourless needles, m. p. 136°, from alcohol (Found: C, 75.6; H, 7.1. $C_{17}H_{16}O_2N$ requires C, 75.8; H, 7.1%). Hydrolysis as for the chloro-compound led to 7-acetyl-6-methyltetrahydrocarbazole, colourless plates, m. p. 207°, from alcohol (Found: C, 78.7; H, 7.4. $C_{18}H_{17}ON$ requires C, 79.3; H, 7.5%).

176. Polycyclic Aromatic Hydrocarbons. Part XXXII. 2'-Methoxy- and 2'-Methoxy-9 : 10-dimethyl-1 : 2-benzanthracene.

By G. M. BADGER.

2'-Methoxy-1 : 2-benzanthracene and 2'-methoxy-9 : 10-dimethyl-1 : 2-benzanthracene have been prepared by the scheme illustrated in formulæ (V—XII), for comparison with the (methylated) metabolic products of 1 : 2-benzanthracene and of 9 : 10-dimethyl-1 : 2-benzanthracene, in rabbits.

IN mice and rats, carcinogenic and related polycyclic hydrocarbons are metabolised to phenolic derivatives (I—IV) in which the hydroxy-group occupies the same relative position (Berenblum and Schoental, *Biochem. J.*, 1945, Proc. lxiv). In rabbits, however, 1 : 2 : 5 : 6-dibenzanthracene

is metabolised to a dihydroxy-derivative which differs from that obtained from mice and rats. This compound has not yet been identified, although several of the 55 possible isomers have been excluded (for references see Cason and Fieser, *J. Amer. Chem. Soc.*, 1940, **62**, 2681; 1941, **63**, 1256). The synthesis of all the remaining isomers would be a difficult task, and the present work was undertaken to provide a clue to the identity of the rabbit metabolite of dibenzanthracene. For this purpose, it was decided to prepare hydroxy-derivatives of 1 : 2-benzanthracene, which could then be compared with the metabolic products of this hydrocarbon, in rabbits. By analogy with dibenzanthracene, it is probable that the rabbit will metabolise benzanthracene to a hydroxy-derivative other than, or in addition to, the 4'-hydroxy-derivative.

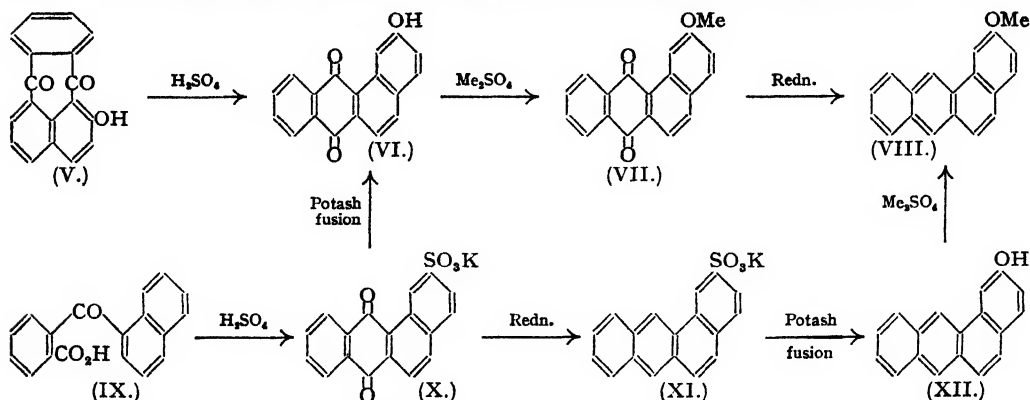

Since rats oxidise benzanthracene and dibenzanthracene at positions which are liable to chemical attack when the *meso*-positions are blocked (Cason and Fieser, *loc. cit.*), it appeared probable that the rabbit would oxidise the same compounds at some other positions which are also liable to chemical attack. In benzantraquinone, this is the 2'-position, for Joffe and Fedorova (*J. Gen. Chem. Russia*, 1941, **11**, 619) have shown that, at high temperatures, benzantraquinone is sulphonated at this position. (Other positions of the benzantraquinone and benzanthracene molecules may also be subject to substitution reactions under certain conditions; see Scholl, *Ber.*, 1911, **44**, 2370; Cook and Hewett, *J.*, 1933, 1408.)

The fact that Berenblum and Schoental (*Cancer Res.*, 1946, **6**, 699) have confirmed the presence of 10-hydroxy-3 : 4-benzpyrene as well as 8-hydroxy-3 : 4-benzpyrene (I) in the excreta of both rats and rabbits, and that more of the 10-hydroxy-derivative is formed in the rabbit, lends added support to this view. For these reasons 2'-methoxy-1 : 2-benzanthracene and 2'-methoxy-9 : 10-dimethyl-1 : 2-benzanthracene have been prepared. The comparison of the former with the (methylated) rabbit metabolic products has been undertaken by Drs. Berenblum and Schoental. Such of the compounds as appear to be suitable will be tested for biological action by Professor A. Haddow. Results of these investigations will be published elsewhere.

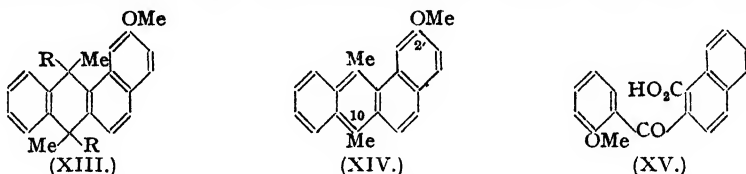

2'-Hydroxy-1 : 2-benzanthracene (XII) was prepared by sulphonation of 2-(1'-naphthoyl)-benzoic acid (IX), followed by reduction and potash fusion, a method substantially the same as that reported by Joffe and Fedorova (*loc. cit.*) except that naphthoylbenzoic acid was used instead of benzantraquinone. Since the melting point of the final product (XII) did not agree with that reported by the Russian workers (although the melting points of the acetates were substantially in agreement), the scheme outlined in formulæ (V—XII) was carried out.

Phthaloylnaphthol (V) was converted into 2'-hydroxy-1 : 2-benzanthraquinone (VI) by the method of Fieser and Fieser (*J. Amer. Chem. Soc.*, 1933, **55**, 3342). The 50% yield claimed by these authors could not, however, be confirmed. In 35—40 runs, the yield of pure product averaged about 10%. The same compound was also prepared by fusion of potassium 1 : 2-benzanthraquinone-2'-sulphonate (X) with potassium hydroxide by the method of Joffe and Fedorova. Methylation with methyl sulphate gave 2'-methoxy-1 : 2-benzanthraquinone (VII), which was reduced with stannous chloride, followed by zinc and alkali, to 2'-methoxy-1 : 2-benzanthracene (VIII). The same compound was also prepared by methylation of 2'-hydroxy-1 : 2-benzanthracene obtained following the sulphonation of naphthoylbenzoic acid (IX—XII).

Treatment of 2'-methoxy-1:2-benzanthraquinone (VII) with methylmagnesium iodide gave 9:10-dihydroxy-2'-methoxy-9:10-dimethyl-9:10-dihydro-1:2-benzanthracene (XIII, R = OH).

R = OH). Methylation with methyl alcohol and a trace of sulphuric acid gave 2':9:10-tri-methoxy-9:10-dimethyl-9:10-dihydro-1:2-benzanthracene (XIII, R = OMe), which, on treatment with sodium, gave 2'-methoxy-9:10-dimethyl-1:2-benzanthracene (XIV) (cf. Bachmann and Chmerda, *J. Org. Chem.*, 1939, 4, 583; *J. Amer. Chem. Soc.*, 1938, 60, 1023).

The Friedel-Crafts reaction between phthalic anhydride and β -methoxynaphthalene, in tetrachloroethane solution, is known to give 2-(2'-hydroxynaphthoyl-1')-benzoic acid or its methyl ether (Fieser, *J. Amer. Chem. Soc.*, 1931, 53, 3546). When nitrobenzene is used as a solvent, the course of Friedel-Crafts reactions between β -methoxynaphthalene and various compounds, especially acyl chlorides, is modified, so that substitution occurs not at the 1-position but at the 6-position (for references, see Hudson, *J.*, 1946, 76). This does not appear to take place with aryl groups, for Hudson (*loc. cit.*) found that the anisoyl group enters the 1-position. The present work shows that phthalic anhydride also reacts at the 1-position, even in cold nitrobenzene solution. In an attempt to convert 2-(2'-hydroxynaphthoyl-1')-benzoic acid lactone into 2'-hydroxy-1:2-benzanthraquinone with sulphuric acid, only phthaloylnaphthol (V) and phthalic acid were formed. That the CO bond at the 1-position should be broken under these conditions is of special interest in view of the conversion of phthaloylnaphthol into 1:2-benzanthraquinone.

In an attempt to prepare 5-hydroxy-1:2-benzanthracene, the Grignard solution from *o*-bromoanisole was condensed with 1:2-naphthalic anhydride. Attempts to prepare the benzanthraquinone from the resulting 2-(2'-methoxybenzoyl)-1-naphthoic acid (XV), by treatment either with sulphuric acid or with benzoyl chloride and a trace of sulphuric acid (Badger and Cook, *J.*, 1939, 802), were unsuccessful.

EXPERIMENTAL.

2'-Hydroxy-1:2-benzanthraquinone.—(i) This was prepared essentially as described by Fieser and Fieser (*loc. cit.*), but the yield claimed could not be confirmed. Phthaloylnaphthol (10 g.) was added to a solution of water (25 c.c.) and sulphuric acid (50 c.c.) and the mixture brought to the boil, with stirring. When oil separated, the mixture was poured on ice (200 g.). The product was extracted with a little boiling alcohol, and some unchanged phthaloylnaphthol filtered off. The crude 2'-hydroxy-1:2-benzanthraquinone obtained from the alcohol was dried, and refluxed for 1 hour with acetic anhydride and sodium acetate. The yellow needles which separated on cooling (1.6 g.) gave, on recrystallisation from acetic acid, 2'-acetoxy-1:2-benzanthraquinone, m. p. 254–255° (1 g.). The acetic acid liquors yielded colourless plates (0.4 g.) which after purification had m. p. 213–214°. This was evidently acetoxyphthaloylnaphthalene (Found: C, 76.1; H, 3.7. Calc. for $\text{C}_{20}\text{H}_{12}\text{O}_4$: C, 76.0; H, 3.8%). Pure 2'-hydroxy-1:2-benzanthraquinone, m. p. 253–253.5°, was obtained from the acetate by hydrolysis with alcoholic sodium hydroxide followed by recrystallisation from alcohol.

(ii) A mixture of 2-(1'-naphthoyl)benzoic acid (15 g.) and concentrated sulphuric acid (150 c.c.) was heated on the water-bath for 1 hour, and then at 160–160° for 6 hours. The dark red solution was poured on ice (150 g.), and the sulphonic acid collected and sucked as dry as possible with the water-pump. The paste was dissolved in hot water, and the solution made alkaline with barium hydroxide. Potassium sulphate (5.1 g.) was added, and the mixture heated on the steam-bath for 2 hours. The filtrate, on evaporation to dryness, gave crude potassium 1:2-benzanthraquinone-2'-sulphonate (13.5 g.). After fusion with potassium hydroxide as described by Joffe and Fedorova (*loc. cit.*) this gave 2'-hydroxy-1:2-benzanthraquinone, identical with that prepared by the first method.

2'-Methoxy-1:2-benzanthraquinone.—2'-Hydroxy-1:2-benzanthraquinone (1.9 g.) was methylated in the usual way by the alternate addition of methyl sulphate and sodium hydroxide, at the temperature of the steam-bath, until a portion of the alkaline filtrate gave no precipitate with hydrochloric acid. Recrystallised from acetic acid, the 2'-methoxy-1:2-benzanthraquinone (1.83 g.) formed long golden-brown needles, m. p. 200–201° (Found: C, 79.3; H, 4.3. $C_{22}H_{14}O_2$ requires C, 79.2; H, 4.2%).

2':9:10-Trimethoxy-1:2-benzanthracene.—2'-Hydroxy-1:2-benzanthraquinone (0.4 g.) was methylated with methyl sulphate and potassium hydroxide in the presence of zinc dust (2 g.) at 100°. The residue after filtration was extracted with boiling alcohol, and the alcohol decolourised with charcoal and concentrated. The 2':9:10-trimethoxy-1:2-benzanthracene (0.21 g.) formed almost colourless crystals, m. p. 173.5–175° (Found: C, 79.4; H, 5.4. $C_{24}H_{18}O_3$ requires C, 79.3; H, 5.7%).

2'-Methoxy-1:2-benzanthracene.—(i) 2'-Methoxy-1:2-benzanthraquinone (0.25 g.), stannous chloride (1.5 g.), hydrochloric acid (3 c.c.) and acetic acid (5 c.c.) were boiled under reflux for 1 hour. The solution was poured into water, and after 1 hour the solid was transferred to a flask containing 2N-sodium hydroxide (15 c.c.) and zinc dust (1 g.). The mixture was boiled under reflux for 3½ hours, cooled, and filtered. The residue was extracted several times with boiling alcohol, and the solution concentrated and allowed to crystallise. The 2'-methoxy-1:2-benzanthracene (0.1 g.) formed almost colourless flat needles, m. p. 165–166° (Found: C, 88.4; H, 5.3. $C_{18}H_{14}O$ requires C, 88.4; H, 5.4%). The alcoholic solution showed an intense blue fluorescence in daylight.

The *picrate*, prepared in alcohol, formed red-brown needles, m. p. 170–171° (Found: C, 61.9; H, 3.6; N, 8.7. $C_{22}H_{14}O_5N_3$ requires C, 61.6; H, 3.5; N, 8.6%).

(ii) Potassium 1:2-benzanthraquinone-2'-sulphonate (7.5 g.) was reduced by 12 hours' boiling with zinc dust (14 g.) in water (300 c.c.) and ammonia (d 0.880; 75 c.c.). The resulting potassium 1:2-benzanthracene-2'-sulphonate (2.6 g.) was obtained as colourless plates from water. This salt (1.6 g.) was converted into the phenol by fusion at 290–300°, for 1 hour, with potassium hydroxide (8 g.). The 2'-hydroxy-1:2-benzanthracene (0.7 g.) formed pale yellow plates from acetic acid, m. p. 191.5–193.5° (lit. 178–179°) (Found: C, 88.5; H, 4.7. Calc. for $C_{18}H_{14}O$: C, 88.5; H, 4.9%). The acetate, prepared by refluxing a portion with acetic anhydride and sodium acetate, formed colourless silky needles, m. p. 156.5–158.5° (lit. 152–153°) (Found: C, 84.1; H, 4.8. Calc. for $C_{20}H_{14}O_2$: C, 83.9; H, 4.9%). The above hydroxybenzanthracene was methylated in almost quantitative yield by the alternate addition of methyl sulphate and sodium hydroxide. The product, crystallised from alcohol, was identical with the 2'-methoxy-1:2-benzanthracene prepared by the first method.

2':9:10-Trimethoxy-9:10-dimethyl-9:10-dihydro-1:2-benzanthracene.—2'-Methoxy-1:2-benzanthraquinone (2 g.), suspended in a Soxhlet thimble under the condenser (compare Bachmann and Chmerda, *J. Org. Chem.*, 1939, 4, 583), dissolved after the Grignard solution (from methyl iodide (3 c.c.), ether (15 c.c.), and benzene (40 c.c.)) had been refluxed for 5 hours. After decomposition with ice-cold ammonium chloride, the organic layer was dried and evaporated. The gummy residue crystallised on stirring with benzene-light petroleum. 2'-Methoxy-9:10-dihydroxy-9:10-dimethyl-9:10-dihydro-1:2-benzanthracene (1.2 g.) formed colourless micro-crystals, from benzene, m. p. 157–160° (decomp.) (Found: C, 78.9; H, 6.3. $C_{24}H_{20}O_2$ requires C, 78.8; H, 6.3%). The methyl ether was obtained by dissolving the diol in methyl alcohol and treating the cold solution with sulphuric acid (2 drops) in methyl alcohol (5 c.c.). It formed colourless needles, from methyl alcohol, m. p. 171–172° (Found: C, 79.4; H, 6.9. $C_{26}H_{22}O_2$ requires C, 79.3; H, 6.9%).

2'-Methoxy-9:10-dimethyl-1:2-benzanthracene.—This was prepared by treatment of the above methyl ether with sodium (cf. Bachmann and Chmerda, *loc. cit.*). Recrystallised from methyl alcohol, 2'-methoxy-9:10-dimethyl-1:2-benzanthracene formed pale yellow lustrous plates, m. p. 112–113° (Found: C, 88.0; H, 6.3. $C_{24}H_{20}O$ requires C, 88.1; H, 6.3%). Its alcoholic solution showed an intense blue fluorescence in daylight.

In one experiment a colourless compound, presumably the *photo-oxide*, was also isolated (cf. Sandin and Fieser, *J. Amer. Chem. Soc.*, 1940, 62, 3098). It formed colourless needles from alcohol, m. p. 210–212° (after sintering) (Found: C, 79.25; H, 5.45. $C_{22}H_{14}O_3$ requires C, 79.3; H, 5.7%).

2-(2'-Methoxynaphthoyl-1')-benzoic acid.—β-Methoxynaphthalene (7.5 g.), phthalic anhydride (8.0 g.), and nitrobenzene (100 c.c.) were cooled in ice and treated with aluminium chloride (12.5 g.) during 1 hour, with stirring. After 3 hours, the solution was kept at room temperature, with shaking, for 70 hours. After decomposition in the usual way, the acid was obtained; it crystallised from toluene as yellow prisms (4.5 g.), m. p. 191–194°. Its constitution was proved by demethylation with aluminium chloride in boiling benzene, followed by conversion into the lactone, m. p. 195–196° (Fieser, *J. Amer. Chem. Soc.*, 1931, 53, 3546).

The same hydroxy-acid was obtained, in poor yield, following a similar experiment with β-naphthol.

Action of Sulphuric Acid on 2-(2'-Hydroxynaphthoyl-1')-benzoic Acid Lactone.—A solution of the lactone (1 g.) in concentrated sulphuric acid (10 c.c.) was heated at 60–70° for 6 hours, and then poured on ice. The solid obtained was dissolved in aqueous alcohol, from which phthaloylnaphthol, m. p. 196–197° (alone, or mixed with an authentic specimen) (0.08 g.), was obtained. The alcoholic liquors, on evaporation, deposited phthalic acid (0.26 g.), m. p. 196° (Found: C, 57.6; H, 3.7. Calc. for $C_8H_6O_4$: C, 57.8; H, 3.6%), converted into phthalic anhydride, m. p. 128–130°, by sublimation. Phthalic acid was also obtained following a similar experiment with the free acid. Both the free acid and the lactone gave cherry-red solutions in sulphuric acid.

2-(2'-Methoxybenzoyl)-1-naphthoic Acid.—A solution in ether (30 c.c.) and benzene (15 c.c.) of

o-anisylmagnesium bromide (from 25 g. of *o*-bromoanisole) was added slowly to a boiling solution of 1 : 2-naphthalic anhydride (26.4 g.) in anhydrous benzene (200 c.c.). The thick yellow precipitate was filtered off and decomposed with ice and dilute sulphuric acid in the presence of ether. The ether solution was extracted with sodium carbonate, and the acid precipitated (20 g.). After purification through the acetoxy-lactone, it formed colourless transparent prisms, m. p. 185–187° (Found: C, 74.45; H, 4.6. $C_{19}H_{14}O_4$ requires C, 74.45; H, 4.6%). The acetoxy-lactone, prepared by heating the acid (20 g.) with acetic anhydride (40 c.c.) and pyridine (130 c.c.) on the steam-bath for 2 hours, formed colourless transparent prisms, from toluene, m. p. 209–211° (Found: C, 72.9; H, 4.7. $C_{21}H_{16}O_5$ requires C, 72.4; H, 4.6%). Attempts to ring-close the acid with sulphuric acid, or with benzoyl chloride and a trace of sulphuric acid, were unsuccessful.

The author thanks Professor J. W. Cook, F.R.S., for his interest in this work, which has been made possible by the award of an Imperial Chemical Industries Research Fellowship. All analyses are microanalyses by Mr. J. M. L. Cameron.

[Received, October 7th, 1946.]

177. *New Potential Chemotherapeutic Agents. Part VII.* *Experiments on the Synthesis of 8-Aminopurines.*

By F. E. KING and T. J. KING.

With the possibility that the synthesis of potential adenine inhibitors might lead to a plasmodicidal compound, the preparation of basically-substituted purines related to adenine, e.g. (II; $R = NH \cdot [CH_2]_3 \cdot NEt_3$), has been investigated. The principal intermediates obtained in this research are the previously unknown purines (V; $R = NHPh$) and (VI; $R = OH$), and the triazole (IX; $R = Me$), but only in (VI; $R = OH$), the methylthio-group of which does not react with amines, was it possible to replace the 6-hydroxyl group by a basic substituent. The arylcarbamides (IV; $R = SH$) and (IV; $R = NH_2$) were resistant to cyclisation, but the derivative (IV; $R = OH$) was successfully converted into (V; $R = NHPh$), which was also directly obtained from the hydrochloride of (III) and phenylcyanamide in boiling butanol, possibly through the *O*-butyl ether (IV; $R = O \cdot C_4H_9$).

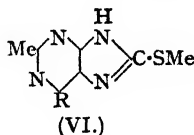

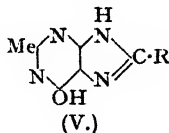

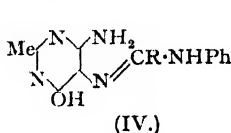

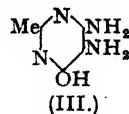

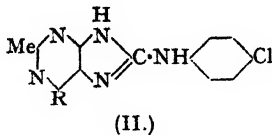

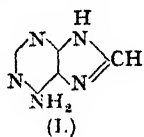

In its application to antimalarial compounds, the current theory as to the mode of action of the more specific chemotherapeutic agents was first expressed by Oesterlin (*Klin. Woch.*, 1936, 15, 1719), who suggested that the activity of mepacrine and pamaquin arose from their easy reduction to dihydro-derivatives, a property which enabled them to inhibit some riboflavin-containing enzyme essential to the metabolism of the parasite. The close structural resemblance of these drugs to riboflavin is in agreement with this idea, and the ability, not only of mepacrine but also of some of the newer pyrimidine antimalarials (see Curd and Rose, *J.*, 1946, 343 *et seq.*), to function as riboflavin antagonists has recently been experimentally demonstrated in nutritional investigations with *Lactobacillus casei* by Madinaveitia (*Biochem. J.*, 1946, 40, 373).

If, as these observations seem to imply, antimalarial action is dependent on the inhibition of well-known enzymes, it should also be possible, by means of suitably constituted reagents, to arrest the growth of the plasmodia by interfering with the synthesis or utilisation of other co-enzyme constituents, for example, the purines adenine and guanine. Such a hypothesis has, in fact, lately been propounded by Hull, Lovell, Openshaw, Payman, and Todd (*J.*, 1946, 360) to account for the antimalarial properties of certain 5-methylpyrimidines, which these authors consider may be due to blocking of the purine biosynthesis by the 5-substituent. From considerations similar to those advanced by Todd and his colleagues (*loc. cit.*), it occurred to us that useful results might follow from the preparation of purine bases as potential antimalarial agents, and we were for a time engaged in the synthesis of appropriately substituted compounds related to adenine (I).

The derivatives of (I) considered most likely to possess biological activity were those incorporating the characteristic dialkylaminoalkylamino- side chain and the chlorinated or methoxylated aniline residue typical of what may be termed the riboflavin antimalarials. Of the several possible arrangements of these presumably essential components about the adenine, or somewhat more readily obtainable 2-methyladenine, nucleus, that shown as (II; $R = NH \cdot [CH_2]_3 \cdot NEt_3$) was selected as the first objective. Although the project has made some progress, its full development has been hindered by unexpected difficulties, the nature of which is indicated in the following account of the experiments.

With 4 : 5-diamino-6-hydroxy-2-methylpyrimidine (III) as the starting point, the sequence of reactions in the proposed synthesis of (II; $R = NH \cdot [CH_2]_3 \cdot NEt_3$) was (i) formation of the 5-*p*-chlorophenylthiocarbamido-derivative; (ii) its cyclisation to 8-*p*-chloroanilino-6-hydroxy-2-methylpurine (II; $R = OH$); (iii) replacement of the 6-hydroxyl group by chlorine, giving

(II; R = Cl); and (iv) substitution of the chlorine by a diethylaminopropylamino-group. Since there was no reason to suppose that the necessary conditions would be appreciably affected by slight variations in structure, the reactions were for the most part investigated with the anilino- rather than the *p*-chloroanilino-derivatives.

The action of ammonium phenyldithiocarbamate on the diaminopyrimidine (III) in aqueous solution at 100° gave the 5-phenylthiocarbamido-derivative (IV; R = SH), but the latter remained unchanged on attempted ring-closure in boiling water, and with lead hydroxide in refluxing ethanol or isoamyl alcohol. Methylation to the potentially more reactive methylthio-compound (IV; R = SMe) could not be accomplished. However, prolonged heating of (IV; R = SH) with pyridine effected cyclisation, but with the elimination of aniline, so that the product was 6-hydroxy-8-mercapto-2-methylpurine (V; R = SH). The constitution of this compound was confirmed by means of an independent synthesis from the diamine (III) by fusion with thiourea, and also by the formation of 6-hydroxy-8-methylthio-2-methylpurine (V; R = SMe) on treatment with methyl iodide in aqueous sodium hydroxide. Unfortunately, the methylthio-derivative could not be utilised for the synthesis of the 8-anilino-purine (V; R = NHPh), or even of (V; R = NH·[CH₂]₃·NET₂), since it failed to react with either aniline or γ -diethylaminopropylamine.

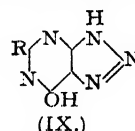

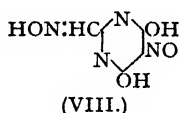

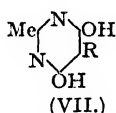

In order to permit of the use of other methods of ring-closure to the required base (V; R = NHPh), the original scheme was modified by substituting as an intermediate 4-amino-5-(N'-phenylcarbamido)-6-hydroxy-2-methylpyrimidine (IV; R = OH), which was prepared from (III) by the action of phenyl isocyanate in boiling toluene. Treatment of the carbamidopyrimidine with both phosphoryl chloride and phosphorus pentachloride under various conditions did not succeed in giving any purifiable substance, but with phosphorus trichloride in refluxing toluene a product having the composition of the required 8-anilino-6-hydroxy-2-methylpurine (V; R = NHPh) was obtained. Since there is also a possibility of reaction between the substituents at the 5- and the 6-position, which would result in the formation of 6-amino-8-hydroxy-9-phenyl-2-methylpurine, the synthesis did not provide definite proof of the constitution of the new base. Moreover, the product exhibited an unexpected stability towards chlorinating agents, a property which could be interpreted as a further manifestation of the inertness of the 8-substituent already encountered in the analogous 8-methylthiopurine (V; R = SMe). Accordingly, a method was designed for the synthesis of (V; R = NHPh) which would leave the structure of the final product in no doubt. This involved the preparation of the guanidine (IV; R = NH₂) which was effected by prolonged heating of (III), in the form of its hydrochloride, with phenylcyanamide in refluxing ethanol. The condensation was repeated with *p*-chlorophenylcyanamide, both guanidines being further identified by their hydrochlorides and picrates, but in no circumstances could the cyclisation of either guanidine be achieved. Nevertheless, the product (V; R = NHPh) was ultimately obtained when attempting to accelerate the reaction of phenylcyanamide with the pyrimidine (III) by using boiling butanol instead of ethanol as solvent. The base gave a dihydrated hydrochloride and was in every respect identical with the substance already prepared from (IV; R = OH), the constitution of which is thus established.

The derivative (IV; R = NH₂) could not be detected in the reaction product, and together with the fact that it failed to cyclise under similar conditions, it is fairly certain that the guanidine is not an intermediate in the cyclisation. It is possible to suggest an explanation for the variation of product with solvent if the likely supposition is made that a preliminary step is the formation from the cyanamide of an imino-ether, Ph·NH·C(=NH)·O-alkyl. Two alternatives are then possible in the subsequent condensation with the pyrimidine 5-amino-group: (i) elimination of alcohol, giving the guanidine (IV; R = NH₂); or (ii) loss of ammonia, a reaction

similar to that introduced by Schmidt (*Ber.*, 1914, 47, 2548) for the preparation of *N*-substituted imino-ethers, giving (IV; R = O-alkyl). Normally, guanidine formation would be expected to occur, but when O-alkyl is the comparatively inert butoxy-group, formation of the substituted imino-ether (IV; R = O·C₄H₉) would take precedence, the final ring-closure to (V; R = NHPh), a reaction of the amidine type, being facilitated by the favourable spatial configuration of the molecule.

Since the anilino-hydroxypurine (V; R = NHPh) was highly resistant to attack by chlorinating agents, further progress in the direction of (II; R = dialkylaminoalkylamino-) was impossible. Shortly afterwards, Adams and Whitmore (*J. Amer. Chem. Soc.*, 1945, 67, 1271) reported similar difficulties in attempting to convert guanine hydrochloride into 6-chloro-2-aminopurine. These results are surprising, particularly when compared with those from later experiments on the methylthiopurine (V; R = SMe). Under the conditions used by Baddiley and Topham (*J.*, 1944, 678) for the preparation of trichloropyrimidine from barbituric acid, *viz.*, heating with phosphoryl chloride and dimethylaniline, the only isolable product was a small yield of 6-*N*-methylanilino-8-methylthio-2-methylpurine (V; R = NMePh), but, with phosphoryl chloride alone, no difficulty was experienced in obtaining the 6-chloro-8-methylthio-2-methylpurine (VI; R = Cl). Heating the latter in toluene with γ -diethylaminopropylamine gave the corresponding basically-substituted purine (VI; R = NH·[CH₂]₃·NEt₂) which was isolated as the hydrochloride. The necessary γ -diethylaminopropylamine was prepared by reduction of β -diethylaminopropionitrile in ammoniacal methanol over Raney nickel, and was characterised by its picrate, picrolonate, and flavianate.

In connexion with other work on purine analogues, 5-amino-4:6-dihydroxy-2-methylpyrimidine (VII; R = NH₂) was required; this we proposed to prepare from 4:6-dihydroxy-2-methylpyrimidine (VII; R = H) *via* the 5-nitroso-derivative. Both the nitrosation of (VII;

R = H) and its reaction with *p*-chlorobenzenediazonium chloride have been described by Lythgoe, Todd, and Topham (*J.*, 1944, 315) but no attempt was made to isolate the products. On repeating these reactions, 5-*p*-chlorobenzenediazo-4:6-dihydroxy-2-methylpyrimidine (VII; R = N₂·C₆H₄·Cl) was obtained and characterised, but the bright green solid which separated on adding nitrous acid to the pyrimidine (VII; R = H) proved to be a dinitroso-compound, and not the expected derivative (VII; R = NO). In view of the reactivity of the 2-methyl group in certain hydroxypyrimidines, *e.g.*, 4-hydroxy-2-methylpyrimidine, which is oxidised by nitrous acid to 4-hydroxy-2-methylpyrimidine-2-carboxylic acid (Huber and Hölscher, *Ber.*, 1938, 71, 87), the product appeared to be 5-nitroso-4:6-dihydroxy-2-isonitrosomethylpyrimidine (VIII). The considerably increased yield obtained on using a second equivalent of nitrite supported this view, which was confirmed by reduction of the derivative to the corresponding diamine.

From the diaminopyrimidine (III) the triazolopyrimidine (IX; R = Me) was prepared by the action of nitrous acid, and was isolated as a hydrated double salt, C₆H₅ON₅·C₆H₄ON₅Na. As with the purine (V; R = NHPh), attempts to replace the 6-hydroxyl group by chlorine were unsuccessful. Roblin, Lampen, English, Cole, and Vaughan (*J. Amer. Chem. Soc.*, 1945, 67, 290) subsequently described the antibacterial activity of the lower homologue (IX; R = H), and when tested *in vitro* against *Staph. aureus* by the method of Heatley (*Lancet*, 1941, 2, 177), the 2-methyltriazole (IX; R = Me) was found to possess comparable activity.

Hydrochlorides of the amine (VI; R = NH·[CH₂]₃·NEt₂), and of the guanidine (IV; R = NH₂) and the analogous *p*-chloro-compound were tested against *P. gallinaceum* infections in chicks. The tests were kindly carried out by Miss I. M. Tonkin, National Institute of Medical Research, London, N.W. 3, who reports that none of the compounds has antimalarial activity.

EXPERIMENTAL.

4-Amino-5-(*N'*-phenylthiocarbamido)-6-hydroxy-2-methylpyrimidine (IV; R = SH).—4:5-Diamino-6-hydroxy-2-methylpyrimidine monohydrate (Traube, *Annalen*, 1923, 43, 287) (5 g., 1 mol.) in aqueous sodium hydroxide (1.43 g., 1.13 mol., in 25 c.c.), and a solution of ammonium phenyldithiocarbamate (*Org. Synth.*, 6, 72) (6.65 g., 1.13 mol.) in water (25 c.c.), were heated on a steam-bath for 6 hours. The precipitate, together with a further quantity of solid obtained by the addition of acid, was collected and purified by dissolving in 2*N*-sodium hydroxide. The phenylthiocarbamide (6.6 g., 76%) obtained on acidifying the filtered solution was crystallised from a large volume of boiling water, and formed

colourless microscopic tablets, m. p. $>310^\circ$ (Found : C, 52.5; H, 5.0; S, 10.8. $C_{12}H_{11}ON_4S$ requires C, 52.4; H, 4.7; S, 11.6%). The compound was insoluble in organic solvents, but dissolved readily in aqueous sodium hydroxide forming a mono-sodium salt and a more soluble di-sodium salt. It was not affected either by heating in boiling water for 48 hours, or on treatment with freshly prepared lead hydroxide in refluxing ethanol or isoamyl alcohol for 24 hours.

6-Hydroxy-8-mercapto-2-methylpyrimine (V; R = SH).—(a) The phenylthiocarbamide (IV; R = SH) (5 g.) was heated in boiling pyridine (50 c.c.) for 36 hours, and the solid collected and dissolved in 2*N*-sodium hydroxide. The micro-crystalline pale fawn powder obtained on acidification passed through filter paper, even after heating to 100° , and the product was accordingly isolated by centrifugation, and washed with water and ethanol. The resulting 6-hydroxy-8-mercapto-2-methylpyrimine, a light brown powder (2.7 g., 81%), m. p. $>310^\circ$, which was very sparingly soluble in water and organic solvents, was purified by precipitation from its aqueous alkaline solution with acid (Found : C, 39.4; H, 3.7; S, 17.4. $C_8H_8ON_4S$ requires C, 39.5; H, 3.3; S, 17.6%). It gave both a mono- and a di-sodium salt, the former being sparingly soluble.

(b) When 4 : 5-diamino-6-hydroxy-2-methylpyrimidine (5 g.) and excess of thiourea (10 g.) were fused over a flame for 30 minutes, the mixture frothed and evolved ammonia. After cooling, the mercaptopyrimine was extracted with dilute alkali, the purified product (4.95 g., 86%) being identical in appearance, solubilities, etc., with that from reaction (a) (Found : S, 17.0%).

6-Hydroxy-8-methylthio-2-methylpyrimine (V; R = SMe).—6-Hydroxy-8-mercapto-2-methylpyrimine (5 g.) in excess of 2*N*-sodium hydroxide was shaken at room temperature with methyl iodide (4.0 g., 1.1 mol.) for 20 minutes. On neutralisation, the methylthiopurine (4.3 g., 81%) separated in pale fawn needles, m. p. $>310^\circ$. The methyl ether is more soluble than the parent compound (V; R = SH), dissolving in both acids and alkalis and crystallising well from water (Found : C, 42.7; H, 4.4; N, 28.8; S, 16.4. $C_9H_{10}ON_4S$ requires C, 42.9; H, 4.1; N, 28.6; S, 16.3%).

On heating with aniline or γ -diethylaminopropylamine the methylthiopurine was either largely unchanged or, under extreme conditions, suffered decomposition.

4-Amino-5-(*N'*-phenylcarbamido)-6-hydroxy-2-methylpyrimidine (IV; R = OH).—4 : 5-Diamino-6-hydroxy-2-methylpyrimidine (7 g., 1 mol.), dried at $140^\circ/0.6$ mm. over phosphoric oxide, was heated with phenyl isocyanate (7 g., 1.17 mol.) in boiling toluene (100 c.c.) for 8 hours. The colourless solid product (11.5 g., 88.8%), which was very sparingly soluble in organic solvents, water, and acids, but readily soluble in alkalis, was crystallised from a large volume of boiling water. The pure phenylcarbamidopyrimidine formed colourless microscopic rhombs, m. p. $>305^\circ$ (Found : C, 55.2; H, 5.0; N, 26.5. $C_{12}H_{13}O_2N_6$ requires C, 55.6; H, 5.0; N, 27.0%).

Heating the derivative (2 g.) with phosphoryl chloride (10 c.c.), followed by removal of halide under reduced pressure, dissolution of the residue in ethanol, and precipitation with water, gave an uncrystallisable solid (1.2 g.) devoid of halogen. Prolonged treatment with phosphoryl chloride or phosphorus pentachloride in toluene gave inseparable mixtures of partly chlorinated products.

8-Anilino-6-hydroxy-2-methylpyrimine (V; R = NHPh).—(a) 4-Amino-5-(*N'*-phenylcarbamido)-6-hydroxy-2-methylpyrimidine (5 g.) in toluene (100 c.c.) was treated with phosphorus trichloride (1.8 g., 2 mol.), and the mixture refluxed for 10 hours. The solid was collected and purified by precipitation from its aqueous solution by addition of a large excess of concentrated hydrochloric acid. The purine (V; R = NHPh) was thus obtained as a sparingly soluble hydrochloride (4.6 g., 80.4%), crystallising in minute pale cream-coloured plates, m. p. $>310^\circ$ (Found : C, 46.2; H, 5.3; Cl, 12.0. $C_{12}H_{11}ON_4HCl \cdot 2H_2O$ requires C, 46.0; H, 5.1; Cl, 11.3%. Found, after drying at 100° : C, 50.0; H, 4.9. $C_{12}H_{11}ON_4HCl \cdot \frac{1}{2}H_2O$ requires C, 50.2; H, 4.5%).

(b) 4 : 5-Diamino-6-hydroxy-2-methylpyrimidine hydrochloride (5 g.) and phenylcyanamide were refluxed in dry *n*-butanol for 25 hours. The cooled product was filtered, thus giving a fawn solid (6 g.), which was extracted with hot water (300 c.c.). The undissolved halogen-free product (2.3 g., 33.5%) was soluble in alkalis and sparingly soluble in organic solvents. It was purified by adding a large excess of hydrochloric acid to its alkaline solution; the hydrochloride, m. p. $>310^\circ$, then separated in minute almost colourless plates (Found : C, 45.7; H, 5.1; N, 22.2; Cl, 11.1%. Found after drying at 100° : C, 50.0; H, 4.5%).

Evaporation of the solution from the hot water extraction gave only unchanged diaminopyrimidine hydrochloride. Yields from the above condensation varied considerably and were sometimes extremely small. Several attempts were made to obtain the 6-chloro-derivative from the purine (V; R = NHPh) using phosphorus chlorides, but only resinous products were obtained.

4-Amino-5-(*N'*-phenylguanidino)-6-hydroxy-2-methylpyrimidine (IV; R = NH_2).—Finely divided 4 : 5-diamino-6-hydroxy-2-methylpyrimidine hydrochloride (1.5 g.) and excess of phenylcyanamide (2 g.) were heated in boiling ethanol (60 c.c.) for 30 hours. The resulting solid (2.2 g., 83%) was collected and the guanidine purified as hydrochloride by crystallisation from dilute hydrochloric acid, from which the salt separated as small colourless plates, m. p. 295° (decomp.), soluble in alkali, very sparingly soluble in organic solvents (Found : C, 45.5; H, 5.6; N, 26.5; Cl, 11.6. $C_{12}H_{14}ON_6HCl \cdot H_2O$ requires C, 46.1; H, 5.4; N, 26.8; Cl, 11.4%. Found after drying at 100° : C, 47.2; H, 5.3. $C_{12}H_{14}ON_6HCl \cdot \frac{1}{2}H_2O$ requires C, 47.4; H, 5.3%).

On treating a solution of the pure hydrochloride with aqueous sodium picrate, the very sparingly soluble picrate separated as thick, minute yellow prisms, m. p. 270° (decomp.) (Found : C, 42.8; H, 3.9. $C_{12}H_{14}ON_6 \cdot C_6H_3O_7N_3 \cdot H_2O$ requires C, 42.7; H, 3.8%. Found after drying at 100° : C, 43.8; H, 3.9. $C_{12}H_{14}ON_6 \cdot C_6H_3O_7N_3$ requires C, 44.3; H, 3.5%).

Attempted ring-closure to (V; R = NHPh) by heating alone, or in high boiling solvents, or with concentrated hydrochloric acid, was unsuccessful.

***p*-Chlorophenylcyanamide.**—To *p*-chlorophenylthiourea (Stolle, *J. pr. Chem.*, 1932, 134, 282) (18.5 g., 1 mol.) and lead acetate (50 g., 1.5 mol.) in water (200 c.c.) at 90° a solution of potassium hydroxide (25 g., 4 mol.) was added. The mixture was shaken during 15 minutes' heating on a steam-bath, and, after removal of lead sulphide, the clear solution was cooled and acidified with acetic acid. *p*-Chlorophenylcyanamide separated as a colourless solid (9.4 g., 61%), insoluble in water, very

soluble in the common organic solvents, and crystallising from aqueous ethanol in long silky colourless needles, m. p. 107° (Found: C, 55.0; H, 3.2; Cl, 24.1. $C_7H_7N_4Cl$ requires C, 55.0; H, 3.3; Cl, 23.3%).

4-Amino-5-(N'-p-chlorophenylguanidino)-6-hydroxy-2-methylpyrimidine.—Finely powdered 4:5-diamino-6-hydroxy-2-methylpyrimidine hydrochloride (5 g.) and excess of *p*-chlorophenylcyanamide (10 g.) were refluxed in ethanol for 30 hours. The crystalline guanidine was collected and purified as the *dihydrochloride* by precipitation from an alkaline solution with hydrochloric acid. The salt formed a colourless microcrystalline powder, m. p. 302° (decomp.), virtually insoluble in organic solvents (Found: C, 39.4; H, 4.1; Cl, 29.4. $C_{12}H_{13}ON_6Cl_2 \cdot 2HCl$ requires C, 39.4; H, 4.1; Cl, 29.8%).

The *picrate*, which was precipitated from aqueous solutions of the hydrochloride and sodium picrate, crystallised from ethanol in minute yellow prisms, m. p. 268° (decomp.) (Found: C, 39.9; H, 3.6; N, 23.6. $C_{11}H_{13}ON_6Cl_2 \cdot C_6H_3O_7N_3 \cdot H_2O$ requires C, 40.2; H, 3.3; N, 23.4%).

6-N-Methylamino-8-methylthio-2-methylpurine (VI; R = NMePh).—6-Hydroxy-8-methylthio-2-methylpurine (3 g.) was refluxed for 3 hours with phosphoryl chloride (3.2 c.c.) and dimethylaniline (2 c.c.). The dark liquid was poured on ice, and after 1 hour the water layer was decanted and the residual tarry product triturated with a little ethanol. The crystalline residue (0.9 g., 22%) was the 6-methylamino-8-methylthio-2-methylpurine, which separated from alcohol-ether as a grey microcrystalline powder, m. p. 270–271° (decomp.), soluble in water, ethanol, and acetone, insoluble in ether (Found: C, 52.5; H, 6.2; Cl, 10.4. $C_{14}H_{15}N_5S \cdot HCl \cdot C_2H_5O$ requires C, 52.2; H, 6.0; Cl, 9.7%).

6-Chloro-8-methylthio-2-methylpurine (VI; R = Cl).—6-Hydroxy-8-methylthio-2-methylpurine (3 g.) was refluxed for 3 hours with excess of phosphoryl chloride. The thick black syrup remaining after evaporation was treated with sodium carbonate (2 g.), water (*ca.* $\frac{1}{2}$ c.c.), and toluene (50 c.c.), and the mixture heated to boiling. The hot toluene solution was decanted, and on cooling it deposited the *chloropurine* (1.75 g., 53%) in long colourless silky needles. The product was easily soluble in ethanol and almost insoluble in water. Crystallised from toluene, the pure compound had m. p. 231° (Found: C, 39.8; H, 3.5; Cl, 16.9. $C_7H_7N_4ClS$ requires C, 39.2; H, 3.3; Cl, 16.6%).

γ -Diethylaminopropylamine (cf. Whitmore *et al.*, *J. Amer. Chem. Soc.*, 1944, **66**, 725).—Reduction of β -diethylaminopropionitrile (Holcomb and Hamilton, *ibid.*, 1942, **64**, 1309) (15 g.) in ammoniacal methanol (150 c.c. saturated at 0°) at 100°/100 atm. for 20 minutes gave γ -diethylaminopropylamine (12.3 g., 82%), b. p. 175°. It was identified by the picrate, m. p. 192° (decomp.) (literature 194°); the *picrolonate*, m. p. 261° (decomp.), a microcrystalline powder, very sparingly soluble in hot alcohol (Found: C, 49.4; H, 5.4. $C_7H_{18}N_2 \cdot 2C_{10}H_8O_6N_4$ requires C, 49.2; H, 5.4%; and the *flavinate*, yellow-orange, felted needles, m. p. 260° (decomp.), readily soluble in hot ethanol (Found: C, 45.8; H, 5.3. $C_7H_{18}N_2 \cdot C_{10}H_8O_6N_4 \cdot S$ requires C, 46.0; H, 5.4%).

6- γ -Diethylaminopropylamino-8-methylthio-2-methylpurine (VI; R = NH \cdot [CH $_2$] $_3$ ·NEt $_2$).—The hydroxypurine (VI; R = OH) (5 g.) was chlorinated as before, and the product remaining after removing excess of phosphoryl chloride was heated with γ -diethylaminopropylamine (5 g., 1.5 mol.) in boiling toluene (75 c.c.) for 10 hours. The solvent was evaporated under reduced pressure and the tarry residue extracted with ethanol (150 c.c.). Dry hydrogen chloride was passed into the extract and the volume reduced to 50 c.c. on a steam-bath. On cooling, the *purine hydrochloride* (14.5 g., 80%) separated as brown tablets, soluble in water, alcohol, and acetone; when recrystallised from ethanol-ether it formed colourless prisms, m. p. 243° (Found: C, 44.0; H, 6.9; N, 22.1; Cl, 19.2; S, 8.0. $C_{14}H_{24}N_6S \cdot 2HCl$ requires C, 44.1; H, 6.8; N, 22.1; Cl, 18.6; S, 8.4%).

On treating the above alcoholic extract with picric acid, the sparingly soluble *picrate* was obtained, which crystallised from alcohol as a monohydrate in yellow needles, m. p. 110° (decomp.) (Found: C, 40.3; H, 4.3; N, 21.0. $C_{14}H_{24}N_6S \cdot 2C_6H_3O_7N_3 \cdot H_2O$ requires C, 39.8; H, 4.1; N, 21.4%).

5-p-Chlorobenzeneazo-4:6-dihydroxy-2-methylpyrimidine (VII; R = N $_2$ ·C $_6$ H $_4$ ·Cl) (cf. Lythgoe, Todd, and Topham, *loc. cit.*).—A solution of *p*-chlorobenzene diazonium chloride, from *p*-chloroaniline (25 g.), in excess of hydrochloric acid was slowly added to 4:6-dihydroxy-2-methylpyrimidine (25 g.) in 2N-sodium carbonate (100 c.c.) containing excess of sodium acetate. The precipitated pale yellow solid (39.9 g., 76%) was collected and dried at 100°. The *pyrimidine* was sparingly soluble in organic solvents, but was crystallised from a large volume of ethanol, forming yellow needles, m. p. > 310°, which dissolved in alkali to an orange solution (Found: C, 50.0; H, 3.5. $C_{11}H_9O_2N_4Cl$ requires C, 49.9; H, 3.4%).

5-Nitroso-4:6-dihydroxy-2-isonitrosomethylpyrimidine (VIII) (cf. Lythgoe, Todd, and Topham, *loc. cit.*).—Sodium nitrite (5.5 g., 2 mol.) was added to the pyrimidine (VII; R = H) (5 g., 1 mol.) (Dox and Yoder, *J. Amer. Chem. Soc.*, 1922, **44**, 361) dissolved in 2N-sodium hydroxide, and the mixture treated with excess of hydrochloric acid. A dark green solid immediately separated, which was collected and washed with alcohol and ether. The *dinitrosopyrimidine* (6.4 g., 89%) became grey at 100° but did not melt below 310° (Found: C, 32.2; H, 2.5. $C_8H_8O_4N_4$ requires C, 32.6; H, 2.2%). It was insoluble in organic solvents, but dissolved in aqueous alkali from which it was precipitated by acid. Repeated dissolution in alkali destroyed the characteristic green colour, and the pyrimidine was better purified through the *sodium salt*. This separated on the addition of alcohol to its aqueous solution as a bright green microcrystalline powder, m. p. > 310°, containing water of crystallisation (Found: C, 21.5; H, 2.6; N, 19.9. $C_8H_8O_4N_4 \cdot Na_2 \cdot 2\frac{1}{2}H_2O$ requires C, 22.0; H, 2.6; N, 20.5%. Found after drying at 100°: C, 24.1; H, 1.4. $C_8H_8O_4N_4 \cdot Na_2 \cdot H_2O$ requires C, 24.4; H, 1.6%).

5-Amino-4:6-dihydroxy-2-aminomethylpyrimidine.—The nitroso-compound (VIII) (11.5 g.) was added to aqueous ammonia (50 c.c. of 17%) saturated with hydrogen sulphide at 0°. After a few seconds the green colour disappeared, and a yellow solid was deposited, probably an ammonium salt. This was dissolved in hot water, and on acidifying with concentrated hydrochloric acid the diamine *hydrochloride* separated as a light pink powder (6.1 g., 42.6%), with decomposition point 200° (Found: C, 26.3; H, 4.8. $C_8H_8O_4N_4 \cdot 2HCl$ requires C, 26.2; H, 4.4%).

Both the hydrochloride and the free base are very soluble in water, sparingly soluble in organic solvents. Heating the base with water led to decomposition with elimination of ammonia.

5:6-(4:5-Triazole)-4-hydroxy-2-methylpyrimidine (IX; R = Me).—The *diaminopyrimidine* (III) (5 g.), dissolved in excess of hydrochloric acid, was treated at 0° with aqueous sodium nitrite (2.2 g. in 10 c.c.), and after 10 minutes the solution was carefully neutralised with solid sodium hydrogen carbonate.

The precipitated solid (3 g., 50%) crystallised from water in long plates, m. p. 310°, soluble in aqueous alkali and acid, and was found on analysis to consist of the triazolopyrimidine acid sodium salt *trihydrate* (Found: C, 31.4; H, 4.8; N, 37.0; Na, 6.1. $C_8H_8ON_3 \cdot C_8H_8ON_3 \cdot Na \cdot 3H_2O$ requires C, 31.7; H, 4.0; N, 37.0; Na, 6.1%). The compound was remarkably resistant to chlorinating agents, being almost quantitatively recovered even after fusion with phosphorus pentachloride.

The authors thank the Medical Research Council for the award of a grant to one of them (T. J. K.)

[Received, October 8th, 1946.]

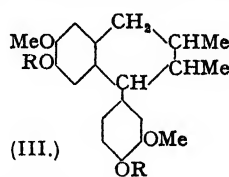

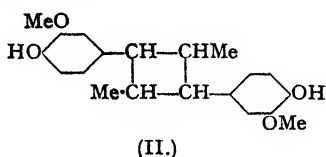

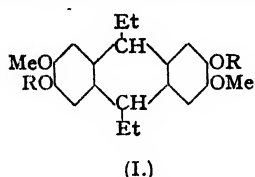

178. The Constituents of Natural Phenolic Resins. Part XXI.* The Structure of Diisoeugenol.

By NEVILLE J. CARTWRIGHT and ROBERT D. HAWORTH.

Structure (I; R = H) suggested for diisoeugenol in 1931 has been disproved by the synthesis of a tetramethoxyanthracene derivative of structure (I; R = Me) which, in its ready dehydrogenation, differs markedly from diisoeugenol dimethyl ether. Structure (III; R = H) is rejected because (a) such a lignan structure would be inconsistent with the difficulties experienced in the dehydrogenation of diisoeugenol derivatives, and (b) synthetic analogues of (III; R = Me) give colour reactions which differ from those shown by diisoeugenol dimethyl ether. Structure (IV; R = H) recently advanced by Müller *et al.* is regarded as the most likely structure for diisoeugenol for the following reasons. The ketone (VIII) has been synthesised and shown to be identical with the red oxidation product of diisoeugenol dimethyl ether which Haworth and Mavin (*J.*, 1931, 1363) had regarded as an anthrone derivative. The hydrindenes (IX) and (IV; R = Me) have been synthesised; both resist dehydrogenation and both give colour reactions resembling those exhibited by diisoeugenol dimethyl ether. The hydrindene (IV; R = Me) is, however, not identical with diisoeugenol dimethyl ether, but the difference may be stereochemical.

THE constitution of diisoeugenol has recently been the subject of eight communications by Müller *et al.* [(i) *Ber.*, 1942, 75, 692; (ii) *ibid.*, p. 891; (iii) *ibid.*, 1943, 76, 855; (iv) *ibid.*, p. 1061; (v) *ibid.*, p. 1119; (vi) *ibid.*, 1944, 77, 6; (vii) *ibid.*, p. 12; (viii) *ibid.*, p. 159] and as conclusions similar to our present views have been reached, it is desirable, in spite of the incomplete nature of our work, to place on record our contributions to this problem.

In 1931, Haworth and Mavin (*J.*, 1931, 1363) suggested that diisoeugenol had structure (I; R = H) instead of the cyclobutane structure (II) proposed by earlier workers. The introduction of this anthracene structure rested very largely on the isolation of 2 : 3 : 6 : 7-tetramethoxyanthraquinone from the products of the chromic acid oxidation of diisoeugenol dimethyl ether, but Szeki (*Annalen*, 1933, 507, 197) and Szeki and Haraszti (*ibid.*, 508, 294), disregarding

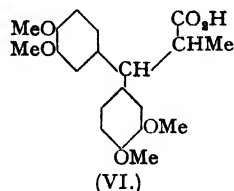

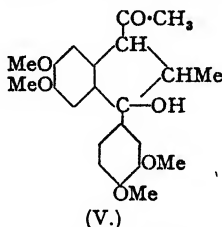

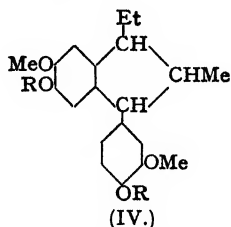

this evidence, adhered to the cyclobutane structure (II). Müller *et al.* [(i) and (ii)] first proposed the lignan structure † (III; R = H) but in later communications they abandoned this in favour of the hydrindene structure (IV; R = H) which resembles the metanethole structure suggested by Baker and Enderby (*J.*, 1940, 1094).

Müller's conclusions depend to a great extent upon the oxidation to *o*-veratroylveratric acid and upon the interpretation of the properties of a hydroxy-ketone obtained as one of the products of oxidation of diisoeugenol dimethyl ether. This substance, formulated as (V) in his later papers, is readily converted into a red anhydro-derivative, which is now regarded as an indene derivative, but for which Haworth and Mavin (*loc. cit.*) had tentatively proposed an anthrone structure. In our opinion Müller's work is inconclusive; the following observations made over a period of years, although equally inconclusive, have led us quite independently to the view that diisoeugenol is best represented by the hydrindene structure (IV; R = H).

* The last communication (*J.*, 1944, 535) of this series was erroneously numbered as Part XIX instead of Part XX.

† Oliverio (*Gazzetta*, 1943, 73, 270) reports that he suggested the lignan formula (III; R = H) for diisoeugenol in 1937.

In 1937, unpublished work with Miss W. Robson, B.Sc., showed that diisoeugenol dimethyl ether resembled 2 : 3 : 6 : 7-tetramethoxy-9 : 10-dihydroanthracene in absorption spectra, both

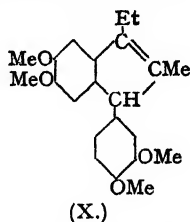

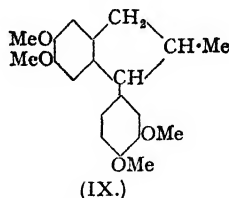

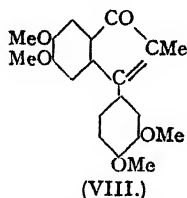

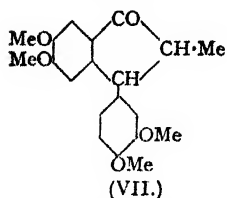

showing maximum absorption at a wave-length of 2850 Å., but structural similarity cannot be inferred, as the veratrole nuclei present in both structures are responsible for the absorption. At this stage, unsuccessful attempts were made to dehydrogenate diisoeugenol dimethyl ether with lead tetra-acetate, palladium black, and selenium and aluminium chloride, and numerous later efforts have been equally unsuccessful. The dihydroanthracene structure (I) can now be discarded, because Müller's observation that an anthracene derivative, and not a dihydroanthracene, is obtained by the condensation of veratrole and propaldehyde, indicates that dihydroanthracenes are characterised by an instability which is not shown by diisoeugenol dimethyl ether. In addition, we have reduced the highly fluorescent 2 : 3 : 6 : 7-tetramethoxy-9 : 10-diethylantracene by means of sodium and amyl alcohol to 2 : 3 : 6 : 7-tetramethoxy-9 : 10-diethyl-9 : 10-dihydroanthracene (I; R = Me), m. p. 148°. Unlike diisoeugenol dimethyl ether, this was readily dehydrogenated with lead tetra-acetate in glacial acetic acid solution to the corresponding anthracene derivative, and when a drop of concentrated nitric acid was added to its acetic acid solution a red coloration with a permanent blue reflex was obtained which differed from the cherry-red test given by diisoeugenol dimethyl ether.

Our failures, mentioned above, to dehydrogenate diisoeugenol dimethyl ether are equally inconsistent with the 1-phenyl-1 : 2 : 3 : 4-tetrahydronaphthalene structure (III); the expected product, dehydroguaiaretic acid dimethyl ether, is sparingly soluble in alcohol or acetic acid, and its isolation from complex selenium dehydrogenation mixtures has previously (J., 1938, 1681) been accomplished without difficulty. Attempts to synthesise the structure (III; R = Me) by the action of methyl-alcoholic hydrogen chloride, glacial acetic, and hydrochloric acid mixtures, 100% formic acid, sulphuric acid of various strengths, acetic and sulphuric acid mixture, or phosphoric oxide in toluene on guaiaretic acid dimethyl ether, have yielded unchanged materials, frequently in high yield but sometimes contaminated with intractable oils. Other routes investigated included: (a) the conversion of isolaricresinol dimethyl ether (J., 1937, 386) into the corresponding 2 : 3-bischloromethyl derivative for subsequent reduction; (b) dehydration and reduction of 4-hydroxy-6 : 7-dimethoxy-1-veratryl-2 : 3-dimethyl-1 : 2 : 3 : 4-tetrahydronaphthalene (J., 1938, 1681); (c) reduction of 6 : 7-dimethoxy-1-veratryl-3-methyl-1 : 2 : 3 : 4-tetrahydronaphthalene-2-carboxylic acid (J., 1938, 811) and the isomeric 2-methyl-1 : 2 : 3 : 4-tetrahydronaphthalene-3-carboxylic acid (*loc. cit.*). These experiments gave either unchanged material or unrecognisable oils, and although these oils may contain diastereoisomeric forms of the structure (III; R = Me), it is unlikely that they contain the highly crystalline diisoeugenol dimethyl ether. In addition, 6 : 7-dimethoxy-1-veratryl-1 : 2 : 3 : 4-tetrahydronaphthalene, synthesised from veratrole and ethyl β-hydroxymethylene-propionate, gave colour reactions differing markedly from those of diisoeugenol dimethyl ether, and it was smoothly dehydrogenated by lead tetra-acetate to 6 : 7-dimethoxy-1-veratryl-naphthalene, m. p. 160° (J., 1935, 636).

These experiments led us to reject the dihydroanthracene and tetrahydronaphthalene structures (I) and (III), respectively, in favour of the hydrindene structure (IV), and synthetical confirmation of the latter has been sought. Condensation of veratrole and ethyl α-hydroxymethylenepropionate yielded ββ-diveratryl-α-methylpropionic acid (VI), m. p. 175°, and the corresponding acid chloride was converted into 5 : 6-dimethoxy-3-veratryl-2-methylhydrindone (VII), m. p. 116°. This cyclic ketone was dehydrogenated by heating with palladium at 250° to 5 : 6-dimethoxy-3-veratryl-2-methyl-1-indone (VIII), m. p. 194–195°, identical with the orange-red ketone which Haworth and Mavin (*loc. cit.*) previously regarded as 2 : 3 : 6 : 7-tetramethoxy-9-ethylantrone. The ketone (VII) was readily reduced by Clemmensen's method to give 5 : 6-dimethoxy-3-veratryl-2-methylhydrindene (IX), m. p. 117°. The ketone (VII) also reacted smoothly with ethylmagnesium iodide to yield the oily indene derivative (X), which combined

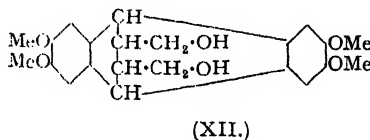

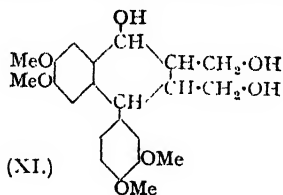

with excess Grignard reagent with the formation of a precipitate and the evolution of ethane. This reaction supports the indene structure (X) and excludes an alternative 1:3-dimethyldi-

hydronaphthalene formula arising from pinacolic change from the intermediate carbinol. The indene derivative (X) was reduced in acetic acid with a very active platonic oxide catalyst to give 5:6-dimethoxy-3-veratryl-2-methyl-1-ethylhydrindene (IV; R = Me), m. p. 105°, depressed to 95–98° by admixture with a specimen of diisoeugenol dimethyl ether, m. p. 105°. The hydrindene (IV; R = Me), like (IX) and diisoeugenol dimethyl ether, resisted dehydrogenation and gave a permanent cherry-red colour with a transient purple reflex when a drop of concentrated nitric acid was added to its solution in glacial acetic acid.

Structure (IV) permits of four racemic modifications. Ciamician and Silber (*Atti R. Accad. Lincei*, 1909, 18, 1216) converted the readily accessible form of diisoeugenol dimethyl ether, m. p. 105°, into an isomer, m. p. 96°, by the action of iodine, and Müller *et al.* (*loc. cit.*) have obtained a third isomer, m. p. 100°, by more indirect methods. These isomeric forms were not available for comparison purposes but the synthetic hydrindene derivative (IV; R = Me), m. p. 105°, is possibly an isomeric modification of diisoeugenol dimethyl ether, although efforts to convert it into a diastereoisomeric form by the action of methyl-alcoholic hydrogen chloride have failed.

The oxidation of diisoeugenol dimethyl ether to 2:3:6:7-tetramethoxyanthraquinone is in no way inconsistent with the hydrindene structure (IV; R = Me). Dreyfuss (*Gazzetta*, 1936, 66, 96) has shown that this anthraquinone, together with *o*-veratroylveratric acid and the lactone of 3:3':4:4'-tetramethoxybenzhydrol-6-carboxylic acid, is obtained by the oxidation of isoolivil dimethyl ether (XI). Structure (XII) is postulated as a possible intermediate stage in the conversion into the anthraquinone, and a similar mechanism could obviously be formulated for the oxidation of the hydrindene (IV; R = Me).

EXPERIMENTAL.

2:3:6:7-Tetramethoxy-9:10-diethyl-9:10-dihydroanthracene (I; R = Me).—2:3:6:7-Tetramethoxy-9:10-diethylanthracene (0.3 g.) (Müller, *loc. cit.*, ii) in boiling amyl alcohol (25 c.c.) was treated with sodium (2 g.). After $\frac{1}{2}$ hour's refluxing, water was added, the amyl alcohol was separated and dried, and the solvent removed under reduced pressure. Ethyl alcohol was added to the residue, and the unreduced anthracene derivative (0.15 g.) was collected and the filtrate concentrated; the 9:10-dihydroanthracene (I; R = Me) crystallised from methyl alcohol in colourless, dense prisms (0.06 g.), m. p. 147–148° (Found: C, 73.7; H, 7.9; OMe, 34.5. $C_{22}H_{24}O_4$ requires C, 74.1; H, 7.7; OMe, 34.8%), which gave the colour reaction described on p. 949.

Diacyl Derivatives of Guaiaretic and Dihydroguaiaretic Acids.—Crude extract (5 g.) of guaiacum resin, fused sodium acetate (5 g.), and acetic anhydride (15 c.c.) were heated on the water-bath for 2 hours. Water was added, and the product was collected and fractionally crystallised from ethyl alcohol. *Diacyl dihydroguaiaretic acid* separated from alcohol in stout irregular prisms, m. p. 112° (Found: C, 69.5; H, 7.1. $C_{24}H_{26}O_6$ requires C, 69.6; H, 7.3%), which gave no colouration with concentrated sulphuric acid. *Diacyl guaiaretic acid* separated from a small bulk of alcohol in slender hexagonal prisms, m. p. 86–87° (Found: C, 69.2; H, 6.8. $C_{24}H_{24}O_6$ requires C, 69.8; H, 6.8%), which gave a deep red colour with concentrated sulphuric acid and absorbed the theoretical amount of hydrogen.

6:7-Dimethoxy-1-veratryl-2-methyl-1:2:3:4-tetrahydronaphthalene-3-carboxylic Acid.—The conversion of the lactone of β -veratroyl- α -veratrylidene-*n*-butyric acid into methyl 6:7-dimethoxy-1-veratryl-2-methylnaphthalene-3-carboxylate (*J.*, 1938, 811) was best effected with methyl-alcoholic hydrogen chloride, saturated at 0°, and the methyl ester has m. p. 198° and not 178° as previously reported. The corresponding acid was reduced in faintly alkaline solution by boiling for 4 hours with 4% sodium amalgam (150 parts), during which time a stream of carbon dioxide was passed through the solution.

Acidification gave 6:7-dimethoxy-1-veratryl-2-methyl-1:2-dihydronaphthalene-3-carboxylic acid, which crystallised from methyl alcohol in clusters of fine needles, m. p. 178—179° (Found: C, 68.4; H, 6.4. $C_{22}H_{24}O_6$ requires C, 68.8; H, 6.3%), rapidly decolorising permanganate in cold alkaline solution. Reduction of this dihydro-acid was effected in acetic acid solution by hydrogen in presence of palladised charcoal; the corresponding tetrahydronaphthalene-3-carboxylic acid separated from methyl alcohol in silky needles, m. p. 162° (Found: C, 68.1; H, 6.9. $C_{22}H_{26}O_6$ requires C, 68.4; H, 6.8%), which were unaffected by cold permanganate. The corresponding acid chloride was not obtained pure, and Rosenmund reduction to the aldehyde was not realised.

4-Keto-6:7-dimethoxy-1-veratryl-1:2:3:4-tetrahydronaphthalene.—A mixture of concentrated sulphuric acid (11 c.c.) and glacial acetic acid (11 c.c.) was gradually added, with ice cooling, to a mixture of ethyl β -hydroxymethylcnepropionate (4 g.), veratrole (10 g.), and glacial acetic acid. After 18 hours, water was added and the product, isolated with chloroform, was hydrolysed by refluxing for 2 hours with 10% methyl-alcoholic potassium hydroxide (35 c.c.). Removal of the solvent and acidification gave the crude acid (9 g.) which was refluxed with excess of thionyl chloride in chloroform. The solvent was evaporated, the residue dissolved in nitrobenzene (50 c.c.), and aluminium chloride (8 g.) added. After 12 hours, dilute sulphuric acid was added, and the nitrobenzene removed in steam. The ketone, isolated with chloroform and washed with dilute sodium hydroxide, was distilled at 0.1 mm. (bath temp. 270°); the distillate (6 g.) crystallised from methyl alcohol in prisms, m. p. 137—138° (Found: C, 69.9; H, 6.5. $C_{20}H_{22}O_5$ requires C, 70.2; H, 6.4%), which gave a 2:4-dinitrophenylhydrazone, m. p. 270° (decomp.).

6:7-Dimethoxy-1-veratryl-1:2:3:4-tetrahydronaphthalene.—The above ketone (1 g.) was reduced by Clemmensen's method, and the product was distilled at 0.01 mm. and crystallised first from aqueous acetone and then from ligroin; clumps of fine needles, m. p. 76° (Found: C, 73.2; H, 7.3. $C_{20}H_{24}O_4$ requires C, 73.2; H, 7.3%), were obtained, which dissolved in concentrated sulphuric acid to give a bright red solution. When nitric acid was added to an acetic acid solution of the tetrahydronaphthalene, a reddish purple colour was obtained which gradually changed through blue and green to orange. Dehydrogenation with lead tetra-acetate in acetic acid solution gave 6:7-dimethoxy-1-veratryl-naphthalene, m. p. 160°.

$\beta\beta$ -Diveratryl- α -methylpropionic Acid (VI).—A mixture of concentrated sulphuric acid (32.5 c.c.) and glacial acetic acid (32.5 c.c.) was added to a cooled solution of ethyl α -hydroxymethylcnepropionate (13 g.) and veratrole (30 g.) in acetic acid (25 c.c.). After 12 hours the oily product, isolated with chloroform, was hydrolysed by refluxing for 2 hours with 10% methyl-alcoholic potassium hydroxide (100 c.c.). The acid (VI) crystallised from ethyl acetate in nodules of needles, m. p. 175° (Found: C, 66.7; H, 6.7; equiv., 362. $C_{20}H_{22}O_6$ requires C, 66.7; H, 6.7%; equiv., 360).

5:6-Dimethoxy-3-veratryl-2-methylhydrindone (VII).—The above acid (VI) (5.5 g.), in chloroform (50 c.c.), and thionyl chloride (3.5 g.) were refluxed for 1 hour, and the solvent removed in a vacuum. Aluminium chloride (5.5 g.) was gradually added with cooling to a solution of the residue in nitrobenzene (50 c.c.) and, after 12 hours, the mixture was decomposed and the nitrobenzene removed in steam. The product, isolated with ether and washed with sodium hydroxide solution, crystallised from methyl alcohol in large prisms (5 g.), m. p. 116° (Found: C, 69.9; H, 6.4. $C_{20}H_{22}O_6$ requires C, 70.1; H, 6.4%), yielding an oxime, which separated from methyl alcohol in long glistening needles, m. p. 149—150° (Found: C, 67.3; H, 6.4. $C_{20}H_{23}O_6N$ requires C, 67.2; H, 6.4%).

5:6-Dimethoxy-3-veratryl-2-methyl-1-indone (VIII).—The hydrindone (VII) (0.5 g.) and palladium black (0.1 g.) were heated for 1 hour at 250°, and the product was extracted with hot alcohol. Concentration of the extract gave orange-red prisms (0.05 g.), m. p. 189—192°, raised by recrystallisation from alcohol to 194—195°, unpressed by admixture with a specimen of the red compound, m. p. 193°, obtained by Haworth and Mavin (*loc. cit.*). The synthetic indone (VIII), and the product obtained by oxidation of diisoeugenol dimethyl ether, both dissolved in concentrated sulphuric acid to deep purple solutions.

5:6-Dimethoxy-3-veratryl-2-methylhydrindene (IX).—The hydrindone (VII) (4 g.) was reduced by Clemmensen's method; the product (3 g.) crystallised from methyl alcohol in long colourless needles, m. p. 117° (Found: C, 73.3; H, 7.4. $C_{20}H_{24}O_4$ requires C, 73.1; H, 7.3%) depressed to 102° when mixed with a specimen of the ketone (VII). The hydrinaene (IX) lacked ketonic properties, dissolved in concentrated sulphuric acid to a yellow solution, and gave the colour reaction described on p. 960. Dehydrogenation with selenium or lead tetra-acetate did not yield recognisable products.

5:6-Dimethoxy-3-veratryl-2-methyl-1-ethylindene (X).—The hydrindone (VII) (5 g.) in benzene (50 c.c.) was gradually added to a solution of ethylmagnesium iodide, prepared from magnesium (1.0 g.) and ethyl iodide (7.5 c.c.) in ether (50 c.c.). After decomposition with ice and ammonium chloride, the product was heated at 180° for $\frac{1}{2}$ hour with an equal weight of potassium hydrogen sulphate. The indene derivative (X), isolated with ether and washed with sodium bicarbonate solution, was obtained as a pale yellow resin, b. p. 195°/0.005 mm. (Found: C, 75.3; H, 7.7. $C_{22}H_{26}O_4$ requires C, 74.6; H, 7.4%), which reacted with ethylmagnesium iodide with formation of a precipitate and the evolution of ethane.

5:6-Dimethoxy-3-veratryl-2-methyl-1-ethylhydrindene (IV; R = H).—The indene derivative (X) (0.5 g.) in glacial acetic acid (10 c.c.) was shaken with hydrogen in the presence of freshly prepared Adams's platonic oxide catalyst (0.05 g.). The theoretical volume of hydrogen was absorbed in $\frac{1}{2}$ hour. After filtration from the catalyst, water was added and the product was isolated with ether, and washed with sodium bicarbonate solution. Removal of the ether left an oil which rapidly solidified and then crystallised from methyl alcohol in elongated prisms, m. p. 105° (Found: C, 74.0; H, 8.1. $C_{22}H_{28}O_4$ requires C, 74.2; H, 7.9%) depressed to 95—98° when mixed with diisoeugenol dimethyl ether.* The

* Note, added 12th October, 1946.—*Chemical Abstracts*, 1946, 40, pp. 5041—5043, which has just been received, contains summaries of two additional papers by Müller and his co-workers, but the original papers (*Ber.*, 1944, 77, 325, 343) are not available. In the second of these papers Müller describes the synthesis, by methods similar to ours, of the hydrindene (IV; R = Me), m. p. 105—106°. No mention of a direct comparison between the synthetic product and diisoeugenol dimethyl ether is included in the abstract, but, contrary to our observations, the title of the paper implies that identity is claimed.—R. D. H.

product, which did not decolorise permanganate in hot or cold acetone solution, was recovered after refluxing with methyl-alcoholic hydrogen chloride for $1\frac{1}{2}$ hours. It dissolved in concentrated sulphuric acid to an orange solution with a green fluorescence, and when a drop of concentrated nitric acid was added to its solution in glacial acetic acid, a red colouration with a purple reflex was obtained, which gradually changed to a pure cherry-red colour. Dehydrogenation with lead tetra-acetate in acetic acid or selenium at 280° yielded either unchanged material or unrecognisable tars.

Our thanks are due to the West Riding Education Committee for a Scholarship.

179. *Substituted Benzilic Acids and Benzophenones.*

By A. H. FORD-MOORE.

A method for preparing substituted benzilic acids is described. Since these acids can be oxidised smoothly to the corresponding benzophenone, a number of the latter compounds which cannot be prepared by the Friedel-Crafts method are made available. The ethochlorides of the dimethylaminoethyl esters of some of these acids have been prepared, and their mydriatic activity measured against atropine sulphate.

IN a recent paper (Ford-Moore and Ing, this vol., p. 55), a number of synthetic mydriatics was described. One of these compounds, benzilyloxyethyl dimethylethylammonium chloride (I; $R_1 = R_2 = \text{Ph}$), for which the name "Lachesine" has been suggested, was found to have a mydriatic activity equal to that of atropine sulphate. Certain other compounds in which

substituents were introduced into the benzene nuclei of (I) were also prepared but were not then described. The result of this substitution was to reduce greatly, or even to abolish, the mydriatic activity of the compound.

This paper describes the preparation of the substituted benzilic acids used. These are mainly symmetrically disubstituted acids, but two monosubstituted acids were prepared and are included.

Two methods are available for the preparation of benzilic acids; oxidation of a benzoin with bromate and alkali, and treatment of a benzil with aqueous-alcoholic potash. Since the benzoin acids of substituted benzaldehydes could not usually be made to solidify, whereas the corresponding benzils were highly crystalline, the second method was adopted. Most of the substituted benzils are, however, so sparingly soluble in aqueous-alcoholic potash that conversion into the benzilic acid either takes place very slowly or not at all. Since these acids decarboxylate somewhat readily to give the benzhydrol, it is not safe to prolong the potash treatment for more than ten minutes.

Rearrangement of the substituted benzils can be brought about very readily by heating for ten minutes or less with a 20% solution of potassium hydroxide in hot *n*-butanol. In certain cases, the potassium salt of the acid separates out and only requires to be filtered off, washed with a little ether, dissolved in water, and acidified. Where the potassium salt is soluble in butanol, it can be extracted with water, a little ether being added to facilitate separation into two layers.

When the aqueous solution of the potassium salt is acidified, there is a strong tendency for the acid to separate in an obstinately gummy condition. Crystallisation can usually be induced by adding a small amount of a suitable solvent (benzene or petrol) and scratching. Seed, if available, will greatly hasten solidification.

The substituted benzilic acids are oxidised smoothly and in good yield by chromic anhydride in acetic acid to the corresponding benzophenone (cf. Jena, *Annalen*, 1870, **155**, 83). A number of the latter compounds, which cannot be prepared by the usual Friedel-Crafts method, are therefore made available.

Two monosubstituted benzilic acids, *viz.*, phenyl- α -naphthyl- and phenyl- β -naphthylglycollic acids, were described by Ford-Moore and Ing (*loc. cit.*). The same method as had been used for preparing these acids, *viz.*, *via* the deoxybenzoin, the isonitroso-derivative, and the benzil, was adopted for preparing phenyl-*p*-tolylglycollic acid and 4-chlorobenzilic acid. The monosubstituted benzils, obtained in the penultimate step, are much more soluble in aqueous-alcoholic potash than are the disubstituted benzils, and no difficulty was experienced in converting them into the corresponding benzilic acids by means of this reagent.

Mydriatics from Substituted Benzoic Acids.—These compounds were made by the same method as was used for preparing (I), *i.e.*, treatment of β -chloroethyltrimethylammonium chloride with the potassium salt of the acid in ethanol (Ford-Moore and Ing, *loc. cit.*). The compounds so obtained were useless as mydriatics. Nevertheless, they serve to illustrate the striking decrease in mydriatic activity on introducing substituents into the benzilyloxy-moiety of (I).

EXPERIMENTAL.

2:2'-Dimethoxybenzoic Acid.—*o*-Anisil (2:2'-dimethoxybenzil) (35 g.) was added to a solution of potassium hydroxide (17 g.) in boiling *n*-butanol (90 c.c.), and the mixture refluxed for 10 minutes. After cooling, the mixture was extracted three times with 100-c.c. portions of water, some ether being added to facilitate separation into two layers. The combined aqueous extracts were extracted once with ether (50 c.c.) to remove any dissolved butanol, freed from ether with a current of air, and acidified to Congo-red with hydrochloric acid. The *dimethoxybenzoic acid* was precipitated as a sticky mass which, if it did not solidify rapidly, could be made to do so by decanting the water, adding about 20 c.c. of benzene, and scratching. The yield was 33 g., m. p. 160°, after crystallising from methanol (Found: C, 66.4; H, 5.5. $C_{10}H_{10}O_5$ requires C, 66.6; H, 5.6%).

Piperonic (3:4:3':4'-bismethylenedioxybenzoic) acid, m. p. 139° from ethyl acetate (Found: C, 61.0; H, 4.0. $C_{16}H_{12}O_8$ requires C, 60.8; H, 3.8%), 4:4'-dimethoxybenzoic acid, m. p. 171° (decomp.), from methanol (Böslér, *Ber.*, 1881, 14, 327, gives 164°) (Found: C, 66.35; H, 5.7. Calc. for $C_{16}H_{12}O_5$: C, 66.6; H, 5.6%), and 3:3'-dichlorobenzoic acid, m. p. 110° from benzene-petrol (Klimont, Diss., Heidelberg, 1891, gives 114–115°) (Found: C, 56.4; H, 3.4. Calc. for $C_{14}H_8O_2Cl_2$: C, 56.55; H, 3.35%), were prepared similarly. The last compound was rather reluctant to crystallise but could be made to do so by adding petrol (b. p. 40–60°) and scratching.

5:5'-Dibromo-2:2'-dimethoxybenzoic Acid.—The corresponding benzil (cf. Kuhn, Birkofer, and Möller, *Ber.*, 1943, 76, 903), m. p. 231° (20 g.), was treated with potash-butanol (7 g.; 40 c.c.) as for the dimethoxybenzil. On cooling, the potassium salt of the acid separated. It was filtered off, washed free from butanol with ether, and freed from ether by standing in the air for a short time. It was dissolved in water and acidified with hydrochloric acid; yield, 18 g., m. p. 181°, after crystallising from methanol (Found: C, 42.9; H, 3.25. $C_{16}H_{10}O_5Br_2$ requires C, 43.1; H, 3.15%).

Veratric (3:3':4:4'-tetramethoxybenzoic) acid was prepared similarly; it melted at 131° after crystallising from ethyl acetate (Vanzetti, *Atti R. Accad. Lincei*, 1936, 24, II, 468, gives ca. 68°) (Found: C, 61.9; H, 5.8. Calc. for $C_{18}H_{20}O_7$: C, 62.05; H, 5.8%).

These acids show a tendency to undergo partial decarboxylation. The benzhydrol so formed is difficult to remove by recrystallisation. Purification is readily effected by dissolution in dilute sodium carbonate solution, filtration (carbon), acidification, and crystallisation from a suitable solvent.

2:2'-Dimethoxybenzophenone.—2:2'-Dimethoxybenzoic acid (21.5 g.) was dissolved in boiling glacial acetic acid (100 c.c.) and oxidised by gradual addition of powdered chromic anhydride (5.5 g.). The reaction proceeded without the application of heat. When it was complete (10 mins.), the mixture was poured into water. The ketone, which rapidly solidified, was filtered off and washed free from chromium salts successively with water, dilute sodium carbonate, and water; yield 15 g., m. p. 103°, after crystallising from methanol (Graebe and Feer, *Ber.*, 1896, 19, 2610, give 104°; Richter, *J. pr. Chem.*, 1883, 28, 287, gives 98°).

3:3':4:4'-Tetramethoxybenzophenone, m. p. 147° from ethanol (Kostanecki and Tambor, *Ber.*, 1906, 39, 4027, give 145°), **5:5'-dibromo-2:2'-dimethoxybenzophenone**, m. p. 128° (Diels and Rosenmund, *ibid.*, p. 2362, give 123°), and **3:3'-dichlorobenzoic acid**, m. p. 123–124° from methanol (Found: C, 62.3; H, 3.5. $C_{18}H_{14}OCl_2$ requires C, 62.2; H, 3.2%), were prepared similarly from the appropriate benzoic acid.

4-Chlorobenzoic acid and **phenyl-*p*-tolylglycollic acid** were prepared by the method described in the text. The former melted at 131° (Found: C, 64.1; H, 4.45. $C_{14}H_{11}O_2Cl$ requires C, 64.0; H, 4.2%), and the latter at 132° (Weiss, *Monatsh.*, 1919, 40, 396, gives 131–133°), both having been crystallised from benzene.

Colour with Concentrated Sulphuric Acid.—The benzoic acids described above gave the following colours with concentrated sulphuric acid: 2:2'-dimethoxy-, brilliant greenish-blue; 4:4'-dimethoxy-, brilliant bluish-green; 3:3':4:4'-tetramethoxy-, brilliant bluish-green; 3:4:3':4'-bis-methylenedioxy-, dark greenish-brown; 5:5'-dibromo-2:2'-dimethoxy-, brilliant bluish-green; 3:3'-dichloro-, violet; 4-chloro-, orange-red; phenyl-*p*-tolylglycollic acid, dark reddish-brown.

180. Some Heterocyclic Methylene Bases and their Anilomethyl Derivatives.

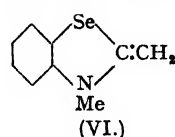

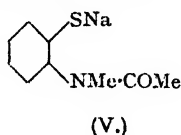

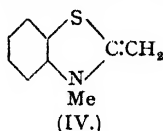

By FRANCES M. HAMER, RUSSELL J. RATHBONE, and BARBARA S. WINTON.

Some heterocyclic methylene bases, not hitherto described in the solid state, have been prepared by the action of alkali on quaternary salts at a low temperature, foregoing extraction. Some new anilomethyl derivatives of bases of this type were prepared by the action of alkali on quaternary salts having a 2- β -anilinoethyl group. They include anilomethyl derivatives of methylene bases derived from a benzoxazolium salt and a thiazolium salt, although the unsubstituted bases of these series are not precipitable. A practical method of preparation of ethylisoformanilide is described. These compounds were made as starting materials for the synthesis of neocyanine and related dyes.

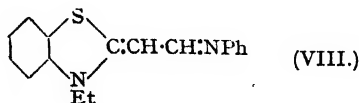

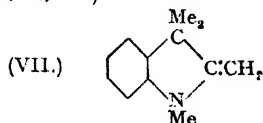

By treating quinaldine ethiodide with aqueous alkali, Vongerichten and Höfchen obtained an oil, which they regarded as the methylene base (I); they showed that it reacted with quinoline ethiodide to give a cyanine dye (*Ber.*, 1908, **41**, 3054). König expressed the opinion that bases such as (I) and (II) play an essential part in the formation of cyanines (*Ber.*, 1922, **55**, 3293).

Mills and Raper, considering that the oils formed by the action of alkali on quinaldine alkiodides could not be obtained analytically pure, examined the crystalline product (III) (*J.*, 1925, **127**, 2466); this led Rosenhauer (with Hoffmann and Unger) to record his preparation of the methyl analogue of (I) (*Ber.*, 1926, **59**, 946). From 2-methylbenzthiazole methoperchlorate König and Meier obtained (IV) (*J. pr. Chem.*, 1925, **109**, 324). Clark studied the conditions favouring formation of this base or of the thiophenol salt (V) and similarly, from 2-methylbenzselazole methiodide, obtained two products, one of which was (VI) (*J.*, 1928, **2313**).

All these methylene bases were prepared from known quaternary salts but (VII), the first to be known, was made by direct synthesis (Fischer and Steche, *Annalen*, 1887, **242**, 348; Brunner, *Ber.*, 1898, **31**, 612).

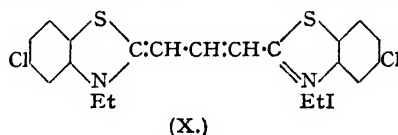

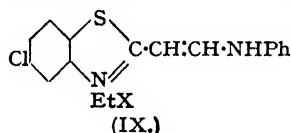

In our work on the synthesis of neocyanines, the methylene bases are of interest as starting points. In the patent literature Brooker and White have described anilomethyl derivatives, e.g. (VIII), of some such bases (Kodak Ltd., B.P. 561,172/1940) and these also have the same interest. The present paper deals with methylene bases and their anilomethyl derivatives.

Success in preparing methylene bases, hitherto inaccessible in the solid state, was achieved by precipitating them at a low temperature, by the action of alkali on a solution of the quaternary salt, and foregoing extraction with a solvent. We began by making the ethyl analogue of (IV), choosing a readily soluble quaternary salt of 2-methylbenzthiazole; it was

liable to manifest its instability by decomposing during drying but we succeeded in recrystallising both it and its 5-chloro-derivative. Its 6:7-benz-derivative showed a greater tendency to decompose and was not recrystallised; in preparing this and the ethyl analogue of (VI), aqueous suspensions of the quaternary salts were performed in place of concentrated solutions. From concentrated solutions of alko-*p*-toluenesulphonates, (I) and (II) were prepared. Colour changes, which indicate reactivity and tendency to cyanine dye formation on the part of the bases, occurred before they could be filtered off but did not proceed progressively after they had been dried.

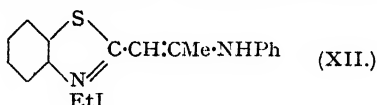

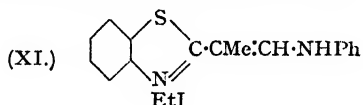

Quaternary salts of certain other heterocyclic bases that are of interest in cyanine dye condensations do not give precipitates of methylene bases when their cold solutions are treated with alkali; such are salts of 2-methylbenzoxazole, 2:4-dimethylthiazole, 2-methylthiazoline, and α -picoline. In the different series of salts it appears that there is more than one cause for this. In the pyridine series, the base may possibly be too soluble and more complex methylene bases of this series have in fact been prepared (Mumm and Hingst, *Ber.*, 1923, 56, 2301). In the benzoxazole series, it is due to fission of the ring, as recognised by König and Meier (*J. pr. Chem.*, 1925, 109, 324).

In preparing the anilomethyl derivative (VIII) of the ethyl analogue of (IV) from 2- β -anilinoethylbenzthiazole ethiodide, the method of the patent (Kodak Ltd., B.P. 561,172/1940) was adopted with some modification. In preparing 5-chloro-2- β -anilinoethylbenzthiazole ethiodide (IX; X = I), in order to make the 5-chloro-analogue of (VIII), the salt was accompanied by so much *thiacarbocyanine* (X) as by-product that we were forced, in order to get rid of the dye, first to isolate the pure 5-chloro-analogue of (VIII), from which we prepared the pure *ethochloride* (IX; X = Cl), and ultimately from that the pure *ethiodide* (IX; X = I). We prepared the 6-nitro-derivative of (VIII), starting from the product of nitration of 2-methylbenzthiazole

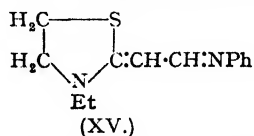

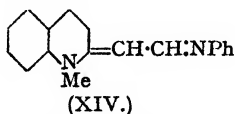

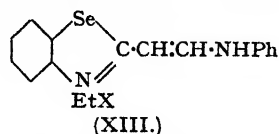

(Browning, Cohen, Ellingworth, and Gulbransen, *Proc. Roy. Soc.*, 1931, B, 108, 119; for orientation of the nitration product see Brooker, Keyes, and Williams, *J. Amer. Chem. Soc.*, 1942, 64, 199). The 6-nitro-2-methylbenzthiazole was converted into its *metho-p-toluenesulphonate*; this was condensed with ethylisoformanilide (cf. Knott, *J.*, 1946, 120), and the resultant salt treated with alkali to give the desired base.

To synthesise the α -methyl derivative of (VIII), 2-ethylbenzthiazole, prepared by two hitherto unpublished methods, was converted into its *etho-p-toluenesulphonate* and this was condensed with diphenylformamidine, or better with ethylisoformanilide, and the product treated with

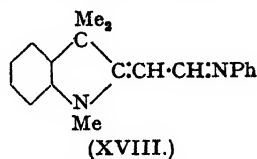

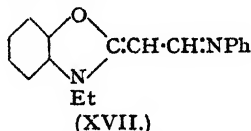

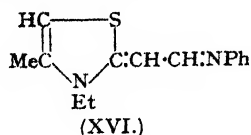

potassium iodide to give (XI), whence the base was liberated by the action of alkali. We also prepared the β -methyl derivative of (VIII) by the action of alkali on the quaternary salt (XII).

In the preparation of the selenium analogue of (VIII), from the quaternary salt (XIII; X = I), the product refused to solidify, but after treatment with hydrochloric acid to give the *ethochloride* (XIII; X = Cl) it was possible to obtain the solid base by the action of alkali. In the quinoline series we prepared (XIV), the ethyl analogue of which has been described (Kodak Ltd., B.P. 561,172/1940). Particularly interesting is the record in the patent that the anilomethyl derivative of a methylene base of the thiazoline series was prepared, since the

unsubstituted methylene base of this series is one of those not precipitable by the action of alkali on the quaternary salt. We were also able to prepare the corresponding ethyl analogue (XV), by applying different conditions, and the anilomethyl derivatives, (XVI) and (XVII), of

methylene bases of a thiazole series and of the benzoxazole series, respectively, where again the parent unsubstituted bases have not been described.

To obtain the *anilomethyl* derivative (XVIII) of the methylene base (VII), 2- β -anilino-3:3-dimethylindolenine methiodide was acted on, in benzene suspension, by aqueous alkali. The quaternary salt was originally prepared either by hydrolysing the corresponding acetanilidovinyl compound or else by heating 1:3:3-trimethylindolenine methiodide with diphenylformamidine (I.C.I. Ltd., Piggott, and Rodd, B.P. 344,409/1929), but we used ethylisoformanilide instead of diphenylformamidine.

Ethylisoformanilide was required for the present work and also for our synthesis of neocyanine, so that its large-scale production became a matter of interest. Claisen's methods for preparing it were to condense ethyl orthoformate (1) with aniline, (2) with diphenylformamidine, or (3) with formanilide in the presence of aniline hydrochloride (*Annalen*, 1895, 287, 362). Monier-Williams (*J.*, 1906, 89, 273) preferred to use the method of Comstock and Kleeburg (*Amer. Chem. J.*, 1890, 12, 497) and treated dry silver isoformanilide with ethyl iodide in absolute ether. This last did not seem practicable on a large scale and we worked out a modification of Claisen's first method, including aniline hydrochloride in order to inhibit the formation of carbylamine.

EXPERIMENTAL.

3-Ethyl-2-methylenebenzthiazoline.—2-Methylbenzthiazole etho-*p*-toluenesulphonate (50 g.; 1 mol.) was dissolved in water (70 c.c.). The solution was cooled with ice and stirred during the addition of a cold solution of sodium hydroxide (6.3 g.; 1.1 mols.) in water (20 c.c.). The white solid was filtered off, and well washed with ice-cold water. It was dried in a vacuum desiccator and obtained in 83% yield (21 g.), being pale pink at this stage. Once dry, it kept for weeks without further deterioration but preparations on a larger scale were apt to decompose during drying. On recrystallisation from light petroleum (b. p. 80–100°; 20 c.c. per g.), the yield was 62%. After drying in a vacuum desiccator, it was analysed by the method of Carius, which method was used throughout this work (Found: S, 18.15. $C_{10}H_{11}NS$ requires S, 18.1%; m. p. 126–128° (decomp.)).

5-Chloro-3-ethyl-2-methylenebenzthiazoline.—Similarly, 5-chloro-2-methylbenzthiazole etho-*p*-toluenesulphonate gave the base in 87% yield; on recrystallisation from light petroleum (b. p. 80–100°; 275 c.c. per g.), it fell to 57% (Found, after drying in a vacuum desiccator: Cl, 16.45; S, 15.1. $C_{10}H_{10}NClS$ requires Cl, 16.75; S, 15.15%). The chalky white solid had m. p. 178–180° (decomp.).

3-Ethyl-2-methylene-6:7-benzbenzthiazoline.—2-Methyl-6:7-benzbenzthiazole etho-*p*-toluenesulphonate (30 g.; 1 mol.) was ground to a paste with ice-cold water (30 c.c.), and an ice-cold solution of sodium hydroxide (3.3 g.; 1.1 mols.) in water (10 c.c.) was added. The sulphur-yellow solid was thoroughly washed with ice-cold water and was obtained in 68% yield (11.65 g.) (Found: S, 14.55. $C_{16}H_{13}NS$ requires S, 14.1%); it was liable to change overnight to a sticky mass at the early stages of drying but, once past those early stages, could be kept unchanged in a vacuum desiccator. When heated, shrinking and darkening began about 40° and it was brown and sticky by 50°; gradual melting and decomposition occurred, and by 90° it was a brown liquid.

3-Ethyl-2-methylenebenzthiazoline.—2-Methylbenzthiazole ethiodide when similarly treated gave a 76% yield of base. Selenium was determined as silver selenite (Becker and Meyer, *Ber.*, 1904, 37, 2550) (Found: Se, 35.45. $C_{10}H_{11}NSe$ requires Se, 35.3%). The yellowish-brown powder softened from 70° and decomposed at about 120°. One specimen, which had been kept for several days in a vacuum desiccator without change, became sticky and dark overnight, although the vacuum had been maintained.

1-Ethyl-2-methylene-1:2-dihydroquinoline (I).—Quinaldine etho-*p*-toluenesulphonate (34.33 g.; 1 mol.), dissolved in ice-cold water (30 c.c.), was treated with ice-cold aqueous sodium hydroxide solution (4.4 g., 1.1 mols., in 11 c.c.). The buff precipitate was filtered off and thoroughly washed with ice-cold water. After drying in a vacuum desiccator, it was obtained in 78% yield (13.37 g.), and was then brick-red (Found: N, 7.95. $C_{15}H_{13}N$ requires N, 8.2%); m. p. 79° (decomp.) with previous softening. A sample which had been kept in a vacuum desiccator for a fortnight appeared to be unchanged.

1-Ethyl-4-methylene-1:4-dihydroquinoline (II).—Lepidine (14.31 g.; 1 mol.) and ethyl *p*-toluenesulphonate (20.02 g.; 1 mol.) were heated together in an oil-bath at 155–160° for 3 hours. A solution of the viscous salt in water (32 c.c.) was extracted with ether, then treated ice-cold with a solution of sodium hydroxide (4.4 g.; 1.1 mols.) in water (11 c.c.). The precipitate was filtered off and well washed with ice-cold water. The filtrate became deep blue. After drying in a vacuum desiccator, the yield of pale blue solid was 73% (12.55 g.) (Found: N, 8.2. $C_{12}H_{13}N$ requires N, 8.2%). It had no definite m. p. On heating, shrinking began at 59°; in one case, with slow heating, it was black and molten by 80°, whilst in another, violent frothing occurred between 95° and 108°.

3-Ethyl-2-aniloethylidenbenzthiazoline (VIII).—The published method (Kodak Ltd., B.P. 561,172/1940) was varied in that the suspension of 2- β -anilino-3:3-dimethylbenzthiazole ethiodide (103 g.; 1 mol.) in acetone (940 c.c.) was shaken with a solution of sodium hydroxide (31 g.; 3 mols.) in water (75 c.c.), instead of

being stirred mechanically. In one instance solution occurred, but in another, very much more acetone (11.4 l.) had to be added, this indicating the conversion of a less stable into a more stable form. The acetone extracts were filtered, with removal of bis-2-(3-ethylbenzthiazole)trimethincyanine iodide (5.81 g.), which was recrystallised from methyl alcohol (75 c.c. per g.; 2.7 g. obtained) and dried in a vacuum at 60–80°, which conditions of drying were used throughout this work, except where otherwise stated (Found: I, 25.95. Calc. for $C_{21}H_{18}N_2IS_2$: I, 25.8%). On pouring the acetone filtrate into its own volume of water, the base was precipitated in 70% yield (49 g.). Two recrystallisations from light petroleum (b. p. 80–100°; 100 c.c. per g.) reduced the yield to 43% (Found, after drying in a vacuum desiccator: S, 11.25. Calc. for $C_{21}H_{18}N_2S$: S, 11.45%). The yellow solid had m. p. 79°, whereas the m. p. quoted in the patent is 98–99° (decomp.). The absorption maximum of a methyl-alcoholic solution containing ammonia was at 3935 Å. and of one containing sulphuric acid at 4175 Å.

5-Chloro-3-ethyl-2-aniloethylidenbenzthiazoline.—5-Chloro-2-methylbenzthiazole ethiodide (20 g.; 1 mol.) and ethylisoformanilide (7 g.; 1 mol.) were heated together with stirring at 140–150° for 1 hour. The product was boiled with spirit (300 c.c.), and the crystals were filtered off after cooling (22 g. obtained). An attempt to separate the quaternary salt from the dye by-product by boiling out five times with spirit (2×100 c.c., 2×150 c.c., 250 c.c.) left a dye residue (5.69 g.), and a 36% yield (9.43 g.) of impure salt crystallised from the extracts. The dye was further boiled out twice with methyl alcohol (50 c.c., 100 c.c.) and the residue (4.96 g.) suspended in acetone (38 c.c.) and shaken with a solution of sodium hydroxide (1.35 g.) in water (5 c.c.), with the object of converting any contaminating salt into base. After two more acetone extractions, the residual dye was well washed with water (3.46 g. obtained) and recrystallised from methyl alcohol (1590 c.c.) (2.81 g. obtained) (Found: $2Cl + I$, 35.45. $C_{21}H_{18}N_2Cl_2IS_2$ requires $2Cl + I$, 35.25%). The blue needles of bis-2-(5-chloro-3-ethylbenzthiazole)trimethincyanine iodide (X) did not melt below 270°. The absorption maximum was at 5625 Å. It sensitised a gelatino-bromide photographic emulsion from 5200 to 6200 Å., with a maximum at 6000 Å. The impure quaternary salt (9.43 g.; 1 mol.) was suspended in acetone (70 c.c.), and the ice-cold solution shaken with one of sodium hydroxide (2.56 g.; 3 mols.) in water (10 c.c.). The acetone extract was filtered and the aqueous part further extracted with acetone, dye by-product being left undissolved. The extracts were precipitated with thrice their volume of water and the resultant solid was obtained in 83% yield (5.57 g.). After recrystallisation from methyl alcohol (335 c.c.) the yield was 70% (Found: Cl , 11.45. $C_{21}H_{18}N_2ClIS$ requires Cl , 11.3%). The yellowish-green powder had m. p. 138°. The absorption maximum of a methyl-alcoholic solution containing pyridine was at 4075 Å. and of one containing sulphuric acid at 4205 Å. The dye sensitised a chloride emulsion to 4900 Å. with the maximum at 4600 Å.

5-Chloro-2-β-anilinovinylbenzthiazole Ethochloride (IX; X = Cl).—5-Chloro-3-ethyl-2-aniloethylidenbenzthiazoline (6.64 g.) was warmed with spirit (13 c.c.), and the suspension treated with concentrated hydrochloric acid (7 c.c.). The crystals which separated on cooling (7.49 g.) were recrystallised from methyl alcohol (60 c.c.) and obtained in 86% yield (6.36 g.) (Found: Cl , 20.2. $C_{21}H_{18}N_2Cl_2S$ requires Cl , 20.2%). The bright yellow powder became orange at 100°, was brown by 200°, and melted at 214–215° (decomp.).

5-Chloro-2-β-anilinovinylbenzthiazole Ethiodide (IX; X = I).—The ethochloride (IX; X = Cl) (0.45 g.; 1 mol.) was dissolved in hot spirit (15 c.c.) and added to a hot solution of potassium iodide (16.6 g.; 10 mols.) in water (30 c.c.). The crude salt (0.47 g.) was recrystallised from methyl alcohol (47 c.c. per g.) and obtained in 58% yield (0.33 g.) (Found: $Cl + I$, 36.8. $C_{21}H_{18}N_2ClIS$ requires $Cl + I$, 36.7%). The dark orange crystals had m. p. 241–244° (decomp.).

6-Nitro-2-methylbenzthiazole Metho-p-toluenesulphonate.—6-Nitro-2-methylbenzthiazole (2.77 g.; 1 mol.) and methyl p-toluenesulphonate (2.66 g.; 1 mol.) were heated together at 130° for 1 hour, and the product was ground with absolute ether (5.16 g. obtained; 95%). After recrystallisation from absolute ethyl alcohol (10 c.c.), the yield was 88% (4.77 g.) (Found: S, 16.8. $C_{21}H_{16}O_4N_2S_2$ requires S, 16.85%). The cream-coloured crystals had m. p. 194–195° (decomp.).

6-Nitro-2-β-anilinovinylbenzthiazole Metho-p-toluenesulphonate.—The foregoing metho-p-toluenesulphonate (19 g.; 1 mol.) and ethylisoformanilide (9 g.; 1.2 mols.) were heated and stirred together at 130–140°. Fusion occurred, then vigorous reaction followed by solidification. Heating was continued for $\frac{1}{2}$ hour. A suspension of the solid in spirit (50 c.c.) was poured into warm water. The product, after being washed with water and with acetone (18 g. obtained), was recrystallised from methyl alcohol (200 c.c. per g.), the yield falling from 75% to 23% (Found: S, 13.45. $C_{23}H_{21}O_4N_3S_2$ requires S, 13.25%). The green crystals had m. p. 255°.

6-Nitro-3-methyl-2-aniloethylidenbenzthiazoline.—The preceding compound (9.66 g.; 1 mol.), acetone (300 c.c.), and 20% sodium hydroxide solution (20 c.c.; 5 mols.) were warmed together on the steam-bath, then shaken vigorously for several minutes. The filtered acetone layer was concentrated to one-third, and poured into ice and water (500 c.c.), coagulation being assisted by addition of ammonium chloride. The washed product (4.83 g.; 78%) was purified by dissolving in benzene (10 c.c. per g.), filtering, and precipitating with an equal volume of light petroleum (b. p. 80–100°); yield, 63% (Found: S, 10.45. $C_{23}H_{21}O_4N_3S$ requires S, 10.3%). The brick-red crystals had m. p. 144° (decomp.) and desensitised strongly. The broad absorption curve of a methyl-alcoholic solution containing ammonia had its maximum at 3850 Å.

2-Ethylbenzthiazole.—This was originally prepared by heating o-aminothiophenol in a sealed tube with propionyl chloride, being characterised as its platinichloride (Hofmann, *Ber.*, 1880, **13**, 8). According to our first method, o-aminothiophenol hydrochloride (80.6 g.; 1 mol.) was treated with propionic anhydride (69.5 c.c.; 1.1 mols.) and with zinc dust (11.2 g.). The reaction was started by warming; after it had subsided, the mixture was heated on the steam-bath for 2 hours, and then made alkaline with sodium hydroxide and steam-distilled; the oil was extracted with chloroform, and the extract dried (Na_2SO_4). After removal of the solvent, the residue was distilled in a vacuum and obtained in 52% yield, b. p. 127–131°/6 mm. (Found: S, 19.8. Calc. for C_8H_9NS : S, 19.65%). Our second method consisted in preparing o-aminothiophenol from o-chloronitrobenzene (cf. I. G. Farbenind. A.-G., F.P. 669,921/1929; Société Anonyme des Matières Colorantes, et Produits Chimiques de Saint-

Denis, F.P. 714,682/1930) and effecting the ring closure to 2-ethylbenzthiazole by means of propionic anhydride. *o*-Chloronitrobenzene (100 g.; 1 mol.), crystalline sodium sulphide (400 g.; 2.63 mols.), and water (400 c.c.) were stirred together, being warmed to start the reaction; after its vigour had abated, heating on the steam-bath and stirring were continued for 4 hours. The mixture was steam-distilled to remove *o*-chloroaniline, formed as a by-product (26 g.; 32%), then it was cooled, treated with a solution of propionic anhydride (83 g.; 1 mol.) in propionic acid (156 g.; 3.3 mols.), and heated under reflux for an hour on the steam-bath. It was cooled, made alkaline and extracted with ether. The extract was dried (Na_2SO_4), the solvent removed, and the residue distilled under a vacuum. After a second vacuum distillation the yield was 34% (35 g.), b. p. 112–114°/5 mm. (Found: S, 19.9%). The preparation according to the first method was carried out by Miss E. M. Wilson, and that according to the second by Mr. J. Fraser.

2-Ethylbenzthiazole Etho-*p*-toluenesulphonate.—2-Ethylbenzthiazole (4.08 g.; 1 mol.) and ethyl *p*-toluenesulphonate (5 g.; 1 mol.) were heated together at 140–150° for 2½ hours. The solidified melt was ground and washed with acetone, being obtained in 84% yield (7.55 g.) (Found: S, 17.8. $\text{C}_{18}\text{H}_{21}\text{O}_2\text{NS}_2$ requires S, 17.65%). The pale pink solid melted at 138°.

2-(β -Anilino- α -methylvinyl)benzthiazole Ethiodide (XI).—The preceding compound (5 g.; 1 mol.) and ethylisoformanilide (2.3 g.; 1.1 mols.) were heated together at 120–140°, vigorous reaction then occurring. Heating was continued for ½ hour, and the red liquid was dissolved in spirit (7 c.c.) and treated with a hot solution of potassium iodide (8.26 g.; 4 mols.) in water (7 c.c.). The iodide crystallised and, after being washed, was obtained in 72% yield (4.3 g.), decreased on recrystallisation from ethyl alcohol (50 c.c. per g.) to 50% (Found: I, 30.1. $\text{C}_{18}\text{H}_{19}\text{N}_2\text{IS}$ requires I, 30.05%). The dull red crystals melted at 212° (decomp.).

When a similar preparation was carried out with diphenylformamidine instead of ethylisoformanilide, the yield of crude washed product was only 24%. Neither diphenylformamidine nor ethylisoformanilide gave a positive result when the starting point was 2-ethylbenzthiazole ethiodide instead of the etho-*p*-toluenesulphonate.

3-Ethyl-2-aniloisopropylidenebenzthiazoline.—2-(β -Anilino- α -methylvinyl)benzthiazole ethiodide (5.44 g.; 1 mol.), 20% sodium hydroxide solution (12 c.c.; 5 mols.), and acetone (150 c.c.) were stirred together and warmed on the water-bath, then shaken in a separating funnel. The filtered acetone layer was poured into ice-water. The aqueous liquid was decanted from the sticky solid, which on crystallisation from light petroleum (b. p. 80–100°; 75 c.c.) gave a 41% yield (1.57 g.) of yellow crystals, m. p. 92° (decomp.) (Found after drying in a vacuum at 50–60°: S, 10.85. $\text{C}_{18}\text{H}_{19}\text{N}_2\text{S}$ requires S, 10.9%). The absorption maximum of a methyl-alcoholic solution containing ammonia was at 4005 Å. The compound sensitised a chloride emulsion fairly strongly with its maximum at 4550 Å., sensitisation extending to 4850 Å.

2-(β -Anilino- β -methylvinyl)benzthiazole Ethiodide (XII).—The steps in the following synthesis of the salt required as starting point were carried out according to directions supplied by Dr. L. G. S. Brooker: 2-methylbenzthiazole etho-*p*-toluenesulphonate was converted successively into 3-ethyl-2-acetylmethylenebenzthiazoline (Kodak Ltd., B.P. 466,269/1935), 2- β -chloropropenylbenzthiazole ethochloride (*idem*, B.P. 533,425/1939), 3-ethyl-2-thioacetylbenzthiazoline (*idem*, B.P. 546,705/1941), and 2-(β -methylthiopropenyl)benzthiazole etho-*p*-toluenesulphonate (*idem*, B.P. 538,857/1941). This last salt (66.1 g.; 1 mol.), aniline (19.7 g.; 1.25 mols.), and absolute alcohol (170 c.c.) were boiled together under reflux for 30 minutes. The yellowish-brown solution was poured into a hot solution of potassium iodide (56 g.; 2 mols.) in water (100 c.c.). The iodide was obtained in 84% yield (60.0 g.). On recrystallising twice from spirit (15 c.c. per g.), the yield dropped to 69% (Found: I, 30.25. $\text{C}_{18}\text{H}_{19}\text{N}_2\text{IS}$ requires I, 30.05%). The bright yellow crystals had m. p. 203° (decomp.).

3-Ethyl-2- β -anilopropylidenebenzthiazoline.—2-(β -Anilino- β -methylvinyl)benzthiazole ethiodide (8.44 g.; 1 mol.), suspended in acetone (250 c.c.), was stirred and warmed for a few minutes on the steam-bath with 20% sodium hydroxide solution (20 c.c.; 5 mols.), and the mixture shaken. The filtered acetone layer was poured into ice-cold water (1000 c.c.). The solid (5.5 g.) was recrystallised from light petroleum (b. p. 80–100°; 25 c.c. per g.), the yield then being 65% (3.85 g.) (Found: S, 10.7. $\text{C}_{18}\text{H}_{19}\text{N}_2\text{S}$ requires S, 10.9%). The pale yellow crystals had m. p. 114° (decomp.). The absorption maximum of a methyl-alcoholic solution containing ammonia was at 3670 Å. The base was photographically inert.

2- β -Anilino- β -vinylbenzthiazoline Ethiodide (XIII; X = I).—2-Methylbenzthiazole ethiodide (28.2 g.; 1 mol.) and ethylisoformanilide (13.2 g.; 1.1 mols.) were heated together at 150–160° for ½ hour. The product was ground with spirit (32.7 g. obtained); after recrystallisation from spirit (30 c.c. per g.) the yield was 59% (Found: I, 27.8. $\text{C}_{17}\text{H}_{17}\text{N}_2\text{ISe}$ requires I, 27.85%). The greenish-golden crystals had m. p. 222° (decomp.).

3-Ethyl-2-anilooctylidenebenzthiazoline.—The above ethiodide (32 g.; 1 mol.), ground to a paste with water, was treated with 40% sodium hydroxide solution (40 c.c.; 5 mols.) and acetone (500 c.c.). The mixture was slightly warmed, then well shaken. The filtered, concentrated acetone extract gave with dilute hydrochloric acid 2- β -anilino- β -vinylbenzthiazoline ethochloride (XIII; X = Cl), which, after recrystallisation from acetone-spirit (3:1, 30 c.c. per g.), was obtained in 55% yield (14.4 g.). Chlorine was determined by the method which has been found suitable for iodine in the presence of selenium (Hamer, *Analyst*, 1933, 58, 26) (Found: Cl, 9.55. $\text{C}_{17}\text{H}_{17}\text{N}_2\text{ClSe}$ requires Cl, 9.75%). The bright yellow crystals had m. p. 205° (decomp.). They were dissolved in hot spirit, and the base precipitated by dilute ammonia (11.2 g.; 49%); it was recrystallised from light petroleum (b. p. 80–100°; 20 c.c. per g.) and the yield was 34% (7.8 g.) (Found: N, 8.55. $\text{C}_{17}\text{H}_{17}\text{N}_2\text{Se}$ requires N, 8.55%). The bright yellow crystals had m. p. 96°. The absorption maximum of a methyl-alcoholic solution containing ammonia was at 3940 Å. and of one containing sulphuric acid at 4235 Å. For a chloride emulsion the base was a medium sensitiser, with the maximum at 4600 Å., sensitisation extending to 5100 Å.

1-Methyl-2-anilooctylidenedihydroquinoline (XIV).—2- β -Anilino- β -vinylquinoline methiodide (7.76 g.; 1 mol.) was suspended in acetone (100 c.c.) and shaken for 12 minutes with a solution of sodium hydroxide (4 g.; 5 mols.) in water (50 c.c.). The filtered acetone layer with ice-cold water (600 c.c.) deposited the base in 97% yield (10.16 g.). On recrystallising from light petroleum (b. p. 80–100°)-benzene (1:1,

10 c.c. per g.), some tar was left undissolved and the yield fell to 62% (Found, after drying in a vacuum desiccator: N, 10.95. $C_{18}H_{16}N_2$ requires N, 10.75%). The bright orange crystals had m. p. 88° (decomp.). The absorption maximum of an alkaline methyl-alcoholic solution was at 4335 Å. In a gelatino-chloride photographic emulsion, sensitisation extended to 5100 Å., with a maximum at 4700 Å.

3-Methyl-2-aniloethylidenethiazolidine.—This was prepared from 2-β-anilinovinylthiazoline methiodide and sodium hydroxide in aqueous acetone, followed by precipitation with water, as described (Kodak Ltd., B.P. 561,172/1940). The yield was 79%, dropping to 73% on recrystallisation from benzene (1 c.c. per g.) (Found, after drying to constant weight in a vacuum desiccator: S, 14.6. Calc. for $C_{18}H_{16}N_2S$: S, 14.7%). The m. p. was 79–80°, whereas that published is 99–100°.

3-Ethyl-2-aniloethylidenethiazolidine (XV).—2-β-Anilinovinylthiazoline ethiodide (36 g.; 1 mol.), benzene (800 c.c.), and 40% sodium hydroxide solution (80 c.c.; 8 mols.) were heated together under reflux on a steam-bath, with vigorous stirring, for 30 minutes. After the solvent had been distilled from the filtered benzene layer, the solid residue was recrystallised from light petroleum (b. p. 80–100°; 1000 c.c.) and obtained in 77% yield (18.0 g.) (Found, after drying in a vacuum desiccator: S, 13.75. $C_{18}H_{16}N_2S$ requires S, 13.8%). The cream-coloured substance had m. p. 65°. The absorption maximum of a methyl-alcoholic solution containing ammonia was at 3585 Å. with an inflexion to the curve at 3200 Å.; one containing sulphuric acid had its maximum at 3660 Å. On a gelatino-chloride photographic emulsion it conferred extra-sensitivity up to 4400 Å.

4-Methyl-3-ethyl-2-aniloethylidene-Δ⁴-thiazoline (XVI).—4-Methyl-2-β-anilinovinylthiazole ethiodide (18.6 g.; 1 mol.) was ground with 20% sodium hydroxide solution (50 c.c.; 4 mols.). The mixture was stirred and warmed with acetone (250 c.c.). The crude product (23 g.), obtained by precipitation of the acetone layer with ice-water (1000 c.c.), was recrystallised from light petroleum (b. p. 80–100°) and benzene (2 : 1, 20 c.c. per g.). A 74% yield of golden crystals (18.0 g.) was obtained (Found: S, 12.95. $C_{18}H_{16}N_2S$ requires S, 13.1%; m. p. 122° (decomp.). The absorption maximum of a methyl-alcoholic solution containing ammonia was at 4090 Å. and of one containing sulphuric acid at 4030 Å. The substance sensitised a chloride emulsion fairly strongly, sensitisation extending to 4900 Å., with the maximum at 4500 Å.

3-Ethyl-2-aniloethylidenebenzoxazoline (XVII).—2-β-Anilinovinylbenzoxazole ethiodide (58.8 g.; 1 mol.), aqueous 40% sodium hydroxide solution (90 c.c.; 6 mols.), and benzene (1500 c.c.) were stirred together and warmed gently on a steam-bath, then shaken vigorously for several minutes. The benzene solution was filtered and distilled down to dryness: the resultant gum was taken up with acetone, and the base precipitated with water, being obtained in 58% yield (23 g.). Recrystallisation was difficult; benzene appeared to be the most suitable solvent (5 c.c. per g.) but the yield fell to 6% (Found, after drying in a vacuum desiccator: N, 10.5. $C_{17}H_{14}ON_2$ requires N, 10.6%). The pale yellow crystals had m. p. 65° (decomp.). The absorption maximum of a methyl-alcoholic solution containing ammonia was at 3660 Å. and of one containing sulphuric acid at 3835 Å. A gelatino-chloride photographic emulsion was weakly sensitised to 4400 Å., with the maximum effect at 4200 Å.

3 : 3-Dimethyl-2-β-anilinovinylindolenine Methiodide.—2 : 3 : 3-Trimethylindolenine methiodide (20 g.; 1 mol.) and ethylisoformanilide (10 g.; 1 mol.) were heated together in an oil-bath at 140° for 40 minutes with continual breaking up of the lumpy solid. After dissolving in hot spirit (130 c.c.), the product crystallised in 75% yield (20 g.). It was boiled out with spirit (25 c.c.) and on recrystallising the residue from spirit (125 c.c.) the yield was 55% (Found: I, 31.35. Calc. for $C_{19}H_{21}N_2I$: I, 31.4%). The yellow crystals had m. p. 236–238° (decomp.).

1 : 3 : 3-Trimethyl-2-aniloethylideneindoline (XVIII).—The foregoing methiodide (3.91 g.; 1 mol.) was suspended in benzene (40 c.c.) and shaken with a solution of sodium hydroxide (1.16 g.; 3 mols.) in water (5 c.c.). Subsequently four more such benzene extractions were carried out. The benzene filtrate was taken to dryness and the residue twice recrystallised from light petroleum (b. p. 80–100°; 2 × 8 c.c.), the yields being 73% and 64% (1.70 g.) (Found, after drying in a vacuum desiccator: N, 10.0. $C_{19}H_{20}N_2$ requires N, 10.15%). The yellow powder had m. p. 89°. The absorption maximum of a methyl-alcoholic solution containing ammonia was at 3745 Å. and of one containing sulphuric acid at 4120 Å. It sensitised a gelatino-chloride photographic emulsion up to 4700 Å.

Ethylisoformanilide.—Ethyl orthoformate (1200 c.c.; 2 mols.), aniline (336 c.c.; 1 mol.), and aniline hydrochloride (36 g.) were boiled together in an oil-bath for 4 hours, in a flask fitted with fractionating column, condenser, and receiver to collect the alcohol eliminated. The temperature of the bath was kept at 120° until the first vigour of the reaction had subsided and was then raised to 140–150°. After cooling, any diphenylformamidine was filtered off, and the filtrate was fractionally distilled under a vacuum. After a forerun, b. p. 50–110°/20 mm., the ethylisoformanilide was collected at 110–120°/20 mm. The foreruns from several batches were fractionated together, the fraction boiling up to 110°/20 mm. being used as ortho-ester for another preparation, and the fraction above 110°/20 mm. being refractionated with ethylisoformanilide. As a result, the 85% yield from a second fractional distillation (504 g.) is slightly larger than that from the first fractionation (81% yield; 480 g.).

We are indebted to Miss M. D. Gauntlett for the absorption spectra, to Dr. B. H. Carroll and Dr. E. B. Knott for the photographic tests, and to Mr. J. Fraser and Miss E. M. Wilson for the preparations specified.

181. Symmetrical Tricarbocyanines having One or More Methyl Groups as Substituents on the Chain.

By FRANCES M. HAMER and RUSSELL J. RATHBONE.

1-, 2-, and 3-Methyl derivatives of glutamic aldehyde dianilide hydrohalide were prepared, also 1:5- and 1:3-dimethyl derivatives, from the appropriate pyridinium cyanobromides. They were condensed with heterocyclic quaternary salts to give tricarbocyanines having β -, γ -, and δ -methyl groups, also $\beta\beta'$ - and $\beta\delta$ -dimethyl groups on the chain. Absorption maxima and photographic sensitising action of the dyes are recorded.

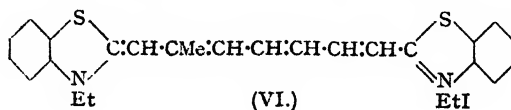

In a patent on photographic sensitising action, the four examples of chain-substituted tricarbocyanines comprise one with a β -methyl and three with a δ -methyl group (I.G. Farbenind. A.-G., B.P. 394,537/1931). It is recorded that the intermediate for the first was prepared by König's method from β -naphthylamine, α -picoline, and cyanogen chloride in ether (*J. pr. Chem.*, 1904, 69, 105), whilst that for the others was obtained analogously from aniline, γ -picoline, and cyanogen bromide. As no preparations whatever are described, we considered it desirable to record some.

Although König did originally describe the preparation of a dye from α -picoline, cyanogen chloride, and *o*-toluidine (*loc. cit.*), he subsequently disclaimed it but claimed that pure β -picoline does indeed form such a dye (*J. pr. Chem.*, 1904, 70, 19). König and Schreckenbach (*ibid.*, 1913, 87, 241) had found that 2:4-dinitrophenylpyridinium chloride does not, whilst pyridinium cyanobromide does, react with indoles to give dyes. α -Picoline and $\alpha\alpha'$ -lutidine do not combine with 1-chloro-2:4-dinitrobenzene to give pyridinium salts but we made them react with cyanogen bromide and thence, with aniline and hydrobromic or hydrochloric acid, obtained dyes (I) and (II). Similarly from β -picoline we prepared (III), referred to (but not described) by König (*ibid.*, 1904, 70, 19), and from γ -picoline we prepared (IV). The product derived from γ -lutidine was used in condensations but we did not isolate a pure specimen of (V).

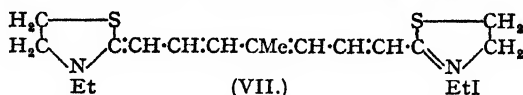

We compared the absorption maxima of (I)–(IV) in methyl-alcoholic solution with that of the parent dye having an unsubstituted chain. In passing from the parent dye to (II) and (III), there were bathochromic shifts of the maximum, of 45 Å. and 10 Å., respectively, and hypsochromic shifts, of 90 Å. and 65 Å., respectively, in passing to (I) and (IV). Whereas the parent dye is a photographic sensitiser, (I) was distinctly weaker, whilst (II), (III), and (IV) showed no sensitising power.

Glutamic aldehyde dianilide hydrohalide condenses in the presence of sodium ethoxide, or of sodium acetate in acetic anhydride, with quaternary salts having reactive methyl groups to give tricarbocyanines (Fisher and Hamer, *J.*, 1933, 189), but these condensing agents seemed unsuitable for use with the present substituted intermediates. However, Brooker had used piperidine at a low temperature (Kodak Ltd., B.P.P. 436,941/1933; 437,017/1933), and this method proved applicable here. By thus condensing 2-methylbenzthiazole ethiodide, with (I), (III), (IV), (II), and the crude (V), respectively, there resulted the β -methylthiatricarbocyanine (VI), which has been already described (I.G. Farbenind. A.-G., B.P. 394,537/1931), and

the corresponding γ - and δ -methyl-, and $\beta\beta'$ - and $\beta\delta$ -dimethyl-thiatricarbocyanines. By condensing 5:6-dimethoxy-2-methylbenzthiazole ethiodide and 2-methyl-6:7-benzbenzthiazole ethiodide, respectively, with (II), the 5:6:5':6'-tetramethoxy- and 6:7:6':7'-dibenz-derivatives of the $\beta\beta'$ -dimethylthiatricarbocyanine were prepared. The dye obtained by condensing 2-methyl-6:7-benzbenzthiazole ethiodide with (IV) has already been described (*idem, ibid.*). By condensing 2-methylbenzselenazole ethiodide with (II), (III), and (IV), respectively, there resulted a $\beta\beta'$ -dimethyl-, and a γ - and a δ -methyl-selenatricarbocyanine.

Condensation of (IV) and (V), respectively, with 2-methylthiazoline ethiodide gave the *8-methylthiazolinocarbocyanine* (VII) and the corresponding $\beta\delta$ -dimethyl compound.

We compared the absorption maxima in methyl-alcoholic solution of the chain-substituted tricarbocyanines with the corresponding parent dyes: the figures are shown in the accompanying table. In one instance, introduction of a β -methyl group caused a bathochromic shift of 60 Å. Introduction of a γ -methyl group caused a bathochromic shift of 5 Å. and a hypsochromic shift

Chain.	Thia-	Absorption (Å.) of tricarbocyanine iodides:			
		Tetramethoxythia-	Dibenzthia-	Selena-	Thiazolino-
Unsubstituted	7620 *	8000	7970 *	7700 *	6450 †
β -Me	7680	—	—	—	—
γ -Me	7610	—	—	7705	—
δ -Me	7900	—	8250	8000	6750
$\beta\beta'$ -Me ₂	7720	7900	8290	7970	—
$\beta\delta$ -Me ₂	7060	—	—	—	6585

* Fisher and Hamer, *Proc. Roy. Soc.*, 1936, A, 154, 703.

† Fisher and Hamer, *J.*, 1933, 189.

of 10 Å. Introduction of a δ -methyl group had a more profound effect; thus, in four instances this caused consistently a bathochromic shift, the values being 280, 280, 300, and 300 Å. The introduction of $\beta\beta'$ -dimethyl groups caused a hypsochromic shift of 100 Å. in one case, but bathochromic shifts, of 100, 320, and 270 Å., respectively, in three others. $\beta\delta$ -Dimethyl groups produced a hypsochromic shift of 560 Å. and a bathochromic shift of 135 Å.

These chain-substituted tricarbocyanines comprise photographic sensitisers but, as already noted for symmetrical dicarbocyanines carrying a methyl group on the chain (Hamer and Rathbone, *J.*, 1945, 595), it cannot be said that they are in general better than the parent dyes with an unsubstituted chain.

EXPERIMENTAL.

1-Anilino-5-anilo-1-methyl-1:3-pentadiene Hydrobromide (I).—Cyanogen bromide (5 g.; 1 mol.) was added to water (30 c.c.) which was cooled with ice. Aniline (10 c.c.; >2 mols.) was added and α -picoline (5 c.c.; 1 mol.) was gradually stirred in. After 30 minutes in ice, the mixture was gradually treated with ice-cold hydrobromic acid (14 c.c., *d* 1.45; 2.5 mols.). After standing in the cold overnight, the red solid was filtered off and ground once with water (20 c.c.) and thrice with acetone (19% yield; 3.00 g.). This and the other pentadiene derivatives were dried in a vacuum desiccator before analysis (Found: Br, 23.25. $\text{C}_{18}\text{H}_{18}\text{N}_2\text{Br}$ requires Br, 23.3%). The maroon crystals had m. p. about 155° (decomp.), depending on the rate of heating. Their absorption maximum was at 4760 Å. whereas the corresponding substance with an unsubstituted chain had its maximum at 4870 Å. They sensitised a gelatino-bromide photographic emulsion weakly up to 5700 Å.

1-Anilino-5-anilo-1:5-dimethyl-1:3-pentadiene hydrochloride (II) was similarly prepared from aniline (10 c.c.), cyanogen bromide in ice-cold water, and α -lutidine, followed by concentrated hydrochloric acid. The solid was filtered off, ground with water (40 c.c.) and thrice with acetone (40 c.c. \times 2, 60 c.c.). The yield (7.28 g.) was 25% (Found: Cl, 11.3. $\text{C}_{19}\text{H}_{21}\text{N}_2\text{Cl}$ requires Cl, 11.3%). The red crystals had m. p. 150–151° (decomp.). The absorption maximum was at 4915 Å. and the dye had no photographic sensitising action.

1-Anilino-5-anilo-2-methyl-1:3-pentadiene hydrobromide (III) was similarly prepared from cyanogen bromide (5 g.) in cold water with aniline and β -picoline, followed by hydrobromic acid. The yield of washed hydrobromide was 37% (Found: Br, 22.8. $\text{C}_{18}\text{H}_{18}\text{N}_2\text{Br}$ requires Br, 23.3%). The maroon crystals had m. p. about 148° but dependent on the rate of heating. The absorption maximum was at 4880 Å. The dye did not sensitise. In another experiment more hydrobromic acid (another 2.5 mols.) was added and produced a pale pink solid. It was filtered off and washed with acetone (2.4 g. obtained; 9% yield) and appeared to be the *dihydrobromide*, m. p. 239° (decomp.) (Found: Br, 37.75. $\text{C}_{18}\text{H}_{20}\text{N}_2\text{Br}_2$ requires Br, 37.7%). The hydrochloride was similarly prepared.

1-Anilino-5-anilo-3-methyl-1:3-pentadiene Hydrobromide (IV).—To cyanogen bromide (5 g.; 1 mol.) in water (10 c.c.), with slight cooling, was added a mixture of γ -picoline (5 c.c.; 1 mol.) and aniline (10 c.c.; >2 mols.). A vigorous reaction occurred with rise of temperature. Hydrobromic acid was stirred in (14 c.c., *d* 1.45; 2.5 mols.), followed quickly by ice-water. The yield of washed solid was 6.65 g. (31%), and this was used in condensations. On recrystallising a sample from methyl alcohol (50 c.c. per g.) the yield was 13% (Found: Br, 23.2. $\text{C}_{18}\text{H}_{18}\text{N}_2\text{Br}$ requires Br, 23.3%). The dark maroon crystals had m. p. 167° (decomp.). The absorption maximum was at 4805 Å. and there was no photographic sensitisation. When the reaction temperature was kept down by cooling with ice, the yield of dye was only 1%.

1-Anilino-5-anilo-1:3-dimethyl-1:3-pentadiene Hydrobromide (V).—A solution of aniline (10 c.c.; 2.2 mols.) and α -lutidine (5 c.c.; 1 mol.) in ether (20 c.c.) was added to a solution of cyanogen bromide

(5 g.; 1 mol.) in ether (10 c.c.), and the mixture warmed for 2 minutes. Hydrobromic acid (14 c.c., d 1.45; 2.5 mols.) was added. The ether-washed solid was obtained in 51% yield (8.08 g.), but tended to become oily on standing in the air. It was used as quickly as possible for dye condensations, being kept meanwhile in a vacuum desiccator.

Bis-2-(3-ethylbenzthiazole)- β -methylheptamethincyanine Iodide (VI).—2-Methylbenzthiazole ethiodide (3.05 g.; 2 mols.) and 1-anilino-5-anilo-1-methyl-1:3-pentadiene hydrobromide (I) (1.72 g.; 1 mol.) were added to ice-cold absolute alcohol (30 c.c.), and a cooled solution of piperidine (1.1 c.c.; 2.2 mols.) in alcohol (5 c.c.) was stirred in. After three days in the ice-chest, the solid was filtered off, washed with alcohol and with ether, and finally with warm water (40 c.c.), after which the yield was 65% (1.84 g.). After recrystallisation from methyl alcohol (650 c.c.), the yield was 33% (0.96 g.) and, after a second recrystallisation (450 c.c. per g.) in the presence of charcoal (0.75 g. per g.), it was 10%. For analysis it was dried to constant weight in a vacuum at 60–80° and this method of drying was applied to the subsequent dyes also (Found: I, 22.6. Calc. for $C_{28}H_{27}N_3IS_2$: I, 22.75%). The green crystals with a golden reflex had m. p. 215° (decomp.) (see B.P. 394,537/1931, example 6).

Bis-2-(3-ethylbenzthiazole)- γ -methylheptamethincyanine Iodide.—A similar preparation was carried out but with (III). The crude product (60% yield) was recrystallised from methyl alcohol (42 c.c. per g.), and gave dark green crystals, in 16% yield (Found: I, 22.8. $C_{27}H_{27}N_3IS_2$ requires I, 22.7%; m. p. 166° (decomp.). The sensitising maximum was at 8150 Å.

Bis-2-(3-ethylbenzthiazole)- δ -methylheptamethincyanine iodide was similarly prepared but with (IV). The crude dye (76% yield) was recrystallised from methyl alcohol (425 c.c. per g.) and gave a 43% yield of light green crystals with a gold reflex (Found: I, 22.8. $C_{28}H_{27}N_3IS_2$ requires I, 22.75%; m. p. 206° (decomp.). Sensitisation extended from 7000 to 9000 Å. with the maximum at 8300.

Bis-2-(3-ethylbenzthiazole)- $\beta\beta'$ -dimethylheptamethincyanine iodide was similarly prepared from 2-methylbenzthiazole ethiodide (2.94 g.) and (II). The product was ground with water (20 c.c.), and twice with acetone (20 c.c. \times 2), boiled out twice with methyl alcohol (50 c.c. \times 2), and recrystallised from methyl alcohol (1350 c.c.), the yield of green crystals then being 10% (0.27 g.) (Found: I, 22.5. $C_{27}H_{29}N_3IS_2$ requires I, 22.2%; m. p. 208° (decomp.). The sensitising maximum was at 8350 Å.

Bis-2-(3-ethylbenzthiazole)- $\beta\delta$ -dimethylheptamethincyanine Iodide.—Starting from 2-methylbenzthiazole ethiodide (12.2 g.) and crude (V), the crude yield was only 2% (0.2 g.). After boiling out with absolute alcohol (5 c.c.) and recrystallisation from methyl alcohol (15 c.c.), it was less than 1% (0.08 g.) [Found (micro-analysis by Weiler and Strauss): I, 22.6. $C_{27}H_{29}N_3IS_2$ requires I, 22.2%]. The bright green crystals had m. p. 155° (decomp.). Photographic sensitisation was from 7200 to 8500 with the maximum at 8200 Å.

Bis-2-(5:6-dimethoxy-3-ethylbenzthiazole)- $\beta\beta'$ -dimethylheptamethincyanine Iodide.—5:6-Dimethoxy-2-methylbenzthiazole ethiodide (5.84 g.; 2 mols.), (II) (2.5 g.; 1 mol.), and absolute alcohol (40 c.c.) were stirred mechanically at 80°. A solution of piperidine (1.8 c.c.; 2.2 mols.) in alcohol (up to 12 c.c.) was added in 12 portions (1 c.c. per minute) and stirring was for 12 minutes. After cooling, the solid was filtered off, washed once with alcohol, twice with warm water (20 c.c. \times 2), and repeatedly with acetone. The residue (0.27 g.; 5% yield) was recrystallised from methyl alcohol (500 c.c.), and the yield was 2% (Found: I, 18.3. $C_{31}H_{37}O_4N_3IS_2$ requires I, 18.3%). The green crystals had m. p. 210° (decomp.).

Bis-2-(3-ethyl-6:7-benzbenzthiazole)- $\beta\beta'$ -dimethylheptamethincyanine Iodide.—This was prepared from 2-methyl-6:7-benzbenzthiazole ethiodide (8.82 g.) and (II), with piperidine in ice-cold alcohol. The washed solid was boiled out with methyl alcohol (100 c.c.) and recrystallised from it (1000 c.c.), being obtained in 8% yield (0.51 g.) (Found: I, 19.2. $C_{28}H_{29}N_3IS_2$ requires I, 18.9%). The bronze crystals had m. p. 187° (decomp.). The sensitising maximum was at 8800 Å. In the corresponding preparation carried out with 2-methyl-4:5-benzbenzthiazole ethiodide, the yield of tricarbocyanine was only 1%.

Bis-2-(3-ethyl-6:7-benzbenzthiazole)- δ -methylheptamethincyanine Iodide.—This was similarly prepared from 2-methyl-6:7-benzbenzthiazole ethiodide (3.55 g.) and (IV). The washed solid (1.02 g.) was boiled out with methyl alcohol (20 c.c.) and recrystallised from it (1100 c.c.). An 18% yield (0.6 g.) was obtained (Found: I, 19.15. Calc. for $C_{28}H_{29}N_3IS_2$: I, 19.3%). The bronze crystals had m. p. 187° (decomp.) (see B.P. 394,537/1931, example 8).

Bis-2-(3-ethylbenzelenazole)- $\beta\beta'$ -dimethylheptamethincyanine Iodide.—2-Methylbenzelenazole ethiodide (5.63 g.) was similarly allowed to react with (II). The washed solid was boiled out with methyl alcohol (70 c.c.), and recrystallised from it (1750 c.c.). The yield (0.97 g.) was 18% (Found: I, 19.3. $C_{27}H_{29}N_3ISe_2$ requires I, 19.4%). The green crystals had m. p. 214–217° (decomp.), the exact temperature depending on the rate of heating. The sensitising maximum was at 8450 Å.

Bis-2-(3-ethylbenzelenazole)- γ -methylheptamethincyanine iodide was similarly prepared from 2-methylbenzelenazole ethiodide (7.71 g.) and (III). The washed product (3.17 g.) was boiled out with methyl alcohol (60 c.c.) and recrystallised from it (1000 c.c.), the yield being 18% (1.26 g.) (Found: I, 19.5. $C_{28}H_{29}N_3ISe_2$ requires I, 19.45%). The green crystals melted at 214° (decomp.). The sensitising maximum was at 8350 Å.

Bis-2-(3-ethylbenzelenazole)- δ -methylheptamethincyanine iodide was similarly prepared from 2-methylbenzelenazole ethiodide (3.52 g.) and (IV). The washed solid (1.65 g.) was boiled out with methyl alcohol (30 c.c.) and recrystallised from it (1400 c.c.), being obtained in 30% yield (0.96 g.) (Found: I, 19.65. $C_{28}H_{29}N_3ISe_2$ requires I, 19.5%). It formed light green crystals with a golden reflex; m. p. 213° (decomp.). Sensitisation was from 7000 to 9000 Å. with a maximum at 8400.

Bis-2-(3-ethyl- Δ^2 -thiazoline)- δ -methylheptamethincyanine Iodide (VII).—This was prepared from 2-methylthiazoline ethiodide (5.14 g.) and (IV). The washed dye (3.85 g.) was recrystallised from methyl alcohol (25 c.c.), and the yield was 59% (2.65 g.) (Found: I, 27.5. $C_{18}H_{21}N_3IS_2$ requires I, 27.45%). It formed bluish-black crystals with a metallic lustre; m. p. 134° (decomp.). Sensitisation was from 6100 to 7500 Å., with the maximum at 7100.

Bis-2-(3-ethyl- Δ^2 -thiazoline)- $\beta\delta$ -dimethylheptamethincyanine Iodide.—In a similar preparation carried out with (V), the yield of washed dye was only 5% and after recrystallisation from methyl alcohol (40 c.c. per g.) was 2% [Found (micro-analysis by Weiler and Strauss): I, 26.8. $C_{19}H_{19}N_3IS_2$ requires

I, 26.65%]. The bluish-grey crystals had m. p. 165° (decomp.). The dye sensitised from 6000 to 7300 with the maximum at 6900 Å.

We are indebted to Miss M. D. Gauntlett for the absorption measurements, and for the sensitising tests to Drs. B. H. Carroll, E. P. Davey, and E. B. Knott.

[Received, October 29th, 1946.]

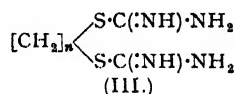

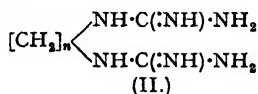

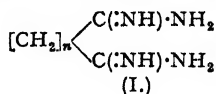

182. Some Alkoxy- and Alkylenedioxydi-amines and Alkoxy- and Alkylenedioxydi-guanidines.

By A. T. FULLER and HAROLD KING.

The aim of the investigation was the preparation of a series of alkoxy- and alkylenedioxydi-amines (*O*-alkyl- and *OO'*-alkylene-hydroxylamines) and the corresponding alkoxy- and alkylenedioxydi-guanidines with a view to their being tested for antiprotozoal and antibacterial activity. Several representatives of all these types have been successfully made, starting from hydroxyurethane. Other methods of approach have been partly successful. Incidentally, two representatives of the hitherto undescribed class of *O*-alkoxydiguanydes have been isolated.*

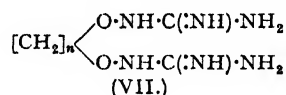

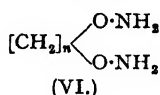

All these substances have been tested on a range of bacteria *in vitro*.

KING, LOURIE, and YORKE (*Lancet*, 1937, ii, 1360; *Ann. Trop. Med. Parasit.*, 1938, 32, 177) discovered that diamidines (I), diguanidines (II), and diisothioureas (III) had a pronounced trypanocidal action, some of the members of the members where $n = 10$ or more being lethal to trypanosomes *in vitro* at a dilution of 1 in 250,000,000

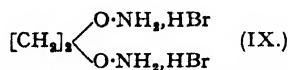

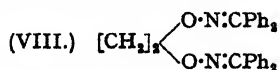

Fuller (*Biochem. J.*, 1942, 36, 548) examined the action of many of these bases, as salts, on a range of bacteria and found that their bacteriostatic titres were lower than their trypanocidal titres, but even so the activity was very pronounced in some of the higher members.

It seemed to us that in further exploration of the parent types the preparation of a series of alkoxyamines (IV), *N*-alkoxyguanidines (V), alkylenedioxydiamines (VI), and alkylenedioxydiguanydes (VII) might be worth undertaking.

Direct alkylation of hydroxylamine leads to *N*-substitution, so for the preparation of *O*-substituted hydroxylamines, the amino-group must be partly or wholly protected. A number of ways of accomplishing this are described in the literature, but without preliminary exploration of these methods it was by no means certain which method would lend itself to the object we had in view.

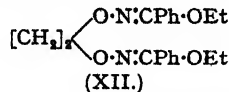

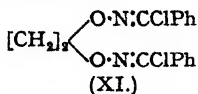

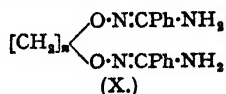

Alkylation of oximes by methyl iodide or methyl sulphate leads, both with the aliphatic ketoximes (Dunstan and Goulding, *J.*, 1901, 79, 628) and with the aromatic ketoximes (Semper and Lichtenstadt, *Ber.*, 1918, 51, 928) to production of *O*- and *N*-methyl ethers. Borek and Clarke (*J. Amer. Chem. Soc.*, 1936, 58, 2020) were, however, able to use acetoxime for the preparation of carboxymethoxyamine, $\text{NH}_2\cdot\text{O}\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$ in 60% yield. On these lines a trial was made of the use of benzophenone oxime, which reacted in alcoholic solution with ethylene bromide and sodium ethoxide to give a single homogeneous *ethylenedibenzophenone oxime* of the probable constitution (VIII). The poor yield and slight dubiety about the structure led to the abandonment of this method of approach.

Luxmoore (*J.*, 1895, 67, 1018) claimed to have prepared ethylenedioxydiamine dihydrobromide (IX) by the direct action of ethylene dibromide on hydroxylamine, but Werner and

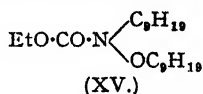

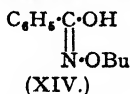

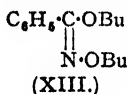

* Curd and Rose (*J.*, 1946, 736) have, however, recently described the preparation of a member of this group of substances.

Gemeseus (*Ber.*, 1896, 29, 1161) pointed out that Luxmoore's claim was inconsistent with the behaviour of hydroxylamine towards alkyl halides. These investigators were, however, able to prepare the corresponding dihydrochloride from the benzamidoxime ethylene ether (X, $n = 2$) of Falck (*Ber.*, 1886, 19, 1481) which, on treatment with nitrite in the presence of hydrochloric acid, gave benzenyl chloride oxime ethylene ether (XI). The latter with sodium ethoxide furnished the ethylene ether of an ethylbenzhydroxamic acid (XII) which, without

characterisation was hydrolysed to ethylenedioxydiamine. As this method seemed applicable to alkylenedioxydiamines, ethylene dibromide, 1:6-dibromohexane, and 1:12-dibromododecane have been condensed with benzamidoxime to give *ethylenedi-OO'-benzamidoxime dihydrochloride*, 1:6-hexamethylenedi-OO'-benzamidoxime (X, $n = 6$), and *dodecamethylenedi-OO'-benzamidoxime* (X, $n = 12$), respectively. In a similar way heptyl bromide was converted into *O-heptylbenzamidoxime* but all attempts to convert the latter or 1:6-hexamethylenedioxybenzamidoxime into the chloride oximes failed completely.

The success of Werner and Gemeseus in obtaining ethylenedioxydiamine, in unstated yield, depended essentially on a method for the preparation of the readily hydrolysable ethylene ether of ethylbenzhydroxamic acid (XII). To explore the possibility of a short route to allied compounds the direct butylation of benzhydroxamic acid was examined. When potassium benzhydroxamate was boiled with butyl bromide in alcohol in presence of potassium carbonate, equal weights of a non-acidic fraction and of an acidic fraction were obtained. The former, on fractional distillation, gave *OO'-dibutyl benzhydroxamate* (XIII) as its main component and

aniline, as a minor component, produced during the reaction by a Lossen rearrangement; (XIII) on hydrolysis with aqueous-alcoholic hydrogen chloride gave mainly ethyl benzoate and butoxyamine hydrochloride.

The acidic fraction on distillation proved to be *O'-butyl benzhydroxamate* (XIV) which on hydrolysis with hydrobromic acid gave *butoxyamine hydrobromide* and benzoic acid.

Whilst the foregoing method might prove suitable for the preparation of the alkoxyamines it would clearly lead to complications with alkylene dihalides.

Most of the above methods of approach to the synthesis of *O*-alkyl- and *OO'*-alkylenedioxyhydroxylamines have involved compounds of oxime type where the nitrogen atom is doubly linked to carbon. Lauder W. Jones and his pupils (cf. Jones and Neuffer, *J. Amer. Chem. Soc.*, 1914, 36, 2202) have successfully used hydroxyurethane, $\text{OH} \cdot \text{NH} \cdot \text{CO}_2\text{Et}$ for the preparation of the simplest *O*-alkylhydroxylamines. In our hands this method has proved capable of extension to the higher *O*-alkylhydroxylamines and to the *OO'*-alkylenedioxyhydroxylamines. In the cases of the lower homologues up to heptyl no evidence was found for significant proportions of *N*-alkyl derivatives but from the products of the reaction between nonyl bromide and hydroxyurethane, *nonoxyurethane* and *nonoxynonylurethane* (XV) were obtained by fractional distillation. Similarly, alkylene dibromides have been found to give alkylenedioxydiurethanes except that with trimethylene and tetramethylene dibromides cyclisation took place with production of derivatives of isooxazolidine and tetrahydroisooxazine (King, *J.*, 1942, 432). For the hydrolysis of the urethanes, alkali and acid have been used successfully, but there is always some fission of ammonia.

All the hydroxylamines have been converted into alkoxyguanidines and alkylenedioxydiguanidines by use of *S*-methylisothiurea or cyanamide. Where cyanamide has been employed in excess, two representatives of the hitherto unknown *O*-alkoxydiguanides have been isolated as exemplified by *butoxydiguanide nitrate* and *hexoxydiguanide nitrate*. The former was also prepared by the action of dicyanodiamide on butoxyamine hydrochloride in boiling butyl alcohol. The parent substance hydroxydiguanide also seems to be unknown.

Finally, the complete methylation of heptoxyamine was attempted in methyl alcohol in the presence of potassium carbonate. The products were tetramethylammonium iodide and 2-*n*-heptylidene-*n*-heptaldehyde, identified as its *dinitrophenylhydrazone*:

This reaction is fundamentally the same as that observed by Meisenheimer (*Annalen*, 1913, **397**, 273; cf. Jones and Major, *J. Amer. Chem. Soc.*, 1927, **49**, 1529), who found that evaporation of alcoholic solutions of ethoxy- and propoxy-trimethylammonium hydroxide led to production of acetaldehyde and propaldehyde respectively.

Antibacterial Activity.

The methods used were similar to those previously described (Fuller, *loc. cit.*). The results are summarised in the following table: the figures of inhibitory concentrations are those which prevented visible growth in 20 hours at 37° and are expressed as mg. per 100 c.c. (parts per 100,000). The sign > indicates that the drug was not active at the highest concentration tested.

As is usual with basic drugs, these drugs are more active against the Gram-positive than the Gram-negative bacteria (*E. coli* and *B. proteus*). In a homologous series it is usual for activity to increase with chain length up to a point above which the activity decreases. The alkoxyguanidines, which are stronger bases than the *O*-alkylhydroxylamines, do not appear to have reached their maximum activity at C₁₂, while the *O*-alkylhydroxylamines show signs of having done so. This power of a more strongly basic group to support activity in a longer chain has been noted before (Fuller, *ibid.*).

The basicity of the compounds increases with the chain length. They are, however, such weak bases (the pH of their salts varies from pH 3 to pH 5.5) that none would be appreciably ionized at pH 7.5, so the observed differences of activity are probably not due to differences in their degrees of ionization.

The *O*-alkylhydroxylamines turned the colour of blood to brown or black, but the change was less marked with the alkoxyguanidines. Blood greatly reduced the activity of the drugs with increasing effect as the series was ascended, until the higher members retained 1% or less of the activity shown in broth.

EXPERIMENTAL.

Hydroxyurethane.—Hydroxylamine hydrochloride (27.8 g.; 1 mol.) was added to a solution of anhydrous sodium carbonate (62.4 g.; 1.5 mols.) in water (184 c.c.). The vigorously stirred solution, with salt in suspension, was slowly treated with ethyl chloroformate (42.4 g.), the temperature being kept approximately at that of the room. The final solution was acidified and extracted with ether in a continuous extractor. The yield of hydroxyurethane, dried over sodium sulphate, was about 94%. This method is based on Hantzsch's process (*Ber.*, 1894, **27**, 1255) and is more convenient than that of Jones (*Amer. Chem. J.*, 1898, **20**, 39).

Butoxyurethane and Butoxyamine Hydrochloride.—Hydroxyurethane (10.5 g.) and butyl iodide (18.4 g.) were added to ethyl alcohol (30 c.c.) containing dissolved potassium hydroxide (6.6 g., 85% pure) and the mixture boiled for 5 hours. The alcohol was removed, and the crude butoxyurethane recovered by ether extraction; yield 11.65 g. This urethane was boiled for one hour with potassium hydroxide (16.2 g.; 4 mols.) in water (32.4 c.c.). A solid potassium salt separated first but this quickly

disappeared and was followed by separation of an oily layer. The latter was taken up in ether, and the ethereal extract treated with slight excess of 3*N*-hydrochloric acid. This acid solution was evaporated to dryness, and the crystalline residue dissolved in boiling ethyl acetate. Butoxyamine hydrochloride, *m. p.* 156–157°, separated in glistening leaflets (5.3 g.) identical with the product obtained from the butylation of benzhydroxamic acid (see below).

Butoxyguanidine Nitrate.—Butoxyamine hydrochloride (9.3 g.) and cyanamide (6.3 g.) were boiled in absolute alcohol (50 c.c.) for six hours. The alcohol was removed, water added, and the required nitrate (9.8 g.) precipitated by adding excess of solid ammonium nitrate. It was twice crystallised from 1.5 vols. of water and separated in well-formed tablets, *m. p.* 77–78° (Found: C, 31.1; H, 7.5. $C_8H_{15}ON_3.HNO_3$ requires C, 30.9; H, 7.3%). On fractionation of the mother-liquors a by-product was obtained in small quantity which separated from water in nodules but from alcohol in clusters of feathery needles, *m. p.* 116–117°. This proved to be *butoxydiguanide nitrate* (Found: C, 30.9; H, 6.3; N, 34.8. $C_8H_{15}ON_6.HNO_3$ requires C, 30.5; H, 6.8; N, 35.6%). A specimen was synthesised for comparison by boiling butoxyamine hydrochloride and dicyanodiamide in butyl-alcoholic solution and conversion into the nitrate. On admixture of the above by-product with this substance there was no depression of *m. p.*

Hexoxyurethane.—Potassium hydroxide (16.8 g.) in boiling absolute alcohol (168 c.c.) was treated with a mixture of hydroxyurethane (31.5 g.) and hexyl bromide (49.5 g.), and the resulting solution boiled for 6 hours. After removal of potassium bromide by filtration the alcohol was distilled off, the residue dissolved in water, and the *hexoxyurethane* extracted by ether and fractionally distilled; *b. p.* 147–148°/16 mm.; yield 36.6 g. (Found: N, 7.3. $C_8H_{19}O_3N$ requires N, 7.4%).

Acid hydrolysis. The foregoing urethane (18 g.) was boiled for two hours with constant-boiling hydrobromic acid solution (40 c.c.). On cooling, an oily layer separated which soon crystallised. It was collected, well pressed, and then washed with a little light petroleum to remove an oil; yield 7.9 g. On crystallisation of the dried solid from ethyl acetate, *hexoxyamine hydrobromide* separated in pearly flakes, *m. p.* 141° (Found: C, 36.7; H, 8.2. $C_8H_{15}ON.HBr$ requires C, 36.4; H, 8.2%). The hydrobromic acid mother-liquor after extraction with ether to remove non-basic material, mainly hexyl bromide, was basified and again extracted with ether. In this way a small quantity (2 g.) of the base was obtained, *b. p.* 159°/750 mm. (Found: C, 61.7; H, 13.0; N, 11.9. $C_8H_{15}ON$ requires C, 61.5; H, 12.8; N, 12.0%).

Alkaline hydrolysis. The urethane (36.4 g.) was boiled with potassium hydroxide (43 g.; 4 mols.) in water (215 c.c.) for 3.5 hours. The oily layer was taken up in ether, and the ethereal extracts combined and extracted with 2*N*-hydrochloric acid (150 c.c.). The acid extract was evaporated to dryness with absolute alcohol, dissolved in a small volume of dry ethyl acetate, and kept at 0°.

Hexoxyamine hydrochloride separated in pearly scales, and a further quantity was obtained from the mother-liquor by addition of dry ether, total yield 20.4 g. The ethereal extract (above) was evaporated and gave unchanged urethane (5.8 g.). The hydrochloride is sparingly soluble in boiling ethyl acetate and melts at 150–151° (Found: C, 46.9; H, 10.6. $C_8H_{15}ON.HCl$ requires C, 46.9; H, 10.5%).

Hexoxyguanidine Nitrate.—(1) *From methylisothiouraea.* Hexoxyamine (3.5 g.; 1 mol.) in alcohol (20 c.c.) was treated with methylisothiouraea sulphate (4.2 g.), and the solution boiled gently for 1 hour and then evaporated to a small volume; on keeping, it deposited methylisothiouraea sulphate (0.7 g.). The residue obtained on evaporation to dryness was dissolved in water, and excess of ammonium nitrate added. Crude *hexoxyguanidine nitrate* (4.7 g.) gradually crystallised. It separated from water on recrystallisation in tablets, *m. p.* 72–73° (Found: C, 38.2; H, 8.5; N, 24.8. $C_7H_{11}ON_3.HNO_3$ requires C, 37.8; H, 8.2; N, 25.2%).

(2) *From cyanamide.* Hexoxyamine hydrochloride (7.68 g.) and cyanamide (4.4 g.; 2 mols.) were boiled in alcohol (25 c.c.) for 6 hours. The solvent was removed, water added, and then excess of ammonium nitrate. The oil which separated gradually solidified and after a tedious fractional crystallisation from water gave *hexoxyguanidine nitrate* (4.1 g.), identical with the above, and *hexoxydiguanide nitrate* (0.6 g.), *m. p.* 115–116°, which separated from water or alcohol in tiny plates (Found: C, 36.8; H, 7.5; N, 31.8. $C_8H_{15}ON_6.HNO_3$ requires C, 36.3; H, 7.6; N, 31.8%).

O-Hexylcholestenone Oxime.—Equimolecular quantities (*M*/1000) of cholestenone and hexoxyamine were boiled in ethyl alcohol (5 c.c.) for an hour. The crystalline *oxime* which separated was recrystallised three times from ethyl alcohol and separated in plates, *m. p.* 70° (Found: C, 81.4; H, 11.8. $C_{33}H_{51}ON$ requires C, 81.9; H, 11.9%).

In a similar way *O-hexylcholestanone oxime*, *m. p.* 51°, was obtained, crystallising in flattened prisms from alcohol (Found: C, 81.9; H, 12.2. $C_{33}H_{53}ON$ requires C, 81.6; H, 12.3%).

Heptoxyurethane.—This was prepared in the same way as the lower homologue, the yield of product, *b. p.* 158°/20 mm., being 47% (Found: N, 6.8, 6.9. $C_{10}H_{21}O_3N$ requires N, 7.0%).

Heptoxyamine Hydrobromide.—This salt was prepared by acid hydrolysis as described for its lower homologue, the yield of *hydrobromide*, *m. p.* 142°, from 38.4 g. of heptoxyurethane being 34.5 g. On crystallisation from ethyl acetate it separated in plates, *m. p.* 143° (Found: C, 39.7; H, 8.8. $C_9H_{17}ON.HBr$ requires C, 39.6; H, 8.6%). The hydrobromic acid mother-liquors on extraction with ether gave heptyl bromide (1.8 g.), *b. p.* 170–180°/749 mm.; and after the mother-liquors had been made alkaline, ether extraction gave *O-heptoxyamine*, 0.9 g. This base was prepared in larger quantity from its salt and had *b. p.* 179°/761 mm. (Found: C, 64.7; H, 13.2. $C_9H_{17}ON$ requires C, 64.1; H, 13.1%).

Methylation of Heptoxyamine.—The amine (1.31 g.) and methyl iodide (3.1 c.c.) in methyl alcohol (25 c.c.) were boiled with anhydrous potassium carbonate (4.1 g.) for 3 hours. The solvent was removed, the residue treated with a little water and ether and filtered from some well-formed prisms (0.7 g.), which were crystallised from methyl alcohol (90 c.c.) and were unmelted at 360°. This substance proved to be tetramethylammonium iodide (picrate, *m. p.* 312° undepressed by an authentic specimen).

The ethereal extract of the aqueous liquor on distillation left an oil with a strong sweet odour with the reactions of an aldehyde. It readily gave a *dinitrophenylhydrazone*, red needles (0.1 g.), *m. p.* 129°, from alcohol. This on analysis proved to be derived from 2-*n*-heptylidene-*n*-heptaldehyde (Found: C, 61.6; H, 7.8; N, 14.5. $C_{20}H_{38}O_2N_4$ requires C, 61.5; H, 7.8; N, 14.4%).

Heptoxyguanine Nitrate.—This salt was prepared in a similar way to the lower homologue, the yield of crude nitrate from 3.9 g. of heptoxamine being 4 g. It crystallised from water in prisms, m. p. 72° (Found: C, 41.6; H, 8.6; N, 24.1. $C_7H_{15}ON_3 \cdot HNO_3$ requires C, 40.7; H, 8.5; N, 23.7%).

Heptoxy-3:5-dinitrobenzamide.—Heptoxamine (1.31 g.) in pyridine (5 c.c.) was heated with 3:5-dinitrobenzoyl chloride (1 mol.) at 100° for 30 minutes. On cooling and adding excess of hydrochloric acid, the product crystallised (2.6 g.). It was purified by grinding with sodium bicarbonate solution and could then be crystallised from ether as pale yellow needles, m. p. 83–84° (Found: C, 52.1, 52.1; H, 6.0, 5.9; N, 12.7. $C_{14}H_{15}O_5N_5$ requires C, 51.7; H, 5.8; N, 12.9%).

Nonoxyurethane.—The crude alkylated urethane prepared in the usual manner from hydroxyurethane (8.4 g.) and nonyl bromide (16.5 g.) was fractionally distilled and gave **nonoxyurethane** (8.4 g.), b. p. 179°/20 mm. (Found: N, 6.1. $C_{11}H_{23}O_2N$ requires N, 6.1%), and a higher-boiling fraction of **nonoxynonylurethane** (3.0 g.), b. p. 189°/2 mm. (Found: N, 3.9. $C_{21}H_{43}O_2N$ requires N, 3.9%).

Nonoxamine Hydrobromide.—The urethane (8.4 g.) was boiled with constant-boiling hydrobromic acid (25 c.c.) for 2 hours. On cooling, the oily layer which separated gradually crystallised. It was collected, washed with a little 48% hydrobromic acid, and finally with a few drops of ether; yield 5.3 g. It was crystallised from ethyl acetate (20 c.c.) and separated in flakes, m. p. 138°; yield 4.1 g. (Found: C, 44.2; H, 9.4. $C_9H_{21}ON \cdot HBr$ requires C, 44.9; H, 9.2%). The hydrobromic acid mother-liquor on extraction with ether gave nonyl bromide (3.0 g.), b. p. 215–220°/756 mm.

Nonoxamine Hydrochloride.—The urethane (33.2 g.) was boiled with 16% hydrochloric acid (100 c.c.) for 24 hours. The hydrochloride separated in needles (10.6 g.), m. p. 146–149° (Found: C, 55.2; H, 11.3; Cl, 18.4. $C_9H_{21}ON \cdot HCl$ requires C, 55.6; H, 11.5; Cl, 18.2%).

Nonoxyguanine Nitrate.—Nonoxamine hydrochloride (3.9 g.) was dissolved in *n*-sodium hydroxide (20 c.c.) and methylisothiouraea sulphate (2.78 g.) in alcohol (15 c.c.) added. After boiling gently for 1 hour, the solution was evaporated to dryness, the residue dissolved in absolute alcohol, and the sodium chloride removed. The solution was again evaporated to dryness, the residue dissolved in water, and ammonium nitrate added in excess. The nitrate was collected (4.8 g.) and crystallised from water, separating in needles, m. p. 61–62° (Found: N, 20.9. $C_{10}H_{22}ON_3 \cdot HNO_3$ requires N, 21.2%).

Dodecoxyurethane.—From lauryl bromide (37 g.) the crude urethane (39.0 g.) was obtained in the usual way. As it could not be distilled without some decomposition, it was hydrolysed without further purification.

Dodecoxyamine Hydrobromide.—The urethane (20 g.) was boiled with constant-boiling hydrobromic acid (40 c.c.) for 3 hours; on cooling, the oily upper layer crystallised. It was collected by filtration, well pressed, and then washed with ether to remove adhering oil. The hydrobromide (9.1 g.) was recrystallised from ethyl acetate, separating in pearly plates, m. p. 133° (Found: C, 51.0; H, 9.9. $C_{12}H_{25}ON \cdot HBr$ requires C, 51.0; H, 10.0%). The hydrobromic acid filtrate was extracted with ether, and the extract on fractional distillation gave lauryl bromide (9.9 g.), b. p. 138–144°/18 mm.

Dodecoxyguanine Nitrate.—The preceding hydrobromide (5.64 g.) was dissolved in *n*-sodium hydroxide solution (20 c.c.) and methylisothiouraea sulphate (2.78 g.) in alcohol (15 c.c.) added. The reaction mixture was worked up as described for the corresponding nonyl derivative. The yield of crude nitrate was 4.1 g., and on crystallisation from water (100 c.c.) it separated in leaflets, m. p. 79° (Found: C, 50.9; H, 9.6; N, 18.0. $C_{13}H_{27}ON_3 \cdot HNO_3$ requires C, 50.9; H, 9.9; N, 18.3%).

1:6-Hexamethylenedioxydiurethane.—Hexamethylene dibromide (24.4 g.), hydroxyurethane (21 g.), and potassium hydroxide (11.2 g.) were boiled together in absolute alcohol (100 c.c.) for 6 hours. The alcohol was removed and an ethereal extract made of the residue when diluted by water. Removal of the ether left the crude urethane (28.7 g.), which could not be distilled at 1 mm. without decomposition.

1:6-Hexamethylenedioxydiamine Dihydrochloride.—The preceding urethane was boiled for 2.5 hours with potassium hydroxide (40 g.) in water (80 c.c.), during which period there was some evolution of ammonia. The oily layer was taken up in ether and distilled, the fraction, b. p. 90–120°/1 mm. (9.8 g.), being collected and redistilled, b. p. 112°/1 mm. (7.5 g.). It was treated with the calculated amount of *n*-hydrochloric acid, and the dihydrochloride was recrystallised twice from spirit. It separated in tiny leaflets, m. p. 220° (Found: C, 32.7; H, 8.1. $C_6H_{16}O_2N_2 \cdot 2HCl$ requires C, 32.6; H, 8.2%).

Attempts to hydrolyse the urethane with constant-boiling hydrobromic acid or 16% hydrochloric acid gave very poor yields of base. For instance, the diurethane (14 g.) was boiled for 1.5 hours with 16% hydrochloric acid (50 c.c.) and gave a basic fraction (0.7 g.). A portion of this was converted into the *dipicrolonate* by mixing the calculated amounts of the components in alcohol. It was very sparingly soluble in boiling absolute alcohol and crystallised in minute needles, m. p. 229° (Found: C, 45.9; H, 4.7. $C_6H_{14}O_2N_2 \cdot 2C_{10}H_7O_2N_2$ requires C, 46.4; H, 4.8%).

1:6-Hexamethylenedioxydiguanidine Dinitrate.—The preceding dihydrochloride (2.21 g.) was boiled in alcohol (20 c.c.) with cyanamide (1.68 g.) for 6 hours. The solvent was removed, and a small volume of water added, followed by excess of ammonium nitrate. An oil separated which eventually crystallised. It was collected, dried, and recrystallised from absolute alcohol or water, separating in pointed prisms, m. p. 123° (efferv.). The behaviour of the solid on heating in a capillary is variable: no melting takes place and the point of effervescence may occur at any temperature between 121° and 125° (Found: C, 27.2; H, 5.9; N, 30.7. $C_6H_{20}O_4N_6 \cdot 2HNO_3$ requires C, 26.8; H, 6.2; N, 31.3%).

1:10-Decamethylenedioxydiurethane.—Dibromodecane (15 g.) and hydroxyurethane (10.5 g.) were boiled in absolute alcohol (60 c.c.) containing potassium hydroxide (5.6 g.) for 6 hours. The alcohol was removed by distillation and replaced by water, and the diurethane extracted with ether. On removal of the ether, the residue (15.9 g.) crystallised on cooling to 0°. A portion was crystallised from ether–light petroleum and gave the urethane, m. p. 53–55° (Found: C, 55.6; H, 9.3. $C_{14}H_{30}O_2N_2$ requires C, 55.1; H, 9.3%). Attempts to hydrolyse the main bulk of diurethane by acid were unsuccessful.

1:10-Decamethylenedioxydiamine Dihydrochloride.—The crude urethane from 15.0 g. of dibromodecane was boiled for 1 hour with potassium hydroxide (20.2 g.) in water (40.6 c.c.). A potassium salt separated at first but was soon replaced by an oily layer. During the hydrolysis some ammonia was given off. The oil was taken up in ether, the ether removed, and the residue distilled; yield 3.9 g.,

b. p. 144—145°/1 mm. The undistilled residue could be again hydrolysed to give a further quantity of base. The pure distilled base which readily solidified was converted into the *dihydrochloride* which could be crystallised from alcohol but preferably from 3*N*-hydrochloric acid, separating in tiny needles, m. p. 220° (Found: C, 43.1; H, 9.2. $C_{10}H_{14}O_2N_2 \cdot 2HCl$ requires C, 43.3; H, 9.4%).

1:10-Decamethylenedioxydiguanylidine Dinitrate.—The preceding dihydrochloride (1.4 g.) was boiled in alcoholic solution (10 c.c.) with cyanamide (0.84 g.) for 6 hours. The alcohol was removed, and the residue dissolved in water and treated with ammonium nitrate. The required *dinitrate* (2.2 g.) readily separated as a crystalline solid which was recrystallised from spirit (5 c.c.) and separated in rosettes of compact crystals, m. p. 135° (efferv.). The point of effervescence, like that observed for the corresponding hexamethylene derivative, is very variable, values as high as 147° being observed (Found: C, 35.1; H, 7.2; N, 26.5. $C_{12}H_{18}O_2N_6 \cdot 2HNO_3$ requires C, 34.8; H, 7.3; N, 27.0%).

Butylation of Benzhydroxamic Acid.—Potassium benzhydroxamate (46.7 g.), spirit (225 c.c.), butyl bromide (41.1 g.), and excess of potassium carbonate were boiled for 15 hours, the alcohol removed by distillation, and the residue diluted with water and ether and filtered from unchanged potassium benzhydroxamate (5.6 g.). The combined ethereal extracts were treated with 7 successive portions of 2*N*-sodium hydroxide (98 c.c. in all) to remove acidic substances. The residual ethereal solution on evaporation left non-acidic substances (A, 23.6 g.). The alkaline extract on acidification and extraction with ether gave an acidic fraction (B, 23.9 g.).

Fraction (A), on fractional distillation, gave aniline (3.0 g.) and a main fraction (16.2 g.), b. p. 175—180°/13 mm., which on redistillation gave *O*-*dibutyl benzhydroxamate*, b. p. 175—180°/13 mm. (Found: C, 72.2; N, 9.1; N, 5.5. $C_{18}H_{25}O_2N$ requires C, 72.3; H, 9.2; N, 5.6%). The dibutyl derivative was boiled with a mixture of absolute alcohol (100 c.c.) and hydrochloric acid (25 c.c., *d* 1.16) for 4 hours. The resultant solution was diluted with 2 vols. of water and extracted with ether. Washing of the latter with aqueous sodium bicarbonate removed benzoic acid (0.72 g.), and fractional distillation gave ethyl benzoate (8.35 g.), b. p. 213°, with no higher fraction. The main hydrochloric acid mother-liquor was evaporated to dryness under reduced pressure, finally with alcohol, and a small crop of ammonium chloride removed. On re-evaporation to dryness and solution in dry ether, butoxyamine hydrochloride separated as leaflets, m. p. 154°, undepressed by an authentic specimen (Found: Cl, 28.6. Calc.: Cl, 28.2%).

The acidic fraction (B), on distillation at 15 mm., had b. p. 182° and was much more viscous than the dibutyl compound; yield 17.0 g. Analysis showed it to be *O*-*butyl benzhydroxamate* (Found: C, 68.1; H, 8.0; N, 7.6. $C_{11}H_{15}O_2N$ requires C, 68.4; H, 7.8; N, 7.2%). It was hydrolysed by boiling with constant-boiling hydrobromic acid for 6.5 hours. The solution was diluted with an equal volume of water, and ether extraction removed benzoic acid in quantitative yield. The hydrobromic acid solution was evaporated to small volume under reduced pressure with two additions of water, and the *butoxyamine hydrobromide* (4.8 g.) collected. It was crystallised from ethyl acetate and separated in pearly leaflets, m. p. 159—160° (Found: Br, 47.2. $C_4H_{11}ON \cdot HBr$ requires Br, 47.0%). It was converted in aqueous solution by treatment with silver chloride into butoxyamine hydrochloride which, unlike the hydrobromide, is very sparingly soluble in boiling ethyl acetate. It crystallised in pearly leaflets, m. p. 156—157° (Found: Cl, 28.4. Calc.: Cl, 28.2%). Neuffer and Hoffman (*J. Amer. Chem. Soc.*, 1925, 47, 1686) gave m. p. 152—153°.

O-Heptylbenzamidoxime.—Sodium (9.2 g.) was dissolved in absolute alcohol (150 c.c.) and, after addition of benzamidoxime hydrobromide (43.4 g.) and heptyl bromide (35.8 g.), was boiled for 6 hours. The alcohol was removed, and the residue treated with water and ether. The ethereal extract on distillation left a crystalline solid (42.7 g.) which distilled at 192°/11 mm. *O*-Heptylbenzamidoxime crystallised from ether in needles, m. p. 40—50° (Found: C, 71.9; H, 9.5. $C_{11}H_{21}ON$ requires C, 71.6; H, 9.5%). Attempts to convert this amidoxime into benzenyl chloride oxime *O*-heptyl ether by the action of nitrite in hydrochloric acid solution were unsuccessful. The amidoxime forms a sparingly soluble, oily hydrochloride which is not attacked by the nitrite, and an attempt to circumvent this by carrying out the reaction in glacial acetic acid with amyl nitrite and hydrochloric acid was also unsuccessful.

Ethylenedi-*O*-benzamidoxime Dihydrochloride.—Ethylene bromide (4.7 g.), benzamidoxime (6.8 g.), and absolute alcohol (20 c.c.), which had reacted with sodium, 1.2 g.) were boiled together for 4 hours. The alcohol was removed by distillation, and the residue dissolved in water and made alkaline by addition of excess of 2*N*-sodium hydroxide solution. The solid which separated was dissolved in 3*N*-hydrochloric acid and readily crystallised in needles; yield 1.1 g., m. p. 234—235° (Found: C, 51.8; H, 5.7. $C_{12}H_{18}O_2N_4 \cdot 2HCl$ requires C, 51.7; H, 5.4%). The hydrochloric acid mother-liquor on basification gave a further 0.25 g., m. p. 161°, of ethylenedibenzamidoxime base. No yields for this reaction are quoted by Falck (*Ber.*, 1886, 19, 1485) or by Werner and Gemseus (*ibid.*, 1896, 29, 1162).

1:6-Hexamethylenedi-*O*-benzamidoxime.—Sodium (4.6 g.) was dissolved in absolute alcohol (100 c.c.), and benzamidoxime hydrobromide (21.7 g.), dissolved in warm absolute alcohol (20 c.c.), was added; a sodium salt separated. Hexamethylene bromide (12.15 g.) was then added, and the solution boiled for 6 hours. The alcohol was removed, and the residue treated with water. *Hexamethylenedi-benzamidoxime* separated as an oil which soon solidified (14.7 g.). When crystallised from 70% alcohol and then from absolute alcohol it had m. p. 106° (Found: C, 67.2; H, 7.6; N, 15.5. $C_{20}H_{28}O_2N_4$ requires C, 67.7; H, 7.4; N, 15.8%). Attempts to convert this substance into hexamethylenedi-*O*-benzenyl chloride oxime were not successful.

1:12-Dodecamethylenedi-*O*-benzamidoxime.—Sodium (8.2 g.) was dissolved in absolute alcohol (250 c.c.), and benzamidoxime (21.7 g.) and dodecamethylene bromide (16.35 g.) added. The solution was boiled for 4 hours, the alcohol removed by distillation, and the residue made alkaline with *N*-sodium hydroxide solution. The oil which separated rapidly crystallised; yield 18 g. The crude *oxime* was very soluble in methyl alcohol but could best be crystallised from this solvent. It separated in broad short needles, m. p. 105—106° (Found: C, 71.4; H, 8.6. $C_{22}H_{30}O_2N_4$ requires C, 71.2; H, 8.7%). With 3*N*-hydrochloric acid it forms an oily hydrochloride.

Ethylenedi-*O*-benzophenone Oxime.—Benzophenone oxime (9.85 g.) and ethylene bromide (4.7 g.) were added to sodium ethoxide solution prepared from absolute alcohol (25 c.c.) and sodium (1.15 g.).

On boiling, sodium bromide rapidly separated; heating was continued for 6 hours. When cold, the sodium bromide and admixed needles were collected and the former removed by water, leaving the oxime (1.7 g.), which crystallised from absolute alcohol (60 c.c.) in pearly leaflets, m. p. 123–124° (Found: C, 80.3; H, 5.4; N, 6.4. $C_{16}H_{18}O_4N_2$ requires C, 80.0; H, 5.6; N, 6.7%). There was no evidence for the presence of any isomeric ether, the alcoholic mother-liquors giving only unchanged benzophenone oxime.

Preparation of Benzamidoxime Hydrobromide. Isolation of 2:4-Diphenyl-1:3:5-oxadiazole.—Phenyl cyanide (103 g.), hydroxylamine hydrochloride (69.5 g.), and anhydrous sodium carbonate (53 g.) were treated with water (150 c.c.), and ethyl alcohol added until the solution was homogeneous. The solution was boiled for 18 hours, the alcohol removed by distillation, and the aqueous residue extracted with ether. The ethereal extract was shaken with 24% aqueous hydrobromic acid (400 c.c.), and the latter on concentration gave a 76% yield of *benzamidoxime hydrobromide*, crystallising in prisms, m. p. 183° (Found: C, 39.0; H, 4.7. $C_7H_8ON_2 \cdot HBr$ requires C, 38.7; H, 4.2%). The ethereal solution on fractional distillation gave phenyl cyanide (9.5 g.) and a non-volatile crystalline residue (2.35 g.). The latter on crystallisation from methyl alcohol separated in long silky needles, m. p. 107°, which proved to be 2:4-diphenyl-1:3:5-oxadiazole (Found: C, 75.4; H, 4.8. Calc. for $C_{14}H_{10}ON_2$: C, 75.7; H, 4.5%). The final hydrobromic acid mother-liquor contained benzamide (4.0 g.).

Wolf (*Ber.*, 1898, **31**, 2111) gives m. p. 168° for benzamidoxime hydrochloride. In our hands this salt crystallised from alcohol and ether in stout prisms, m. p. 203° (Found: C, 48.9; H, 5.3; Cl, 20.5. Calc. for $C_7H_8ON_2 \cdot HCl$: C, 48.7; H, 5.3; Cl, 20.5%).

Our thanks are due to Mr. E. V. Wright for able assistance in the experimental work.

183. 3-Deoxy-1-xylose.

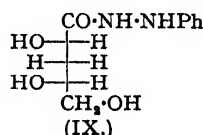

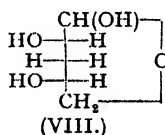

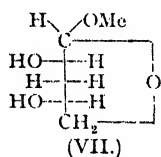

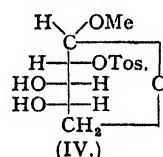

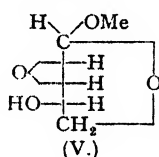

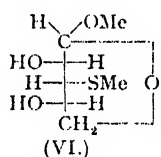

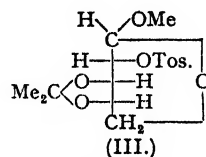

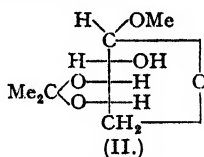

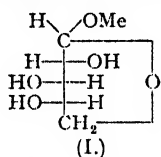

By S. MUKHERJEE and A. R. TODD.

In the course of experiments initiated in search of new synthetic routes to 2-deoxyribose derivatives, 2:3-anhydro- β -methyl-1-ribofuranoside, prepared from β -methyl-1-arabopyranoside, has been treated with sodium thiomethoxide and the product refluxed in alcohol with Raney nickel. The product was 3-deoxy- β -methyl-1-xylopyranoside containing at most only traces of a 2-deoxypentoside. Acid hydrolysis gave 3-deoxy-1-xylose as a syrup, characterised as its *p*-nitrophenylosazone, and yielding on oxidation *l*-erythro-1:3:4-trihydroxyvaleric acid isolated as its phenylhydrazide. Hydrogenolysis of the same anhydro-glycoside gave mainly 3-deoxy- β -methyl-1-xylopyranoside, apparently accompanied by a small amount of a 2-deoxypentoside, since the product showed a small uptake of oxidant on titration with periodate. 2:3-Anhydro- α -methyl-1-ribofuranoside treated in similar fashion with sodium thiomethoxide, followed by refluxing in alcohol with Raney nickel, also gave a product whose major constituent was 3-deoxy- α -methyl-1-xylopyranoside, since the syrupy sugar obtained from it by hydrolysis yielded 3-deoxy-1-xylose *p*-nitrophenylosazone on warming with *p*-nitrophenylhydrazine.

THE work described in this paper was undertaken in connection with studies on the synthesis of purine and pyrimidine nucleosides in progress in this laboratory, and which required for extension to the deoxyribonucleosides considerable quantities of 2-deoxy-*D*-ribose. 2-Deoxy-*L*-ribose has been prepared from *L*-arabinose (Levene and Mori, *J. Biol. Chem.*, 1929, **83**, 803; Levene, Mikeska, and Mori, *ibid.*, 1930, **85**, 785) using the standard glycol route first developed by Fischer (*Ber.*, 1914, **47**, 196), but the exploration of other routes which might give better yields of 2-deoxyribose derivatives seemed desirable. The use of 2:3-anhydro-sugar derivatives as intermediates in the synthesis of deoxy-hexoses has recently been described by Prins, Reichstein, and their co-workers who have prepared in this way various derivatives of 3-deoxy-*D*-glucose (Prins, *Helv. Chim. Acta*, 1946, **29**, 1), 2-deoxy-*D*-allose (Jeanloz, Prins, and Reichstein, *ibid.*, p. 371), cymarose (Prins, *ibid.*, p. 378) and 3-deoxy-*L*-mannose (Bollinger and Prins, *ibid.*, p. 1061). Following a discussion with the Swiss workers it was agreed that we should seek to apply similar methods in the pentose series in the hope that they would lead to a preparative method for 2-deoxyribose derivatives. For convenience we first carried out the proposed sequence of reactions starting with *L*-arabinose, which was expected to yield finally either 2-deoxy-*L*-ribose or 3-deoxy-1-xylose or possibly a mixture of both. In fact, it was found that 3-deoxy-1-xylose was formed as the main product; no 2-deoxy-*L*-ribose derivative could be isolated, although there was some evidence that traces of 2-deoxy-derivatives were formed.

β -Methyl-1-arabopyranoside (I) condensed with acetone to give an acetone derivative whose formulation as 3:4-isopropylidene β -methyl-1-arabopyranoside (II) follows from the transformations described below. Treatment of (II) with *p*-toluenesulphonyl chloride in pyridine yielded 2-*p*-tosyl 3:4-isopropylidene β -methyl-1-arabopyranoside (III) hydrolysed to 2-*p*-tosyl β -methyl-1-arabopyranoside (IV). The location of the tosyl group in (IV), and hence the structures

allotted to (II) and (III), are confirmed by the fact that on titration of (IV) with periodate 1 mol. of oxidant is consumed. Cold methanolic sodium methoxide converted (IV) into a crystalline anhydro-compound formulated from its mode of preparation as 2:3-*anhydro*- β -methyl-1-ribofuranoside (V) which, warmed with methanolic sodium thiomethoxide, yielded a syrupy sulphur-containing glycoside. Assuming a *trans*-opening of the ethylene oxide ring of (V) with inversion at the carbon atom to which the sulphur attaches itself this product might have been 3-methylthio β -methyl-1-xylopyranoside (VI), 2-methylthio β -methyl-1-arabopyranoside, or a mixture of both. Although from the experience of Jeanloz, Prins, and Reichstein (*loc. cit.*) in the *d*-allose series production of the 2-methylthio-product in reasonable amount might have been expected, subsequent reactions show that our product consisted almost entirely of (VI), the 2-methylthio-compound being present at most in traces. The syrupy methylthio-compound was refluxed in alcoholic solution with Raney nickel, prepared according to Mozingo *et al.* (*J. Amer. Chem. Soc.*, 1943, 65, 1013); it then yielded a sulphur-free glycoside which was stable to periodate, the uptake of oxidant on titration being within the limits of experimental error. This product we regard as 3-deoxy- β -methyl-1-xylopyranoside (VII). The possibility that it was contaminated by a trace of 2-deoxy- β -methyl-1-ribose cannot be excluded since it could not be crystallised and it gave a feeble green colouration in the Keller-Kiliani test commonly regarded as specific for 2-deoxy-sugars. Acid hydrolysis of (VII) yielded the free 3-deoxy-1-xylose (VIII) as a syrup yielding a crystalline *p*-nitrophenylosazone. The structure allotted to (VIII) was confirmed by oxidation with bromine water, lactonisation of the acid produced, and conversion into a crystalline phenylhydrazide, which agreed in m. p., analysis, and, within the limits of error, optical rotation with *l*(+)-*erythro*-1:3:4-trihydroxyvaleric acid phenylhydrazide (IX) prepared by Nef (*Annalen*, 1910, 376, 48), who on the basis of its dextrorotation described it as the *d*-*erythro*-compound.

As an alternative route the ethylene oxide ring in (V) was opened by hydrogenolysis under pressure using a nickel catalyst. The syrupy product produced was again mainly (VII) but there was more evidence of the presence of an appreciable amount of a 2-deoxy-pentose derivative, since the green colour produced in the Keller-Kiliani test, although weak, was stronger than in the case of the product obtained *via* the methylthio-glycoside, and on periodate titration 0.17 mol. of oxidant was consumed. On acid hydrolysis followed by treatment of the syrupy free sugar with *p*-nitrophenylhydrazine, however, only the *p*-nitrophenylosazone of 3-deoxy-1-xylose could be isolated. No further attempts were made to isolate any 2-deoxy-pentose present, since it was evident that even if they were successful the method would hardly be of preparative value.

In the preparation of β -methyl-1-arabopyranoside a considerable amount of a syrupy mixture of the α - and the β -isomer was left after removal of the crystalline β -compound. This syrup was condensed with acetone and the product tosylated. After separation of a quantity of the crystalline 2-*p*-tosyl 3:4-isopropylidene β -methyl-1-arabopyranoside the residual syrup was subjected to mild hydrolysis; from the resulting syrup 2-*p*-tosyl α -methyl-1-arabopyranoside was isolated. By methods exactly analogous to those used above in the β -series this compound

was converted into 2:3-anhydro- α -methyl-1-ribose, the latter reacted with sodium thiomethoxide, and the product treated with Raney nickel. The resulting syrup gave analytical values corresponding to a deoxy-methylpentoside, and from the fact that it consumed ca. 0.3 mol./mol. of periodate on titration it appeared to be a mixture of (VII) with a smaller amount of a 2-deoxy-compound; on hydrolysis and treatment of the product with *p*-nitrophenylhydrazine only 3-deoxy-1-xylose *p*-nitrophenylosazone was isolated. This was rather surprising in view of the periodate titration value mentioned above, but it is possible that this value may give an exaggerated estimate of the content of 2-deoxy-pentoside in the mixture.

The results obtained indicate that the projected route to 2-deoxyribose from arabinose via the 2:3-anhydroarabinosides is unlikely to be of any practical interest if, indeed, it can be realised. The route, however, does form a fairly convenient method for the preparation of 3-deoxy-1-xylose and its derivatives, since the overall yield from methyl-1-arabopyranoside is very satisfactory. Other possible routes to 2-deoxyribose derivatives are under investigation and will be reported upon in due course.

EXPERIMENTAL.

β -Methyl-1-arabopyranoside.—Following the procedure of Hudson (*J. Amer. Chem. Soc.*, 1925, **47**, 267) we obtained from *l*-arabinose (100 g.) pure β -methyl-1-arabopyranoside (32 g.), together with a syrupy mixture of the α - and the β -isomer (ca. 75 g.).

3:4-isopropylidene β -Methyl-1-arabopyranoside.—To an ice-cold suspension of finely powdered β -methyl-1-arabopyranoside (32 g.) in dry acetone (750 c.c.), phosphoric oxide (26 g.) was gradually added with stirring. The temperature was kept below 5° and stirring continued until the starting material dissolved (ca. 3 hours), then set aside overnight in the refrigerator. The supernatant liquid was decanted from the mixture of phosphoric acid, etc., which had settled to the bottom of the flask, and neutralised by gradually adding concentrated aqueous potassium hydroxide. The mixture was filtered and the filtrate concentrated under reduced pressure (bath temp. 35°). The syrupy product was distilled at 80–90° (bath temp.)/5 \times 10⁻⁴ mm. giving the isopropylidene derivative as a colourless syrup (29 g.; 72.5%). $[\alpha]_D^{20} +175.7^\circ \pm 0.5^\circ$ (c, 5.2 in chloroform) (Found: C, 53.3; H, 7.7. C₁₃H₁₈O₅ requires C, 52.9; H, 7.8%). The same product was obtained although in much lower yield by carrying out the condensation of β -methyl-1-arabopyranoside with acetone in presence of anhydrous copper sulphate and sulphuric acid.

2-p-Tosyl 3:4-isopropylidene β -Methyl-1-arabopyranoside.—*p*-Tosyl chloride (28.5 g.) was added to a solution of 3:4-isopropylidene β -methyl-1-arabopyranoside (27.3 g.) in dry pyridine (136 c.c.) and the mixture warmed at 40° for 24 hrs. A small amount of water (1 c.c.) was added, and the solution set aside at 0° for 30 minutes. More water (ca. 100 c.c.) and chloroform (ca. 250 c.c.) were added and the mixture was shaken. The chloroform layer was separated, and the aqueous layer extracted several times with small quantities of chloroform. The combined chloroform extracts were washed successively with ice-cold dilute sulphuric acid, sodium hydroxide, and water, dried (Na₂SO₄), and evaporated under reduced pressure. The residue recrystallised from alcohol gave colourless rod-shaped prisms (37.5 g.), m. p. 133°, $[\alpha]_D^{20} +187.3^\circ \pm 2^\circ$ (c, 1.55 in chloroform) (Found: C, 53.8; H, 6.1; S, 8.6. C₁₈H₂₂O₅S requires C, 53.6; H, 6.2; S, 8.9%).

2-p-Tosyl β -Methyl-1-arabopyranoside.—A solution of 2-p-tosyl 3:4-isopropylidene β -methyl-1-arabopyranoside (34 g.) in a mixture of methanol (1400 c.c.) and dilute sulphuric acid (280 c.c. of N) was heated at 40° for 4 hours; a further quantity of sulphuric acid (280 c.c. of N) was then added and the solution maintained at 40° for a further 4 hours, then cooled and neutralised by shaking with precipitated barium carbonate. Filtration followed by removal of solvents under reduced pressure (bath temp. 40°) gave a syrup which was taken up in ether; the solution was dried (Na₂SO₄) and evaporated. The residue solidified on removal of the last traces of solvent in a vacuum. The product (30 g.) could be purified by precipitation from ethereal solution with pentane; it then had m. p. ca. 43°, but was very hygroscopic. $[\alpha]_D^{20} +115^\circ \pm 1^\circ$ (c, 3.47 in chloroform) (Found: C, 49.1; H, 5.9. C₁₃H₁₈O₅S requires C, 49.0; H, 5.7%).

2:3-Anhydro- β -methyl-1-ribose.—Ice-cold methanolic sodium methoxide (75 c.c. of a solution prepared by dissolving 6 g. sodium in 100 c.c. methanol) was added to a solution of 2-p-tosyl β -methyl-1-arabopyranoside (28.2 g.) in chloroform (350 c.c.) at 0°, and the mixture set aside in the refrigerator for 3 days with occasional shaking, then left at room temperature for a further 24 hours and neutralised with *N*-sulphuric acid. The chloroform layer was separated and the aqueous layer extracted with chloroform, and the combined chloroform extracts were dried (Na₂SO₄) and evaporated under slightly reduced pressure (bath temp. 40°). The anhydro-glycoside was obtained as a colourless syrup (11.4 g.), which on being kept in a desiccator over phosphoric oxide slowly set to a mass of needles which were so hygroscopic that a satisfactory m. p. determination could not be made. $[\alpha]_D^{20} +35.7^\circ \pm 1^\circ$ (c, 2.7 in chloroform) (Found: C, 49.3; H, 6.9. C₈H₁₀O₄ requires C, 49.3; H, 6.9%).

3-Methylthio β -Methyl-1-xylopyranoside.—2:3-Anhydro- β -methyl-1-ribose (5 g.) was dissolved in methanolic sodium thiomethoxide (37.5 c.c. containing 1.87 g. of sodium and 5 g. of methylthiol) and the solution refluxed for 2 hours, then cooled, exactly neutralised with *N*-sulphuric acid, and evaporated to dryness under reduced pressure (bath temp. 40°). The residue was extracted with chloroform, and the extract dried (Na₂SO₄) and evaporated. The brownish syrup (6.9 g.) could be purified by chromatography on active alumina in benzene solution; a small amount of material passed through the column, and elution of the adsorbed material with methanol gave the product (0.8 g. from 1 g.) as a faintly yellow syrup (Found: C, 43.2; H, 7.2. C₇H₁₄O₄S requires C, 43.3; H, 7.3%).

3-Deoxy- β -methyl-1-xylopyranoside.—(1) From 3-methylthio β -methyl-1-ribosepyranoside. The crude methylthio-compound (6 g.) was dissolved in a mixture of alcohol (300 c.c.) and water (70 c.c.), and

Raney nickel (150 g. prepared according to Mzingo *et al.*, *loc. cit.*) added. The mixture was heated under reflux for 2 hours and filtered, the nickel being thoroughly washed with alcohol, and the combined filtrate and washings were evaporated under reduced pressure. The residue was dissolved in water (35 c.c.), the solution thrice extracted with chloroform, and the aqueous phase evaporated under reduced pressure (bath temp. 40°) to a syrup, which was dissolved in acetone (30 c.c.) and filtered from inorganic material, and the acetone again evaporated under reduced pressure. The residue so obtained distilled at 110° (bath temp.)/ 4×10^{-3} mm. as a colourless hygroscopic syrup (3.6 g.). $[\alpha]_D^{25} + 142.2^{\circ} \pm 5^{\circ}$ (c. 2.25 in chloroform) (Found: C, 48.0; H, 8.5. $C_6H_{12}O_4$ requires C, 48.6; H, 8.2%). The product was virtually unaffected by sodium metaperiodate (0.2163 g. consumed 0.02 c.c. of M-periodate in 24 hours; 0.07 c.c. in 48 hours) but it gave a feeble green coloration in the Keller-Kiliani test.

(2) From 2: 3-anhydro- β -methyl-*l*-ribosepyranoside. Raney nickel (4 g.) was added to the anhydro-compound (3.3 g.) dissolved in alcohol (60 c.c.) and the mixture hydrogenated at $110^{\circ}/100$ atm. during 24 hours. Catalyst was removed by filtration and the filtrate evaporated under reduced pressure, yielding a colourless syrup which distilled at $100-105^{\circ}$ (bath temp.)/ 10^{-3} mm. The product (2.2 g.) had $[\alpha]_D^{25} + 143^{\circ} \pm 4^{\circ}$ (c. 2.868 in chloroform) (Found: C, 48.7; H, 8.3; OMe, 19.9. $C_6H_{12}O_4$ requires C, 48.6; H, 8.2; OMe, 20.9). It gave a weak colour in the Keller-Kiliani test, and on titration with periodate it took up 0.17 mol. of reagent in 48 hours, suggesting that it may have been contaminated with some of the corresponding 2-deoxy-riboside.

3-Deoxy-1-xylose.—The syrupy glucoside obtained by method (1) above (0.3868 g.) was heated to 100° with dilute sulphuric acid (25 c.c. of 0.5N) until a constant rotation was attained (75 minutes). Specific rotations: after 60 minutes, $+8.4^{\circ}$, after 75 minutes, $+7.9^{\circ} \pm 1.5^{\circ}$ (constant). The solution was neutralised with freshly precipitated barium carbonate, filtered, and evaporated under reduced pressure. The residual syrup was evaporated once under reduced pressure with methanol and dissolved in absolute alcohol. Inorganic matter was precipitated by addition of ether and the solution evaporated under reduced pressure yielding the sugar as a colourless syrup which immediately reduced Fehling's solution but could not be crystallised (Found: C, 44.4; H, 7.7. $C_6H_{10}O_4$ requires C, 44.8; H, 7.5%). Calculated from the final rotation of the hydrolysis solution the sugar had $[\alpha]_D^{25} + 8.7^{\circ} \pm 1.5^{\circ}$.

A similar product was obtained by hydrolysing a sample of 3-deoxy- β -methyl-*l*-xylopyranoside prepared by method (2) above; the specific rotation became constant after 90 minutes at $+9^{\circ}$.

3-Deoxy-1-xylose *p*-Nitrophenylosazone.—This was prepared by heating 3-deoxy-1-xylose (230 mg. prepared *via* the methylthio-compound) in water (6 c.c.) with *p*-nitrophenylhydrazine (600 mg.) in glacial acetic acid (1 c.c.) for 1 hour on the steam-bath, and recrystallised from alcohol; dark red micro-crystalline powder, m. p. $254-256^{\circ}$ (Found: C, 51.2; H, 4.8; N, 20.9. $C_{11}H_{18}O_8N_2$ requires C, 50.7; H, 4.6; N, 20.9%). Similar treatment of a sample of the sugar prepared by the procedure involving hydrogenolysis of the anhydro-compound gave the same product, no other product could be isolated, although the m. p. of the crude osazone was somewhat lower.

1-erythro-1:3:4-Trihydroxyvaleric Acid Phenylhydrazide.—Bromine (0.25 c.c.) was added to a solution of 3-deoxy-1-xylose (470 mg.) in water (6 c.c.) and the mixture shaken in a closed vessel for 48 hours in the dark. Unchanged bromine was then removed under reduced pressure in a stream of air, the solution neutralised with freshly precipitated silver carbonate, and excess of silver removed with hydrogen sulphide. The solution obtained by filtering through charcoal was evaporated under reduced pressure and the residue evaporated once with methanol. The syrup (370 mg.) so obtained was lactonised by distillation at 120° (bath temp.)/ 3×10^{-4} mm. and the syrupy lactone (114 mg.) heated for 30 minutes at 100° with phenylhydrazine (100 c.mm.). After 3 hours a semi-crystalline mass had separated; ether was added and the colourless crystalline precipitate filtered off. Recrystallised from alcohol the hydrazide formed colourless needles, m. p. 149° , $[\alpha]_D^{25} + 4.5^{\circ} \pm 5^{\circ}$ (c. 0.4 in alcohol) (Found: N, 11.7. Calc. for $C_{11}H_{16}O_4N_2$: N, 11.7%). Nef (*loc. cit.*) records for *d*-erythro-1:3:4-trihydroxyvaleric acid phenylhydrazide, m. p. 150° and $[\alpha]_D^{25} + 9.4^{\circ}$.

2-*p*-Tosyl α -Methyl-*l*-arabopyranoside.—The syrupy residue remaining after removing the crystalline β -methyl-*l*-arabopyranoside from the glycosidisation mixture from 100 g. of *l*-arabinose was condensed with acetone (1700 c.c.) in presence of phosphoric oxide (60 g.) as described above for the pure β -compound. The product (40 g.), a mixture of the α - and the β -isomer of 3:4-isopropylidene methyl-*l*-arabopyranoside, distilled at $100-110^{\circ}$ (bath temp.)/ 10^{-3} mm. (Found: C, 52.8; H, 8.0. Calc. for $C_9H_{16}O_6$: C, 52.9; H, 7.8%).

The above α - β -mixture (40 g.) was dissolved in pyridine (200 c.c.) and tosylated as described under the β -compound. The product, a colourless syrup, was dissolved in a minimum amount of alcohol and set aside overnight in the refrigerator. Pure 2-*p*-tosyl 3:4-isopropylidene β -methyl-*l*-arabopyranoside (17.5 g.) separated, m. p. and mixed m. p. 135° . The alcoholic mother liquor gave on evaporation a syrup (42 g.) which was hydrolysed for 8 hours with methanol (1600 c.c.) and dilute sulphuric acid (650 c.c. of N). The hydrolysis solution was neutralised with precipitated barium carbonate, filtered, and evaporated under reduced pressure giving a syrup containing some crystalline material. This product was dissolved in ether, dried (Na_2SO_4), concentrated to ca. 250 c.c., and set aside overnight in the refrigerator. 2-*p*-Tosyl α -methyl-*l*-arabopyranoside separated as colourless needles (5.3 g.), m. p. $129-130^{\circ}$, $[\alpha]_D^{25} - 15.4^{\circ} \pm 0.4^{\circ}$ (c. 4.88 in chloroform) (Found: C, 48.8; H, 5.7; S, 10.2. $C_{12}H_{18}O_6S$ requires C, 49.0; H, 5.7; S, 10.1%). On titration with sodium metaperiodate 1.1 mols. of oxidant were taken up.

2:3-Anhydro- α -methyl-*l*-ribosepyranoside.—Prepared from 2-*p*-tosyl α -methyl-*l*-arabinoside (3.8 g.) in a manner similar to that described above for the β -isomer, the anhydro-compound (1.7 g.) was obtained as a syrup which crystallised on being kept for a few days in a desiccator and then had m. p. ca. 73° (sealed tube); $[\alpha]_D^{25} - 145.1^{\circ} \pm 3^{\circ}$ (c. 1.9 in chloroform) (Found: C, 49.2; H, 6.9. $C_6H_{10}O_4$ requires C, 49.3; H, 6.9%).

When the anhydro-compound (1.7 g.) was treated with methanolic sodium thiomethoxide and the product refluxed in alcohol with Raney nickel as described for the β -isomer, a hygroscopic syrup (1 g.) was obtained which distilled at $100-105^{\circ}$ (bath temp.)/ 10^{-3} mm. and had $[\alpha]_D^{25} - 141.8^{\circ} \pm 1^{\circ}$ (c. 2.48 in chloroform) (Found: C, 48.0; H, 8.0. Calc. for $C_6H_{12}O_4$: C, 48.6; H, 8.2%). It gave a weak green

Keller-Kiliani reaction and on titration with periodate took up ca. 0.3 mol./mol. That it contained 3-deoxy- α -methyl-*l*-xylopyranoside as its major constituent was proved by hydrolysis with 0.5*N*-sulphuric acid (specific rotations: after 20 minutes in the cold, -116° ; after 30 minutes' heating, -3.4° ; after 45 minutes' heating, $+4.5^\circ$ constant) when a syrupy sugar was obtained (Found: C, 44.4; H, 7.7. Calc. for $C_8H_{10}O_4$: C, 44.8; H, 7.5%). Warmed with *p*-nitrophenylhydrazine the sugar yielded 3-deoxy-*l*-xylose *p*-nitrophenylosazone, m. p. 254° undepressed in admixture with an authentic specimen (m. p. $254-256^\circ$) prepared above from the β -methylglycoside; no other crystalline material was isolated.

184. *An Experimental Study of the Alkylation of Aromatic Amines using (1) Aluminium Alkoxides and (2) Alumina with Alcohols.*

By J. CAMPBELL EARL and NOEL G. HILLS.

The alkylation of aniline salts and complexes by means of aluminium alkoxides has been explored, and the influence of various anions and cations present on the rate of alkylation roughly examined. The vapour-phase methylation of methylaniline with methanol in the presence of alumina has also been studied in some detail, together with the effect on the rate of *N*-alkylation and on the tendency towards nuclear alkylation of the addition to the catalyst of various metallic salts.

THE demand for *N*-alkylated amines for war purposes led the authors to a review of alternative methods of alkylation which might be preferable in some respects to those at present used industrially. Some of the experimental results obtained with two such methods are described here. Not enough evidence is available to indicate whether the two processes under consideration differ fundamentally from one another or whether either or both of them involve the same reacting entities as the other known alkylation processes. It would therefore be premature to introduce a theoretical discussion at this stage. The catalytic action of alumina presents many points of interest which have often been discussed in the literature. Further information will no doubt be gained from a strictly quantitative study of the vapour-phase alkylation process. Requirements of such a study include rigid temperature control and a constant rate of passage of the reaction mixture over the catalyst. The considerable mechanical difficulties involved in meeting these requirements are gradually being overcome and it is hoped that the experimental results eventually obtained will be precise enough to justify theoretical treatment. Meanwhile, many of the facts brought to light during our preliminary studies seem to be of sufficient interest to describe here.

(1) *Alkylation of Aniline Salts and Complexes with Aluminium Alkoxides.*—Lazier and Adkins (*J. Amer. Chem. Soc.*, 1924, 46, 741) described the successful alkylation of aniline by heating it with the requisite aluminium alkoxide in a sealed tube at $250-350^\circ$. It is possible, however, to alkylate salts of aniline or aniline-metallic salt complexes under atmospheric pressure with aluminium alkoxides at considerably lower temperatures than those needed for aniline itself. The following table summarises a series of experiments in which various aniline salts were mixed with four times the amount of aluminium ethoxide required for complete diethylation and heated under a reflux condenser for several hours. The ease of alkylation of the iodide is

Salt.	Temp.	Time, hours.	Primary base in product, %.
Ph·NH ₂ Cl	184°	5	91.8
Ph·NH ₂ Br	184	5	46.7
Ph·NH ₂ I	184	5	2.4 *
Ph·NH ₂ Br	198	5½	6.3
(Ph·NH ₂) ₃ PO ₄	198	5½	91.3
(Ph·NH ₂) ₂ SO ₄	240	5	30.0

* Tertiary base 18.6%.

remarkable but is in agreement with a recorded observation that the direct action between alcohols and aniline is catalysed by iodides (Brit. Pat. 145,743).

Complexes of aniline with metallic salts can also be ethylated by a similar procedure, but the reaction does not take place as readily as with the anilinium salts:

Complex.	Temp.	Time, hours.	Primary base in product, %.
CdSO ₄ ·2Ph·NH ₂	240°	5	69.8
ZnSO ₄ ·2Ph·NH ₂	240	5	80.3
ZnCl ₂ ·2Ph·NH ₂	240	5	56.2
ZnBr ₂ ·2Ph·NH ₂	240	5	41.8
NiCl ₂ ·2Ph·NH ₂	240	5	90.3

It is evident that both cations and anions have an influence on the rate of alkylation.

The addition of sodium halides to reaction mixtures containing anilinium halides generally increased the rate of alkylation:

Anilinium salt.	Added salt.	Temp.	Time, hours.	Primary base in product, %.
Ph·NH ₃ Cl	NaCl (1 mol.)	184°	5	44·1
Ph·NH ₃ Cl	NaCl (2 mols.)	184	5	27·4
Ph·NH ₃ Br	NaBr (1 mol.)	183	5	43·6
Ph·NH ₃ Br	NaBr (1·5 mols.)	184	5	34·3

Some experiments on the *n*-butylation of aniline hydrochloride were made in which the different sodium halides were used as catalysts:

Na halide per mol. of Ph·NH ₃ Cl.	Temp.	Time, hours.	Composition of basic product:		
			Primary, %.	Secondary, %.	Tertiary, %.
NaCl (1 mol.)	198°	16	65·1	34·9	—
NaBr (1 mol.)	198	10	43·3	48·7	8·0
NaI (1 mol.)	198	10	3·3	64·0	32·7

The following routine was adopted for isolating and examining the products from all experiments. The reaction mixture was mixed with a concentrated solution of sodium hydroxide and steam-distilled until no further oil came over. The distillate was extracted thoroughly with ether, and the ethereal solution dried with sodium sulphate. After removal of the ether the bases were distilled. If the distillation temperature indicated that no high-boiling fraction was present, the absence of important amounts of tertiary amine was assumed and no attempt was made to estimate it. Aniline in the product was determined by taking advantage of the fact that it forms a stable complex CdCl₂·Ph·NH₃, precipitated when it is shaken with a saturated aqueous solution of cadmium chloride. The secondary and tertiary bases do not form water-stable complexes with cadmium chloride. For the actual estimation about 1 g. of the mixed bases was weighed in a 25-ml. graduated flask and 20 ml. of light petroleum (b. p. 40—60°) added with just sufficient 1:4-dioxan to form a homogeneous solution. The volume was then made up to 25 ml. with more light petroleum. Then 2 ml. of this solution, or more if the aniline content was low, were run into a small separating funnel and shaken with 3 ml. of saturated cadmium chloride solution. The white complex salt was immediately precipitated together with some cadmium chloride. Generally, most of the precipitate adhered to the wall of the funnel. The liquid was run off through a fritted-glass filter, and the precipitate remaining, partly in the funnel and partly on the filter, was washed with a little light petroleum. The precipitate was then dissolved in 10% hydrochloric acid and titrated with standard bromide-bromate solution and thiosulphate, and the result calculated as aniline. When the preliminary distillation showed the presence of much tertiary amine the above procedure was supplemented by an acetylation of the total bases with a known weight of acetic anhydride and determination of the amount unused after half an hour by decomposition with water and titration with alkali.

(2) *The Vapour-phase Methylation of N-Methylaniline by Methanol in the Presence of an Alumina Catalyst.*—Mailhe and de Godon (*Compt. rend.*, 1918, 166, 467, 564; 1920, 171, 1154; 1921, 172, 1417) successfully alkylated aromatic amines by passing the mixed vapour of the amine and the requisite alcohol over a heated alumina catalyst. The reaction was further studied by Schujkin, Balandin, and others (*J. Gen. Chem. Russ.*, 1934, 4, 1444; *J. Physical Chem.*, 1935, 39, 1192), especially in respect of the effect of other oxides in admixture with the catalyst. In general, the other oxides diminished the activity of the catalyst, but were sometimes beneficial in inhibiting side reactions.

The large-scale manufacture of alkylated anilines by vapour-phase catalytic methods was successfully practised during the war. With suitably chosen catalysts, much lower temperatures than those specified by the above-mentioned workers (350—400°) were effective in bringing about a high degree of alkylation. It was, therefore, of interest to study the reaction more closely and especially to search for promoters which would increase the activity of the catalyst. To enable large numbers of experiments to be performed in reasonable time, their scale was kept as small as possible. The methods used for the analysis of the products were chosen for their rapidity and reproducibility rather than for their absolute accuracy. The experiments here described were exploratory and only roughly quantitative and were intended to give the preliminary information needed for planning more strictly quantitative work on the reaction. However, they themselves led to definite and interesting conclusions, which justify their description at this stage.

The apparatus used was simple. The liquid mixture of alcohol and amine (with any miscible promoting agent, if used) was placed in a feed chamber terminating in a capillary which projected well into the catalyst tube. A finely adjustable pressure of nitrogen was maintained above the reaction mixture to regulate its speed of introduction, and a by-pass also admitted a regulated stream of nitrogen into the catalyst tube. The tube itself was 35 cm. long and 13 mm. in diameter and terminated in a beak to facilitate the collection of the products in a small flask. The temperature of the catalyst mass was observed by means of a thermometer immersed in it. The tube was heated in an electric furnace.

To avoid unnecessary complications in the analysis of the products, attention was concentrated on the second stage of the methylation of aniline, namely, the conversion of *N*-methyl- into *NN*-dimethylaniline. Accompanying this reaction there is also some nuclear alkylation, the amount of which varies considerably according to the catalyst and experimental conditions used. The principal nuclear alkylation product to be expected is *N*-methyl-*p*-toluidine because it is known that in the large-scale methylation and ethylation of aniline the nuclear by-products consist mainly of *N*-methyl-*p*-toluidine and *N*:*p*-diethylaniline respectively [private communication from F. Kaufer and (Miss) J. Fildes]. A rapid, approximate method of determining the amounts of *N*-methylaniline, *N*-methyl-*p*-toluidine, and *NN*-dimethylaniline in the presence of one another depends on a combination of acetylation and refractive-index measurement. The secondary bases can be determined by quantitative acetylation, and the sum of *N*-methyl-*p*-toluidine and *NN*-dimethylaniline by measurement of the refractivity of the mixed bases. The refractive indices (n_D^{20}) of the three bases are: *N*-methylaniline, 1.5714; *NN*-dimethylaniline, 1.5587; *N*-methyl-*p*-toluidine, 1.5582.

The catalytic activity of alumina, it is well known, varies greatly with the method of preparation. For these experiments, with a few exceptions specifically mentioned, the catalyst was made by decomposing aluminium *n*-butoxide with water, and drying and heating the product at 400° for 2 hours. It was then broken up and sifted, the fraction passing a 10-mesh and retained by a 20-mesh sieve being used. The weight of catalyst used for each experiment was 3 g., occupying approximately 10 c.c.

When the effect of a promoter in the catalyst itself was being examined, a quantity equivalent to 0.5 g. of sodium iodide was dissolved in methanol or aqueous methanol and mixed with 3 g. of the alumina, the solvent being then removed by heating on a water-bath.

For each of the experiments tabulated below, a reaction mixture containing 2 g. of *N*-methylaniline and 0.6 g. of methanol was introduced during 3½ hours into the catalyst tube, heated at 250° unless otherwise specifically mentioned.

In view of the accelerating effect of iodides in the alkylation of aniline salts by aluminium alkoxides mentioned above, a series of experiments were made using iodine or iodides in the reaction mixture. The percentage of acetyltable bases in the product was determined and calculated as monomethylaniline. The same charge of catalyst was used for the whole series of 11 experiments.

Amt. of iodine or iodide added.	Acetyltable bases expressed as NHPhMe, %.	Amt. of iodine or iodide added.	Acetyltable bases expressed as NHPhMe, %.
(None)	73.0	None	59.0
0.5% CH ₃ I	67.5	None	64.0
0.9% CH ₃ I	57.2	None	70.0
1.0% NH ₂ PhMeI	46.5	1% I	56.5
1.5% NH ₂ PhMeI	46.5	1% I	49.3
None	52.0		

These results show that iodine and iodides have a strongly accelerating effect on the reaction and that the effect is retained by the catalyst for some time.

When *N*-methylanilinium chloride is added to the reaction mixture there is not a marked increase in *N*-alkylation but a certain amount of nuclear alkylation takes place. The catalyst in this group of experiments was that used on the manufacturing scale for the methylation of aniline.

NH ₂ PhMeCl added, %.	NHPhMe in product, %, from refractivity.	Acetyltable bases, %, calc. as NHPhMe.	Diff. due to nuclear alkylation.
None	43	42	- 1
None	42	43	1
None	45	49	4
5%	38	43	5
None	25	40	15
None	31	43	12
None	38	44	6
None	38	45	7
2½%	38	44	6
2½%	39	41	2
2½%	38	53	15
None	38	47	9
None	37	43	6
None	43	42	- 1

It is clear from the above two series of experiments that a lag must be expected when a promoter is introduced with the reaction mixture, the promoted catalyst not showing its full activity for some time. The second series also shows what degree of accuracy is to be expected from the method described for estimation of nuclear alkylation.

A third series of experiments shows the effect of adding to the catalyst itself various salts which might be expected to have some effect in increasing the activity of the catalyst or in promoting nuclear alkylation. Each group of four experiments, three at 250° and one at 290°, was done with one charge of catalyst, a fresh charge being then introduced for the next group.

Temp.	Salt added.	NHPhMe, % from refrac-tivity.	Acetyl-atable bases, % as NHPhMe.	Diff. (nuclear alkyl-ation).	Temp.	Salt added.	NHPhMe, from refrac-tivity.	Acetyl-atable bases, % as NHPhMe.	Diff. (nuclear alkyl-ation).

250	NiCl ₂	15.6	22.2	6.6	250	FeCl ₃	15.0	43.7	28.7
250	NiCl ₂	22.5	26.3	3.8	250	FeCl ₃	16.4	40.5	24.1
290	NiCl ₂	14.0	56.0	42.0	290	FeCl ₃	15.6	58.2	42.6
250	CuCl ₂	11.2	43.3	32.1	250	SnCl ₂	9.0	21.8	22.8

Although the figures in the above table show certain obvious irregularities, and minor variations in the values in cols. 3 and 5 cannot be regarded as having any real significance, yet there are major trends which lead to useful conclusions. All the salts used, except sodium chloride, increased the activity of the catalyst at 250°. Raising the temperature from 250° to 290° increased the rate of alkylation with pure alumina and when sodium halides, manganese chloride, or zinc chloride was present; but cobalt and cadmium chlorides definitely depressed the rate of alkylation at the higher temperature. Whilst with pure alumina there is no significant amount of nuclear alkylation even at 290°, yet most of the added salts promoted nuclear alkylation at that temperature and sometimes at 250° also.

The practical experience gained with the simple apparatus showed clearly that for a quantitative study of the kinetics of the alkylation reaction it would require much modification. This work has been undertaken and will be described in a later paper.

The authors' thanks are due for the award of a Commonwealth Government Scholarship to one of them (N. G. H.).

THE UNIVERSITY, SYDNEY, N.S.W.

[Received, October 17th, 1946.]

185. Reactions of Alkylisoformanilides. Part III. With Phenols.

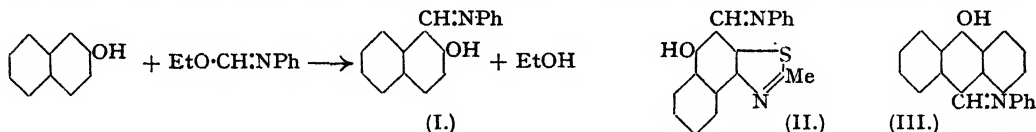

By EDWARD B. KNOTT.

Ethylisoformanilide will react with polycyclic phenols containing a free, active *o*- or *p*-position to form hydroxyanils. Phenol does not react, but various substituted monocyclic phenols showed slight activity. The reagent may be formed *in situ* by using mixtures of ethyl orthoformate and aniline or diphenylformamidine. Replacement of the aniline by other aromatic amines leads to analogues. The reaction may be used as a qualitative test for reactive phenols since all the anils are highly coloured.

In Parts I and II (*J.*, 1945, 686; *J.*, 1946, 120) of this series the activity of alkylisoformanilides towards substances containing reactive or ionisable hydrogen has been described. It was of interest to determine the reactivity of these reagents towards polycyclic phenols, since the latter contain both ionisable and reactive hydrogen atoms.

Although phenol did not react with ethylisoformanilide at temperatures up to 220°, the naphthols showed considerable reactivity even in boiling ethanol, and particularly at temperatures above 100°. The product from β -naphthol, an intensely yellow compound, was homogeneous, and was 2-hydroxy-1-naphthaldehyde anil (I). The orange solid from α -naphthol appeared to be a mixture of anils. The naphthols function therefore like substances containing a reactive methyl or methylene group, and the reaction is not dissimilar to the coupling with

diazonium salts. A variety of phenols were then heated with the reagent, the formation of colour being taken as an indication of reaction. Amongst the monocyclic phenols, the cresols and polyhydroxybenzenes all gave yellow colours but no products were isolated. Polycyclic phenols with active *o*- or *p*-positions gave colours varying from yellow to red. Substances of this type not containing an active hydrogen in the *o*- or *p*-position, such as 1-bromo-2-naphthol,

8-hydroxyquinoline, 4'-hydroxy-2:3'-dimethylnaphtha-1':2':4:5-thiazole, or 2-acetyl-1-naphthol, did not give any colour. Two other anils were isolated, *viz.*, 4'-hydroxy-2-methyl-naphtha-1':2':4:5-thiazole-3'-aldehyde anil (II) and 9-hydroxy-10-anthraldehyde anil (III). The latter gave an intense red solution in aqueous sodium hydroxide. Its solution in acetic acid developed a similar intense red colour on the addition of concentrated hydrochloric acid, the colour fading rapidly as hydrolysis to the aldehyde occurred. The aldehyde differed in m. p. from that given in F.P. 648,069 for the product obtained from 9-hydroxyanthracene formomethylanilide and phosphorus oxychloride; but since in no case was reaction observed where both *o*- and *p*-positions were blocked, it is most likely that the aldehyde group in the present substance was introduced into the 10-position. Somewhat lower yields of anil may be obtained by the formation of the reagent *in situ*. This can be achieved (*cf.* Claisen, *Annalen*, 1895, 287, 365) by fusing the phenol with mixtures of aniline or diphenylformamidine and ethyl orthoformate. Other aromatic amines may replace the aniline to give analogues.

Substance.	Colour.
Phenol	None
<i>m</i> -Cresol	Yellow
<i>o</i> - and <i>p</i> -Cresol	Faint yellow
Resorcinol	Yellow
Adrenalin.....	Red
<i>o</i> -Hydroxybenzylideneacetone	Yellow
2:5-Dihydroxydiphenyl	Orange-yellow
β -Naphthol	Yellow
α -Naphthol	Orange
1:5-Dihydroxynaphthalene	"
1-Bromo-2-hydroxy-naphthalene.....	None
1-Hydroxy-2-acetylnaphthalene	"
1-Hydroxy-4-phenylnaphthalene	Yellow
1-Hydroxy-4-furylnaphthalene-3-carboxylic acid	"
9-Hydroxyanthracene	Orange-red
4-Hydroxy-7-phenylcoumarone-6-carboxylic acid	Yellow
8-Hydroxyquinoline	None
2-Amino-6-hydroxypyridine sulphate	Orange
Aesculin	"
2-Hydroxy-3:4-benzfluorene	Red
4'-Hydroxy-2-methylnaphtha-1':2':4:5-thiazole	Orange-red
2-Acetamido-4'-hydroxynaphtha-1':2':4:5-selenazole	Red
4'-Hydroxy-2:3'-dimethylnaphtha-1':2':4:5-thiazole	None
4'-Hydroxy-2-methylphenanthra-1':2':4:5-thiazole	Red
1'-Hydroxy-2-methylphenanthra-4':3':4:5-thiazole	"
4'-Hydroxy-2-methylthionaphtheno-7':6':4:5-thiazole	Orange

The reaction may be used as a sensitive test for many phenols since the reaction products are highly coloured. The table indicates the colours obtained on boiling a small quantity of the phenol with an excess of reagent in a test-tube over a free flame.

EXPERIMENTAL.

(Microanalyses are by Drs. Weiler and Strauss, Oxford; m. p.'s uncorrected.)

2-Hydroxy-1-naphthaldehyde Anil (I).—(a) β -Naphthol (14.4 g.; 0.1 mol.) and ethylisoformanilide (14.9 g.; 0.1 mol.) were fused at 160° for 30 minutes, by which time the evolution of ethyl alcohol had ceased. Methyl alcohol (5 c.c.) was added to the melt. The yellow solid (17.0 g., 81%) crystallised as glossy needles, m. p. 92°, with an intense green fluorescence to ultra-violet light, when the methyl alcoholic solution was chilled, or shiny plates, m. p. 92°, with no fluorescence in ultra-violet light, if the same solution were allowed to cool (Found: C, 82.3; H, 5.4; N, 5.75. Calc. for C₁₇H₁₃ON: C, 82.55; H, 5.3; N, 5.65%).

(b) β -Naphthol (2.88 g.; 0.02 mol.), diphenylformamidine (2.92 g.; 0.02 mol.), and ethyl orthoformate (2.96 g.; 0.02 mol.) were fused at 150° for 60 minutes. After cooling, light petroleum was added and the whole shaken until the melt had solidified. From methyl alcohol (10 c.c.), 2.25 g. (46%) of the anil were obtained. If the ethyl orthoformate is omitted a yellow colour develops but the yield of anil is very low.

2-Hydroxy-1-naphthaldehyde p-Methoxyanil.— β -Naphthol (5.96 g.; 0.04 mol.), ethyl orthoformate (5.92 g.; 0.04 mol.), and *p*-anisidine (4.92 g.; 0.04 mol.) were fused at 145° for 60 minutes. The melt gave a crystalline solid on addition of methyl alcohol. From the same solvent it formed bright yellow needles, m. p. 111°, in 65% yield (Found: N, 5.1. $C_{18}H_{15}O_2N$ requires N, 5.05%).

9-Hydroxy-10-anthraldehyde Anil (III).—9-Hydroxyanthracene (3.84 g.; 0.02 mol.) and ethylisoformanilide (3 g.; 0.02 mol.) were fused at 180° for 60 minutes. Ethyl alcohol (10 c.c.) was added to the red melt, and the orange-red crystalline solid (4.9 g., 82.5%) was collected and washed with alcohol. It formed garnet red crystals, m. p. 204°, from acetic acid (Found: N, 4.95. $C_{21}H_{18}ON$ requires N, 4.7%).

9-Hydroxyanthracene-10-aldehyde. The anil (2 g.) was dissolved in boiling acetic acid (20 c.c.), and concentrated hydrochloric acid (4 c.c.) added. The intense red colour so formed slowly faded as the aldehyde crystallised. It formed flat, creamy needles, m. p. 230° onwards, from benzene (Found: C, 81.3; H, 4.4. $C_{18}H_{10}O_2$ requires C, 81.05; H, 4.55%).

4'-Hydroxy-2-methylnaphtha-1':2':4:5-thiazole-3'-aldehyde Anil (II).—4'-Hydroxy-2-methylnaphtha-1':2':4:5-thiazole (10.75 g.; 0.05 mol.) and ethylisoformanilide (14.9 g.; 0.1 mol.) were fused at 170° for 60 minutes. On cooling, the orange melt solidified. It was ground with alcohol and well washed with the same solvent. It formed orange needles (13.2 g. = 86% yield), m. p. 228°, from benzene (Found: N, 8.5; S, 9.8. $C_{18}H_{14}ON_2S$ requires N, 8.8; S, 9.75%). The aldehyde was obtained by dissolving the anil (2 g.) in dioxan (30 c.c.), adding concentrated hydrochloric acid (10 c.c.) and water (10 c.c.), and heating for 30 minutes on the steam-bath. The solid was dissolved in an excess of 2*N*-sodium carbonate, filtered from a little unhydrolysed anil, and the yellow solution acidified. From ethyl alcohol it formed yellow-green needles, m. p. 160° (Found: S, 13.1. $C_{13}H_6O_2NS$ requires S, 13.2%).

NOTE.

Infra-red Spectrum and Structural Diagnosis: Substituted Carbazoles. By R. E. RICHARDS.

THIS note describes an example, not only of the value to the organic chemist of infra-red measurements in structural diagnosis, but also of an experimental method developed in this laboratory for measuring the spectra of very small amounts of material. A sample was received for examination which had been formed by degradation of a substance of which the structure was not completely known. The specimen was a crystalline solid, only 1.5 mg. being available, and was suspected to be a mixture of carbazole and one or more of its methyl derivatives. It was required to determine which methyl derivatives were present and approximately in what proportions.

The experimental method had been mentioned by early workers (see also Thompson, *J.*, 1944, 191), but had not been widely used until it was developed in this laboratory in connection with recent studies on penicillin.

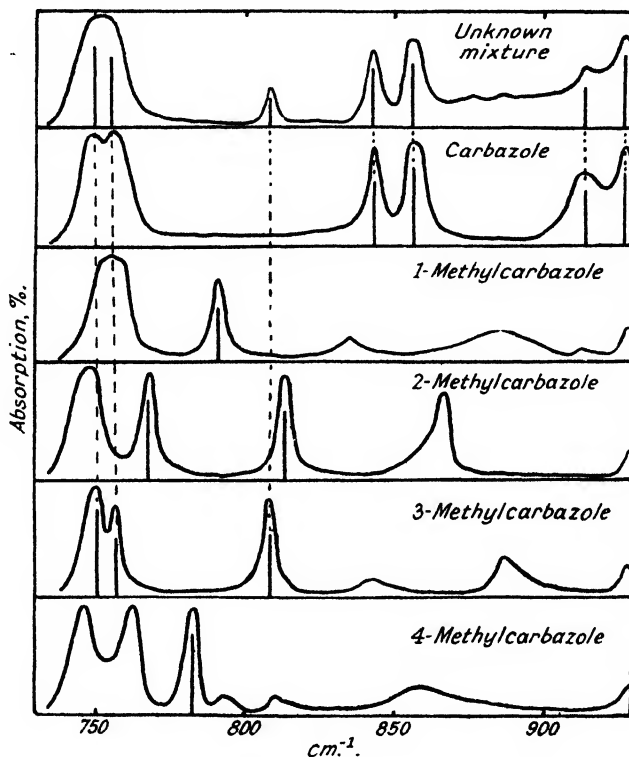

The specimen is ground to a very fine powder in a small glass or agate mortar. A suitable glass mortar can easily be made by rounding off a short piece of narrow glass tubing, and a piece of well-fitting glass rod with rounded end is used as the pestle; a small quantity of dry medicinal paraffin is then added to the powder, and the whole is ground to a smooth paste. This is transferred to a rock-salt plate, about 1.5 × 0.5 cm. in area, and another similar plate is placed on top. With the aid of a small spatula it is possible to prepare the specimen as a long narrow film between the plates, and almost any desired thickness can be obtained by appropriate manipulation, although it is obviously impossible to obtain an exact measure of the thickness of the absorbing layer. No clamping device or spacing washer is necessary, since the surface tension of the oil is sufficient to hold the plates together. The plates are placed on a flat platform so that the film lies exactly at a sharply focused image of the source of radiation, which is usually a Nernst filament. The sample, when thus prepared, causes very little scattering of the infra-red radiation, and a good spectrum can be obtained. The paraffin has strong absorption bands at about 720, 1375, 1460, 2850, 2925 cm^{-1} , but in all other regions of the spectrum it shows no appreciable absorption except in very thick layers. When the spectrum has been measured, a large proportion of the sample can be recovered by extraction with a suitable solvent or by washing away the paraffin with a solvent which does not dissolve the specimen.

This method is often preferable to the alternative procedure of measuring the spectrum in solution; it is very simple, quick, and requires little of the sample. If it is desired to study such a small quantity of a specimen in solution, arrangements must be made to recover it from the solution in the absorption cell, and this requires a rather elaborate technique. This may, however, be essential, since more than one solvent must be used in order to cover the whole range of the infra-red spectrum, no single solvent being available which is completely transparent over the whole spectral range 1–14 μ . Such difficulties imply that in many cases the measurements in solution are impossible. In some circumstances it is useful to study the whole range of the spectrum of the solid as above, then to recover the sample, and to study some particularly interesting region in a suitable solvent which is transparent in that particular range.

The spectrometer used in this problem was a single-beam recording instrument, using a rock-salt prism (Whiffen and Thompson, *J.*, 1945, 268).

Results.—The figure shows the spectrum, over the range 730–930 cm^{-1} , of the unknown mixture,

together with the spectra of pure samples of carbazole and 1-, 2-, 3-, and 4-methylcarbazoles, obtained by the same method. Key bands are emphasised by the vertical lines. The presence of carbazole in the mixture is confirmed by the complete correspondence between the bands in the pure specimen and similar bands in the mixture. The complete absence of bands at either 790 or 782 cm^{-1} indicates the absence of 1- and 4-methylcarbazoles, whereas the band in the mixture at 808 cm^{-1} exactly corresponds to the strong key band of 3-methylcarbazole at this frequency—its weaker band at 886 cm^{-1} is lost between the strong bands of carbazole itself at 856 and 915 cm^{-1} . The strong key bands of 2-methylcarbazole lie rather close to those of 3-methylcarbazole and make it impossible to establish the complete absence of the former, although if it is present, it can only be in very small amounts, for not a trace of the band at

767 cm^{-1} appears in the mixture, and the band at 808 cm^{-1} is not broadened noticeably towards 813 cm^{-1} . It was therefore concluded that the unknown mixture contained mostly carbazole and 3-methylcarbazole. Comparison of the original spectrum with mixtures made from the pure materials shows that the unknown mixture contained between 5% and 12% of 3-methylcarbazole. A closer estimate of the relative proportions was not justifiable owing to the unknown differences in thickness and homogeneity of the different solid samples studied, but if larger amounts of material were available, solutions could be made up and compared with solutions of either the pure components or known match mixtures, so as to obtain a far more exact quantitative estimate.

I should like to thank Mr. K. H. Pausacker, who prepared the pure materials used in this investigation, and the Department of Scientific and Industrial Research for a maintenance grant.—THE PHYSICAL CHEMISTRY LABORATORY, SOUTH PARKS ROAD, OXFORD. [Received, October 24th, 1946.]

Twelfth Report of the Committee on Atomic Weights of the International Union of Chemistry.

By G. P. BAXTER (Chairman), M. GUICHARD, O. HÖNIGSCHMID, and R. WHYTLAW-GRAY.

OWING to delays in communication it was impossible for the Committee to publish a report in 1942. The following report therefore covers the two-year period from September 30, 1940, to September 30, 1942. No changes have been made in the table, although the new values for samarium and ytterbium appear to be more reliable than those given in the table.

Carbon.—Murphy and Nier (*Physical Rev.*, 1941, 59, 771) have determined with a mass spectrometer the abundance ratio of ^{12}C to ^{13}C in carbon from different sources to fall between 88.8 and 93.1, corresponding to the values 12.0117 and 12.0112 for the atomic weight of carbon. Both values support the existing chemical evidence that the atomic weight of carbon is very close to 12.01.

Oxygen.—Murphy (*ibid.*, p. 320) with a mass spectrometer finds the abundance ratio of ^{16}O to that of ^{18}O to be 500 ± 15 to 1. This confirms the value of Smythe, 503 ± 10 , and the conversion factor 1.000275.

Fluorine.—Hutchison and Johnston (*J. Amer. Chem. Soc.*, 1941, 63, 1580) have computed the atomic weight of fluorine from density and X-ray data of lithium fluoride and calcite, using the equation

$$\text{LiF} = \left[\frac{\text{CaCO}_3 \times d_{\text{LiF}}}{d_{\text{calcite}} \times \phi_{\text{calcite}}} \times R^3 \right]$$

where ϕ_{calcite} denotes the volume of a calcite cleavage rhombohedron for which the distance between opposite faces is unity and R denotes the ratio between the true grating spaces for lithium fluoride and calcite.

The following data (20°):

d_{LiF}	2.64030 g./c.c.	Ca	40.075
d_{calcite}	2.71030 g./c.c.	Li	6.939
ϕ_{calcite}	1.09594	C	12.010
R	0.663045		

yield 18.994 for fluorine. If the atomic weight of calcium found by Hönigschmid and Kempter, 40.085, is used, fluorine becomes 18.996.

Zinc.—Hönigschmid and v. Mack (*Z. anorg. Chem.*, 1941, 246, 363) have compared zinc chloride with silver. The zinc chloride was prepared by the action of hydrogen chloride on metal which had been purified by distillation in high vacuum and had been found by Gerlach by optical spectroscopy to be free from all metallic impurities. Further purification by two distillations in hydrogen chloride followed. Comparison of weighed quantities of the chloride with equivalent weights of silver was made by the conventional nephelometric method and the resulting silver chloride also was weighed. Weights are corrected to vacuum.

The Atomic Weight of Zinc.

2.23578	3.53951	0.631664	65.374	4.70270	0.475425	65.378
2.54724	4.03245	0.631686	65.379	5.35790	0.475418	65.376
2.32850	3.68614	0.631691	65.380	4.89779	0.475418	65.376
2.03634	3.22369	0.631680	65.377	4.28307	0.475439	65.382
Average		0.631681	65.378	—	0.475426	65.378

The average of all the experiments, 65·377, confirms the present value in the International Table, 65·38, but is 0·05 unit higher than that calculated from mass spectroscopic data, 65·33.

Molybdenum.—In the tenth report of the Committee the mean mass number as computed by Aston, 96·03, was stated to be in error. This statement is incorrect, and was due to an oversight of the fact that the summation of the percentages of the isotopes as given by Aston is 99·9 instead of 100. With the packing fraction — $6\cdot0 \times 10^{-4}$ and the conversion factor 1·000275 the atomic weight of molybdenum obtained from Aston's mean mass number is 95·95. A more recent determination of the abundance ratios by Valley (*Physical Rev.*, 1940, 57, 945) yields 96·00 and 95·92 as the mean mass number and atomic weight respectively, while Hönigschmid and Wittner by analysis of the pentachloride found 95·95.

Samarium.—Hönigschmid and Hirschbold-Wittner (*Z. physikal. Chem.*, 1941, 189, A, 38) have analysed anhydrous samarium trichloride. The samarium material had been purified by Feit and shown by Noddack by X-ray analysis to be of atomic weight purity. Further purification consisted of double precipitation of the oxalate followed by ignition to oxide in each case and crystallisation of the chloride from solution saturated with hydrogen chloride at ice temperature. The chloride was dehydrated by heating in a current of dry hydrogen chloride at gradually increasing temperatures, finally at 450°. Fusion was avoided since it was found experimentally that dissociation occurs at temperatures above the melting point. After being weighed, the chloride was dissolved and compared with a nearly equivalent weight of pure silver by the usual nephelometric method and the silver chloride was collected and weighed. Weights are corrected to vacuum.

The Atomic Weight of Samarium.

SmCl ₃ fused in HCl.						
Wt. of SmCl ₃ , g.	Wt. of Ag, g.	SmCl ₃ : 3Ag.	At. wt. of Sm.	Wt. of AgCl, g.	SmCl ₃ : 3AgCl.	At. wt. of Sm.
3·27893	4·13279	0·79339	150·403	5·49102	0·59715	150·408
SmCl ₃ dried at 450° in HCl.						
3·08886	—	—	—	5·17381	0·59702	150·354
2·96740	3·74054	0·79331	150·375	4·96975	0·59709	150·385
3·87834	4·88888	0·79330	150·372	6·49574	0·59706	150·371
3·37089	4·24914	0·79331	150·376	5·64562	0·59708	150·380
4·40134	5·54798	0·79332	150·380	7·37129	0·59709	150·385
Average		0·79331	150·376	—	0·59708	150·375

The average of all determinations, 150·38, is 0·05 unit lower than the present international value, 150·43, which depends on analyses of *fused* chloride by Stewart and James (*J. Amer. Chem. Soc.*, 1917, 39, 2605) and Owens, Balke and Kremers (*ibid.*, 1920, 42, 515). Although no change in the table is made at the present time, the new higher value seems to be a more reliable one.

Gadolinium.—Wahl (*Soc. Sci. Fennica, Commentationes Phys.-Math.*, 1941, II, 3, 1) finds the isotopic constitution of gadolinium to be as follows :

Mass	152	154	155	156	157	158	160
Per cent.	0·2	2·86	15·61	20·59	16·42	23·45	20·87

These figures lead to the atomic weight 157·18 if the packing fraction — $1\cdot5 \times 10^{-4}$ is employed.

Ytterbium.—Hönigschmid and Hirschbold-Wittner (*Z. anorg. Chem.*, 1941, 248, 72) have compared anhydrous ytterbium trichloride with silver. The starting material had been prepared by v. Bruckl by repeated electrolytic reduction and when subjected to X-ray analysis by Noddack was found to contain no other rare earths except lutecium, and this element only to the extent of 0·04%. The effect of this impurity would be to raise the atomic weight by only 0·001 unit. After repeated precipitation as hydroxide and oxalate, with intermediate ignition to oxide, the chloride was prepared and crystallised from a solution saturated with hydrogen chloride at 0°. Dehydration in preparation for weighing was effected by heating in a current of dry hydrogen chloride at gradually increasing temperatures up to 450°. Fusion was avoided since Hönigschmid had already found dissociation of the salt to occur above the melting point. Comparison with silver was effected in the usual way with the help of a nephelometer and the resulting silver chloride was collected and weighed. Weights are corrected to vacuum.

The Atomic Weight of Ytterbium.

Wt. of YbCl ₃ , g.	Wt. of Ag., g.	YbCl ₃ : 3Ag.	At. wt. of Yb.	Wt. of AgCl, g.	YbCl ₃ : 3AgCl.	At. wt. of Yb.

2.08411	2.41356	0.863500	173.092	3.20680	0.649904	173.095
1.72464	1.99732	0.863477	173.085	2.65378	0.649881	173.085
3.12912	3.62361	0.863537	173.089	4.81490	0.649883	173.086
3.92599	4.54636	0.863546	173.107	6.04062	0.649932	173.107
4.98554	5.77369	0.863493	173.090	7.67151	0.649877	173.083
Average		0.863526	173.098	—	0.649916	173.100

The average, 173.10, is 0.06 unit higher than that found by Hönigschmid and Striebel (*Z. anorg. Chem.*, 1933, 212, 385) with less pure material isolated by Prandtl. The new, higher value is evidently to be preferred although Wahl (*Naturwiss.*, 1941, 29, 536) by determination of isotopic abundances obtains the lower figure.

Mass	168	170	171	172	173	173	174	176

*Thirteenth Report of the Committee on Atomic Weights of the International Union of Chemistry.*¹

By G. P. BAXTER (Chairman), M. GUICHARD, and R. WHYTLAW-GRAY.

IN the very regrettable death of Professor Otto Hönigschmid the International Committee on Atomic Weights has suffered a great loss. Professor Hönigschmid not only very actively promoted the work of the Committee but was himself responsible for a large portion of recent experimental work in this field.

Owing largely to difficulties of communication no report of the International Committee on Atomic Weights has been published for some time. The twelfth report was published only in Germany and France but essentially the same material appeared as the Report of the Committee on Atomic Weights of the American Chemical Society² at about the same time as the German Report.³ Since no changes in the Table of Atomic Weights have been made since the Eleventh Report of the International Committee was published in 1941 until this year, this situation can have caused no serious difficulty. In the Table of Atomic Weights at the end of this report changes have been made in the cases of sulphur and copper. Attention is called to the fact that the atomic weight of common lead as determined from isotopic composition varies with the source over a range of 0.03–0.04 unit. At the present time it seems unwise to try to include values for the new elements Nos. 93–96, neptunium, plutonium, curium and americium.

Beryllium.—Johannsen (*Naturwiss.*, 1943, 31, 592) synthesised beryllium chloride from beryllium oxide and carbon in a stream of chlorine and purified the product by sublimation without melting, first in chlorine, then in nitrogen, and finally in vacuum. The product was collected in sealed glass bulbs and was analysed in the usual way both by comparison with silver and by weighing the silver chloride, with the same resulting atomic weight 9.013 for beryllium. This result is somewhat lower than that found earlier by Hönigschmid and Birkenbach by analysis of the chloride, 9.018, and agrees closely with the mass spectroscopic value 9.0126.

Carbon and Nitrogen.—Casado (Thesis, University of Santiago, 1943) has redetermined experimentally the densities of oxygen, nitrous oxide, and methyl oxide at pressures of one atmosphere and below, as well as the deviations from Boyle's law at low pressures. Corrections of weights to the vacuum standard, for the contraction of the globes at pressures below one atmosphere, and for gravity were made. The average values from a large number of determinations are given in the following table.

	Oxygen.	Nitrous oxide.	Methyl oxide.
$1 + \lambda$	1.00089	1.00710	1.02574
d_1	1.428905	1.97747	2.10809
$d_{\frac{1}{2}}$	1.42844	1.97308	2.08987
$d_{\frac{1}{3}}$	—	—	2.08194
$d_{\frac{1}{4}}$	1.42799	1.96848	2.07330

If the densities plotted against the pressures are assumed to follow a straight line calculated by the method of least squares, the limiting densities and molecular weights are found to be as follows:

	Limiting densities.	Mol. wt.
Oxygen	1.42760	32.000
Nitrous oxide	1.96380	44.019
Methyl oxide	2.0561	46.088

From the molecular weights of nitrous oxide and methyl oxide the atomic weights of nitrogen and carbon may be calculated to be 14.009 and 12.020. If the values of $1 + \lambda$ are used together with the densities at one atmosphere the following results are obtained.

	d_1 .	$1 + \lambda$.	d .	M .
Oxygen	1.428905	1.00089	1.42763	32.000
Nitrous oxide	1.97747	1.00710	1.96352	44.012
Methyl oxide	2.10809	1.02574	2.05518	46.066

from which the atomic weights $N = 14.006$ and $C = 12.009$ result.

Fluorine and Calcium.—In a series of papers, following the first by C. A. Hutchison and Johnston (*J. Amer. Chem. Soc.*, 1941, 63, 1580), the method of calculating the atomic weights of

¹ Authors of papers bearing on the subject are requested to send copies to each of the three members of the Committee at the earliest possible moment: Prof. G. P. Baxter, Coolidge Laboratory, Harvard University, Cambridge, Mass., U.S.A.; Prof. M. Guichard, Faculté des Sciences, Sorbonne, Paris, France; Prof. R. Whytlaw-Gray, University of Leeds, Leeds, England.

² *J. Amer. Chem. Soc.*, 1943, 65, 1443.

³ *Ber.*, 1943, 76, 35; *Bull. Soc. chim.*, 1944, 11, 214.

fluorine and calcium from density and X-ray data has been continued by Johnston and D. A. Hutchison (*Physical Rev.*, 1943, 62, 32), C. A. Hutchison (*J. Chem. Physics*, 1942, 10, 489), D. A. Hutchison (*Physical Rev.*, 1944, 66, 144), and D. A. Hutchison (*J. Chem. Physics*, 1945, 13, 383). The atomic weights and densities used in the calculations of the last paper are as follows :

Atomic weights.		Densities (20°).	
C	12.0104	C	3.51540
Li	6.9390	LiF	2.64030
Na	22.9970	NaCl	2.16360
Cl	35.4570	KCl	1.98826
K	39.0960	CaCO ₃	2.64030

The most reliable results as given in the last of the papers cited are as follows :

Calcium.

Reference substances.	Assumed atomic weights.	Atomic wt. of Ca.
Calcite, NaCl	Na, Cl, C	40.0851
Calcite, KCl	K, Cl, C	40.0851
Calcite, C (diamond)	C	40.0844
Calcite, LiF	K, Cl, Li, C, Na	40.0850
	Average	40.0849

Fluorine.

Reference substances.	Assumed atomic weights.	Atomic wt. of F.
LiF, KCl	K, Cl, Li	18.9967
LiF, NaCl	Na, Cl, Li	18.9967
LiF, C (diamond)	Li, C	18.9967
LiF, CaCO ₃	Na, Cl, C, Li, K	18.9967
	Average	18.9967

The extraordinary concordance of the above results is of course dependent upon the values assumed in the calculation. If, for instance, the atomic weight of sodium is 22.994, the most recent value determined by Johnson, all molecular weights depending on that of sodium chloride will be lowered by 0.005%, and if the atomic weight of potassium is 39.098 instead of the one used, values depending on potassium chloride will be raised by 0.003%. The effect of this upon the atomic weight of calcium in the first two instances in the above table would be - 0.005 and + 0.002 unit. Because of the small molecular weight of lithium fluoride these uncertainties would affect the atomic weight of fluorine by only 0.001 unit. At the present time these results are to be considered as confirmatory rather than definitive.

Potassium, Aluminium, Magnesium and Sodium.—Batuecas, Casado, and Alonso (*Rev. Real Acad. Cienc. Madrid*, 1944, 38, 349), using the method of Hutchison and Johnston (*J. Amer. Chem. Soc.*, 1941, 63, 1580), have calculated the atomic weights of potassium, magnesium, aluminium, and sodium. Calcium and carbon are assumed to have the atomic weights 40.080 and 12.010. They find

$$\begin{aligned} \text{K} &= 39.091 \\ \text{Al} &= 26.963 \end{aligned}$$

$$\begin{aligned} \text{Mg} &= 24.317 \\ \text{Na} &= \begin{cases} 22.961 \\ 22.989 \end{cases} \end{aligned}$$

Silicon.—Ney and McQueen (*Physical Rev.*, 1946, 69, 41) and Williams and Yuster (*ibid.*, p. 556) have obtained the following results for the isotopic proportions of silicon :

Isotope	28	29	30
Ney and McQueen	92.24	4.69	3.07
Williams and Yuster	92.27	4.68	3.05

If the packing fractions - 4.86×10^{-4} , - 4.54×10^{-4} and - 5.79×10^{-4} are used the calculated atomic weight is 28.087. This value lies midway between that found by Baxter, Weatherill, and Scripture, 28.063, by comparing the halides with silver, and those obtained by Hönigschmid and Steinheil, 28.105, by the same method, and by Weatherill, 28.103, from the ratio of the tetrachloride to the dioxide.

Sulphur.—Hönigschmid (*Ber.*, 1942, 75, 1814) has redetermined the ratio between silver and sulphur from the synthesis of silver sulphide, by essentially the method used by Hönigschmid and Sachtleben (*Z. anorg. Chem.*, 1931, 195, 207), and with essentially the same result. Weighed quantities of fused buttons of pure silver were heated in a current of nitrogen and the vapour of purified sulphur, then in pure nitrogen at 250–300°. Below 300° the variations in the weight of sulphide were slight. Above 300° both the weight and the appearance of the sulphide were attended with variations. Vacuum corrections were applied.

It is unfortunate that owing to decomposition above 300° the silver sulphide could not be fused in order to make certain of complete conversion, but the fact that repeated heating of the silver sulphide in sulphur vapour at the lower temperature failed to effect appreciable alteration tends to favour the view that the above difficulty was not serious.

In the following table the weights of sulphide are the averages of the concordant observations when the sulphide was heated at various temperatures between 250° and 300°.

Wt. of Ag in vacuum, g.	No. of heatings with S.	Av. wt. of Ag ₂ S in vacuum, g.	Ag ₂ S : Ag.	At. wt. of S.
22-63155	2	25-99501	1-148618	32-0658
23-35829	4	26-82982	1-148621	32-0665
22-64273	1	25-89313	1-148621	32-0671
21-83830	2	25-08394	1-148621	32-0665
21-47088	2	24-66194	1-148623	32-0669
20-98104	4	24-09928	1-148622	32-0663
17-35371	6	19-93282	1-148620	32-0663
16-84347	16	19-34675	1-148620	32-0663
		Average	1-148620	32-0665

Richards and Jones (*J. Amer. Chem. Soc.*, 1907, **29**, 826) from the ratio of silver sulphate to silver chloride found 32-069, while Scheuer (*Sitzungsber. Akad. Wiss. Wien*, 1914, **123**, IIa, 1004) from the ratios $2\text{Ag} : \text{SO}_3 : \text{Ag}_2\text{SO}_4 : 2\text{AgCl}$ obtained the value 32-067. On the basis of the above two investigations by Hönigschmid, especially in view of the extraordinary concordance of the one reported here, there seems little doubt that the atomic weight of sulphur is very close to 32-066 if silver is taken as 107-880, and this value has been adopted for the table in place of the less precise one, 32-06.

Potassium.—Paul and Pahl (*Naturwiss.*, 1944, **32**, 226) have determined the relative abundance of ³⁹K and ⁴¹K in common potassium to be 13.96 ± 0.1 . With the packing fraction -6.1×10^{-4} and the conversion factor 1-000275 the atomic weight of potassium is found to be 39-099. This agrees closely with the average of the most recent determinations of this constant, 39-097.* In the same way a sample of potassium partially separated by ideal distillation by Hevesy and Lögstrup was found to have the atomic weight 39-011. Hönigschmid and Goubeau, and Baxter and Alter both obtained the same value for this sample.

Copper.—Hönigschmid and Johannsen (*Z. anorg. Chem.*, 1944, **252**, 364; *Naturwiss.*, 1942, **31**, 548) have analysed cuprous chloride. Cupric sulphate was crystallised three times in the case of one sample, five times in the case of another. After electrodeposition on a platinum dish at 2 volts, the metal was dissolved in nitric acid and the nitrate crystallised and centrifugally drained. Decomposition to oxide in platinum followed. Spectroscopic examination by Dr. Schöntag revealed no impurities.

Conversion of the cupric oxide into cuprous chloride was carried out in the following operations: drying of the oxide in nitrogen at 200°, reduction in electrolytic hydrogen at 800°, conversion of the metal into cuprous chloride in nitrogen and chlorine mixtures, and resublimation of the cuprous chloride in nitrogen into a weighing tube, all in a quartz bottling apparatus. In the last two steps it was important to avoid a temperature above 600°.

Analysis followed, by solution in ammonia, oxidation to the cupric state with oxygen, acidification with nitric acid and comparison with silver in the conventional way.

Vacuum corrections were applied. In the following table two analyses believed by the authors to have been made with defective material are omitted.

Atomic Weight of Copper.

Wt. of CuCl in vacuum.	Wt. of Ag in vacuum.	CuCl : Ag.	At. wt. of Cu.	Wt. of AgCl in vacuum.	CuCl : AgCl.	At. wt. of Cu.

* 39-096, Baxter and Alter, *J. Amer. Chem. Soc.*, 1933, **55**, 3270; 30-096, Hönigschmid and Sachtleben, *Z. anorg. Chem.*, 1933, **213**, 365; 39-100, Johnson, *J. Physical Chem.*, 1935, **39**, 781; 39-098, Baxter and Harrington, *J. Amer. Chem. Soc.*, 1940, **62**, 1836; 39-096, McAlpine and Bird, *ibid.*, 1941, **63**, 2960.

The outcome of this work, 63.542, is appreciably lower than that of Richards and his collaborators, 63.57, on which the International value has depended for some time, but is in close agreement with that obtained by Ruer (*Z. anorg. Chem.*, 1924, 187, 101), 63.54, by reduction of cupric oxide, and with a recent isotopic analysis of copper by Ewald (*Z. Physik*, 1944, 122, 487) which gives the value 63.53.

Selenium.—Hönigschmid and Görnhardt (*Naturwiss.*, 1944, 32, 68) prepared pure selenium oxychloride by distillation in high vacuum in a glass still and collected the product in sealed glass bulbs. Analysis by comparison with silver chloride gave 78.961, while determination of the silver chloride produced 78.963 for the atomic weight of selenium. This investigation confirms the present International value which depends on the earlier synthesis of silver selenide by Hönigschmid and Kapfenberger. The value calculated from the proportions of isotopes is 78.95 (Flügge and Mattauach, *Ber.*, 1943, 76, A, 1).

Ruthenium.—Ewald (*Z. Physik*, 1944, 122, 491) has determined the isotopic proportions of ruthenium to be as follows:

Isotopic weight	96	98	99	100	101	102	104
Per cent.	5.68	2.22	12.81	12.70	16.98	31.34	18.27

With the packing fraction -6.49×10^{-4} and the conversion factor 1.000275 the atomic weight is calculated to be 101.04. Although Gleu and Rehm (*Z. anorg. Chem.*, 1937, 235, 352) by analysis of the *purpureo*-chloride obtained the value 101.08, the uncertainties in their determination make it unwise to make any change in the Atomic Weight Table at the present time.

Silver, Bromine, and Potassium.—McAlpine and Bird (*J. Amer. Chem. Soc.*, 1941, 63, 2960), by quantitative decomposition of potassium bromate, have found the ratio of potassium bromide to oxygen, and by comparison of the resulting potassium bromide with silver have found the ratio of these two substances. The results furnish a direct determination of the molecular weight of potassium bromide and an indirect determination of the atomic weight of silver.

Silver and bromine were purified by methods standard in atomic weight work. Potassium bromate was prepared from high-grade potassium hydroxide and an excess of bromine. After the solution had been boiled to remove excess of bromine and possibly iodine, the bromate was many times recrystallised until essentially free from bromide and sodium.

After prolonged drying in a vacuum the salt was further dried at 85–90° in the special weighed quartz decomposition flask, which was provided with a quartz filter disc to prevent loss of solid material, in a dry air stream, and was weighed. Very slow decomposition in a dry air stream followed, at gradually increasing temperatures up to 550°, until constant weight was obtained. During the decomposition the outgoing air stream was passed through a weighed phosphorus pentoxide tube to absorb residual water in the potassium bromate. In preliminary experiments it was found that decomposition of the bromate was complete and that the resulting bromide was neutral.

In the following table the weight of potassium bromate has been corrected for the water content as determined in each experiment. Vacuum corrections have been applied.

The Molecular Weight of Potassium Bromate.

KBrO ₃ , g.	KBr, g.	Ratio, KBr : O ₃	Mol. wt. of KBr.	KBrO ₃ , g.	KBr, g.	Ratio, KBr : O ₃	Mol. wt. of KBr.
10.67696	7.60833	2.47939	119.011	10.69361	7.62021	2.47941	119.012
7.54279	5.37493	2.47937	119.010	10.36524	7.38620	2.47939	119.011

9.62010	6.85524	2.47942	119.012				
8.50007	6.06711	2.47941	119.012				
				Average		2.47940	119.011

* Corrected in private communication from the authors.

Further evidence that the potassium bromide resulting from the decomposition was normal and free from moisture was obtained by comparing this bromide with silver in the conventional way by the nephelometric method. Similar experiments were made with potassium bromide prepared from pure bromine and potassium oxalate, and fused in nitrogen. Weights are corrected for air buoyancy.

If the established ratio of bromine to silver, 0.740786, is assumed, the atomic weights of bromine and potassium referred to silver as 107.879 are 79.915 and 39.096, respectively. All three values are in excellent agreement with those in the Table.

The Atomic Weight of Silver (KBr = 119.011).

* Recalculated from authors' data.

† 1.103200 in the authors' paper.

Incidental to the investigation three syntheses of silver chloride from silver were made.

The Ratio of Silver to Silver Chloride.

Ag, g.	AgCl, g.	Ag : AgCl.	Ag, g.	AgCl, g.	Ag : AgCl
6.95254	9.23774	0.752623	6.63263	8.81249	0.752640
7.03045	9.34116	0.752631	Average		0.752631

The previously established value of this ratio is 0.752632.

Silver.—Paul (*Naturwiss.*, 1943, 31, 419) has determined the proportions of the two isotopes of silver electrometrically with a mass spectroscope. The mean ratio from twelve determinations was found to be $\frac{^{107}\text{Ag}}{^{109}\text{Ag}} = 1.080 \pm 0.006$. If the packing fraction -4.8×10^{-4} is used the atomic weight of silver is found to be 107.880.

Dysprosium.—Wahl (*Suomen Kem. Tied.*, 1942, 51, 64; *Chem. Abstracts*, 1944, 38, 5142) finds the following isotopic proportions for dysprosium.

Isotope	158	160	161	162	163	164
Per cent.	trace	0.1	21.1	26.6	24.8	27.3

The mean mass number calculated from these percentages is 162.581, and with the packing fraction -1.3×10^{-4} and the conversion factor 1.000275 the atomic weight may be calculated to be 162.52. Owing apparently to the fact that the author's percentages total only 99.9, he calculates the incorrect value 162.42. Hönigschmid found, by analysis of the chloride, 162.46.

Hafnium.—Mattauch and Ewald (*Z. Physik*, 1944, 122, 314) by photometric measurement of intensities in mass spectrographic plates have found the relative abundances of the hafnium isotopes to be as follows :

Isotope	174	176	177	178	179	180
Per cent.	0.18	5.30	18.47	27.10	13.84	35.11

The mean mass number calculated from these results is 178.54, and the atomic weight calculated with the packing fraction $+0.2 \times 10^{-4}$ and the conversion factor 1.000275 is 178.50 ± 0.01 . This result is appreciably lower than the atomic weight found by Hönigschmid and Zintl (*Ber.*, 1925, 58, 453) in the usual chemical way. With two samples containing 0.57 and 0.16% of zirconium Hönigschmid and Zintl's results after correction for the zirconium content were 178.64 and 178.57.

Lead.—Permyakov (*Bull. Acad. Sci. U.R.R.S., Classe sci. chim.*, 1941, 581) has determined the atomic weight of lead from both Sadon galena and Khito-Ostrov uraninite by the conventional chloride-silver-silver chloride method. Weights are corrected to the vacuum standard.

Sadon galena.

Wt. of PbCl ₂ .	Wt. of Ag.	Ratio PbCl ₂ : 2Ag.	At. wt. of Pb.	Wt. of AgCl.	Ratio PbCl ₂ : 2AgCl.	At. wt. of Pb.

Average		1.28392	206.10	—	0.96639	206.13

Radium.—Attention is again called to the fact that in the most recent and accurate determination of the atomic weight of radium, by Hönigschmid and Sachtleben (*Z. anorg. Chem.*, 1934, 221, 85), by conversion of radium bromide into radium chloride, no correction was made for the fact that weights of salt are too low since the temperature of the salts is always higher than that of the balance. The ratio involved is $\text{RaBr}_2 : \text{RaBr}_2 - \text{RaCl}_2$, in which the second term is far less affected than the first. In earlier work by Hönigschmid a positive correction of 0.01 unit was used. Although the mass spectrographic value is 226.05, identical with Hönigschmid and Sachtleben's uncorrected result, the application of the above rather uncertain correction produces a discrepancy of 0.01 unit.

OBITUARY NOTICE.

ARTHUR LAPWORTH.

1872—1941.

ARTHUR LAPWORTH was born on October 10th, 1872, at Galashiels; his father was Charles Lapworth (F.R.S., 1888, Royal Medallist, 1891), the eminent first Professor of Geology in the University of Birmingham, who was a pioneer in laying the foundations of stratigraphy. After early education at St. Andrews and at King Edward's School, Birmingham, he graduated at Mason College and, as an 1851 Exhibitioner (1893—95), proceeded to the City and Guilds of London Institute, where the presiding genius was H. E. Armstrong. However, Lapworth came more directly under the care of F. S. Kipping, who was at that time in charge of the main organic laboratory.

Professor Kipping writes :

" From the very first it was obvious that Lapworth had the experimental skill, as well as the powers of acute observation and sound deduction which would ensure his success in scientific work, and that his vivid imagination and high intellect would take him far in his profession. Any one who made Lapworth's acquaintance could not fail to wish for closer ties, and although he was considerably my junior in age we soon became fast friends; perhaps it would be truer to say that our relationship, even in those early days, was rather that of congenial brothers. He became a frequent visitor at our house in South Kensington, where he often met Pope, Forster, and other workers in Armstrong's laboratories, and my wife soon shared with me the great pleasure of his friendship. During one vacation when he had made no holiday plans, we asked him to stay with us at Bridgwater: here it was that he met his future wife, Kathleen Holland, with whom during forty years he spent the rest of his life in peaceful and loving marital harmony."

To this may be added that Kathleen was the younger sister of Mrs. Kipping and of Mrs. W. H. Perkin; thus Mrs. Holland was the mother-in-law of three distinguished chemists and Fellows of the Royal Society.

His postgraduate course at the " Central " included crystallography under the late Sir Henry Miers and following this he worked with Armstrong on the sulphonation of ethers of β -naphthol and with Kipping on derivatives of camphor and camphene. So began two of his main interests in later research, the chemistry of camphor and the mechanism of aromatic substitution. His D.Sc. thesis,* submitted at the age of twenty-three, on the naphthalene topic was the occasion for a characteristic display of courageous independence. He refused to alter some sections of the theoretical treatment which his formidable professor had criticised.

Lapworth's first post (1895) was that of Demonstrator in Collie's laboratory at the School of Pharmacy in Bloomsbury. One joint paper (*J.*, 1897, **71**, 838) on picoline derivatives from this period bears the Collie stamp. In 1900 he went to the Goldsmiths' Company's Institute at New Cross as Head of the Chemistry Department (1906, Goldsmiths' College) and in 1909 became Senior Lecturer in Inorganic and Physical Chemistry and Schunck Fellow at the University of Manchester. Four years later he succeeded W. H. Perkin, jun., in the Chair of Organic Chemistry and in 1922 became Sir Samuel Hall Professor (primarily responsible for physical and inorganic chemistry) and Director of the Laboratories. The writer, first as a Junior Demonstrator and, after an interval of years, as Professor of Organic Chemistry, had the inestimable privilege of his friendship and collaboration. At lunch in the refectory and at many other times we exchanged ideas, often expressed on the back of envelopes by what Armstrong was pleased to call " noughts and crosses ". During this latter period Mrs. Lapworth acted as his secretary in the department.

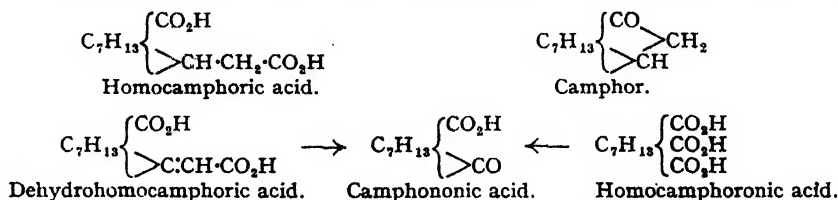

His last appointment demonstrates Lapworth's remarkable breadth and versatility; very few men in the twentieth century would be thought competent to hold in succession chairs of organic and physical chemistry. He retired in 1935 and was appointed Professor Emeritus. He was elected F.R.S. in 1910, served on the Council (1927—29), received the Davy Medal in 1931, and was an honorary LL.D. of Birmingham and of St. Andrews universities. These distinctions are mentioned with some uneasiness; high as they are they afford no measure of the achievement of a man whose influence on chemical philosophy was outstanding.

His modest disposition did not bring him into the limelight; he was not a showman, tending rather to disparage his wares; he made no dramatic discoveries such as to catch the public eye;

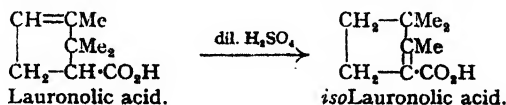

* " Sulphonic acids of betamethoxy- and betaethoxy-naphthalene." Thesis for D.Sc. (London), April, 1895.

he never flogged a dead horse and even left some promising live ones to fend for themselves. He investigated in order to learn something, to educate himself, and not with the primary object of producing elegant and finished scientific memoirs, though he did indeed leave many such on record. Much of his work seems, therefore, incomplete, and his output of over a hundred papers was, judged by some standards, relatively small. Yet the power of his genius triumphed and it is now possible to see how his ideas, always many years ahead of those of his contemporaries, played a leading part in the contribution which organic chemists have made to the revolution in chemical thought. The electronic theory of valency has made it possible to give a measure of precision to many of the suggestions he advanced on an electrochemical basis, but Lapworth's preparation of the ground was essential. During many years little attention was paid to his views; now they are the commonplaces of the textbooks.

One of Lapworth's first major interests was the constitution of camphor and the way he attacked the problem was very significant. There are quite a number of ordinary papers on the detailed chemistry of derivatives; just the kind of thing that many workers in the field could, and did, produce. Certainly some of this material was of great importance and demonstrated his skill as an experimentalist, in particular his study of homocamphoric acid (*J.*, 1899, 75, 986; 1900, 77, 446, 1053) forged a vital link in the chain of evidence. In this investigation he showed that homocamphoric acid can be degraded to dehydrohomocamphoric acid and then to camphononic acid, which must be a *cyclopentane* derivative because it could be synthesised by ketonisation of homocamphoronic acid. But his characteristic contribution was an idea—an

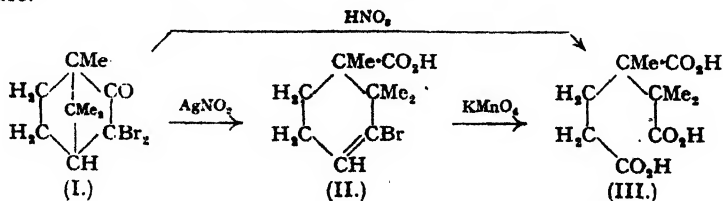

interpretation of the chemistry of camphor which reconciled apparently conflicting data (*Brit. Assoc. Rep.*, Sec. B, Bradford, 1900). In other words he saw through the mist and by recognising the occurrence of a remarkable molecular rearrangement in the formation of *isolaunonic* acid removed the chief stumbling block to the general acceptance of *Bredt's* camphor formula.

The postulated intramolecular change was compared by Lapworth with the pinacol-pinacolone rearrangement and a similar explanation was also applied to the change of α - to β -campholenic acid, which was another source of confusion.

Homocamphoronic acid (III) itself and the stages of its production from $\alpha\alpha$ -dibromocamphor (I) gave a great deal of trouble, as may well be understood when the direct formation of the acid by oxidation of (I) with nitric acid is considered (*J.*, 1899, 75, 986). A carbon atom seems to get out of place.

It was shown, however, that Forster's bromocamphorenic acid (II) is probably an intermediate product, and the very remarkable molecular rearrangement, (I) \longrightarrow (II), was suggested as the result of an extensive series of investigations (*J.*, 1899, 75, 1134; 1900, 77, 309, 446; 1902, 81, 17). Lapworth carried these out in a systematic fashion by the careful study of the properties and reactions of the substances mentioned and, in addition, of camphonic acid, camphononic acid, and various bromo-lactones. It does not seem to have occurred to him to

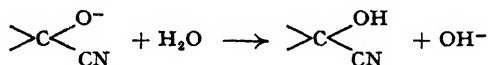

attempt the synthesis of homocamphoronic acid, although that is perhaps due to the fact that the structures became clear only towards the end of a prolonged study.

The examples cited of the mobility of the camphor complex could be supplemented by many others and there is no doubt that the general acceptance of Bredt's formula owed as much to Lapworth's searching analysis as to the eventual synthesis of camphoric acid. Much later he prepared homocamphor (*J.*, 1920, 117, 743), but the connecting link with later activities was perhaps his work on cyanocamphor and homocamphoric acid (*J.*, 1900, 77, 1053). He was led to consider the problem of the addition of hydrocyanic acid to carbon compounds more generally and especially to the $\alpha\beta$ -unsaturated ketones and the ketones and aldehydes themselves (*J.*, 1903, 83, 995; *Proc.*, 1904, 20, 245; *J.*, 1904, 85, 1206—1214, 1355; 1906, 89, 1819, 1869; 1907, 91, 694, 977; 1910, 97, 11; *Proc.*, 1911, 27, 240; *J.*, 1911, 99, 1877; 1928, 2533; 1930, 1976). The studies ranged from observations of the β -addition of cyano-groups to $\alpha\beta$ -unsaturated ketones such as mesityl oxide, benzylideneacetone, carvone, and pulegone to the later, careful examination of the conditions of formation and the stability of cyanohydrins. There is little doubt that reflection on the mechanism of these reactions played an important part in directing his attention to the principle of "alternate polarities". From the first he adopted ionic mechanisms, and a good illustration of his ideas is seen in the view he put forward of the course of the formation of benzoin from benzaldehyde (*J.*, 1907, 91, 694). The production of a cyanohydrin was regarded by Lapworth as involving the direct attack of cyanidion on a carbonyl group:

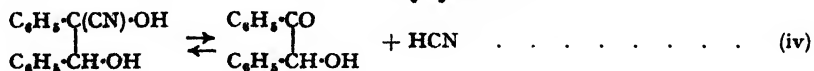

This he made very probable by a study of the effect of catalytic agents on the velocity of the addition (*J.*, 1903, 83, 995) and by showing that the cyanohydrins are complex acids of which he was able to prepare the salts (*J.*, 1904, 85, 1206). Thus by the action of potassium cyanide on benzaldehyde and camphorquinone he obtained crystalline potassium salts of the cyanohydrins. This view was confirmed by much subsequent research by Lapworth himself, by Bredt, and by Goldschmidt.

The second stage in the formation of a cyanohydrin is the decomposition of water, or an alcohol or acid, by the complex ion:

He early recognised that these processes must be reversible and that normally an equilibrium will be set up. The theory explained very well why cyanohydrins are so advantageously prepared by the action of pure hydrocyanic acid on a ketone in the (necessary) presence of a small proportion of an alkaline catalyst, which may be potassium cyanide, or may even be derived from the glass container.

To complete the scheme of the benzoin synthesis it was assumed that benzaldehyde undergoes an aldol-like synthesis with mandelonitrile, and that the cyanohydrin of benzoin is relatively unstable. This was probable on theoretical grounds, and from analogies, but it was also experimentally demonstrated. The complete scheme was (*J.*, 1907, 91, 694):

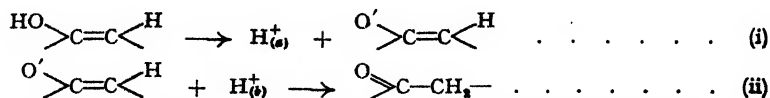

It will be noticed that Lapworth postulated reversibility of each stage. The theory has stood the test of forty years and is generally accepted as correct: undoubtedly it represented a landmark in the progress of our understanding of the course of chemical change.

Another outcome of the early camphor period was the use made of optical activity to study the phenomena of desmotropic, or tautomeric, change (*J.*, 1902, 81, 1491, 1499, 1508; 1903, 83, 114; 1904, 85, 46; 1911, 99, 1785). From the first Lapworth regarded these processes from the ionic point of view first advanced by Brühl in 1899, but in a less explicit form. He, however,

greatly extended the conception and supported it by many experimental researches carried on throughout his active career.

Mechanisms were invariably adopted which stressed the fact that the ions, particularly hydrogen ions, must often be regarded as coming in from outside and also as leaving for an unknown, and possibly remote, destination. Thus in keto-enol tautomerism catalysed by acids we have :

where the two protons *a* and *b* are not the same. Although these views, and perhaps some others that he advocated, were not completely novel, Lapworth made a better combination of them than any other chemist. His consistency and theoretical insight made a great impression on his contemporaries and exercised a powerful influence on the development of organic chemical theory. At a later stage he became interested in the mechanism of esterification and hydrolysis (*Proc.*, 1908, 24, 100, 152, 153; *J.*, 1908, 93, 2163, 2187; *Proc.*, 1909, 25, 20; *J.*, 1910, 97, 19; 1911, 99, 917, 1417, 1427, 2242; 1912, 101, 2249; 1913, 103, 252; *Proc.*, 1914, 30, 141; *J.*, 1915, 107, 857; 1922, 121, 76). Here again the emphasis was on hydrogen ion catalysis and the theory of acids and complex ions in various media. The researches were developed with the refinements of physico-chemical techniques and cannot usefully be summarised in the course of a short discussion. Many aspects of the work were unfinished and inconclusive but, taken as a whole, it must be admitted that this series of memoirs made an essential contribution to a subject which has excited great interest, and has of course been advanced by many other workers.

Another penetrating suggestion made by Lapworth concerned the mechanism of the bromination of ketones; the case chosen for study was acetone. The rate of bromination was found to be independent of the concentration of bromine and the process was catalysed by acids.

Lapworth suggested that the rate-determining change is the formation of enol from the acetone and that this is immediately brominated. The reaction is therefore autocatalytic due to the accumulation of hydrogen bromide. This view is accepted to-day for the acid-catalysed reaction, but other ions than hydrogen ions play a part and the complexity of the system is illustrated by H. M. Dawson's subsequent examination of the iodination of acetone. Anionotropic as well as prototropic reactions are in evidence. Considering the date (1913) of Lapworth's work (*Proc.*, 1913, 29, 283) the advance he made was remarkable.

The conception of very rapid bromination of an enol was later utilised by K. H. Meyer for the analysis of mixtures of enols and ketones, for example, ethyl acetoacetate, under various circumstances. Lapworth often told the writer that he ought to have made this ingenious but obvious application. It is, however, doubtful whether full enolisation occurs, and it is not necessary to postulate it. Thus Leuchs has shown that an optically active ketone, the enol of which must be optically inactive, can be brominated without loss of activity. This recalls the observation of Kuhn and Albrecht that optically active *sec.*-nitrobutane yields an optically active sodium salt. Many other examples of Lapworth's concern with reaction mechanisms could be cited, including his early generalisations of the form of intramolecular changes (*Proc.*, 1895, 11, 49; *J.*, 1898, 73, 445; *Proc.*, 1901, 17, 2; *J.*, 1901, 79, 1265) and an examination of the synthesis of acetoacetic ester (*Proc.*, 1903, 19, 189). Moreover he made kinetic studies of many reactions other than those mentioned and his work on the rate of oximation and the properties of oximes (*J.*, 1902, 81, 549; 1907, 91, 1133; 1908, 93, 85) may be given in illustration.

Lapworth discovered many new reactions and transformations of which the following are among the more interesting.

Possibly his investigations of the addition of hydrogen cyanide to unsaturated ketones suggested that the quality of reactivity of the carbon of a carbonyl group can be transmitted to the β -carbon of an $\alpha\beta$ -unsaturated ketone. If so, he may have argued, a carbonyl might activate a methylene group through a double bond. At any rate, in 1900 he made an experiment that must have had some such theoretical background.

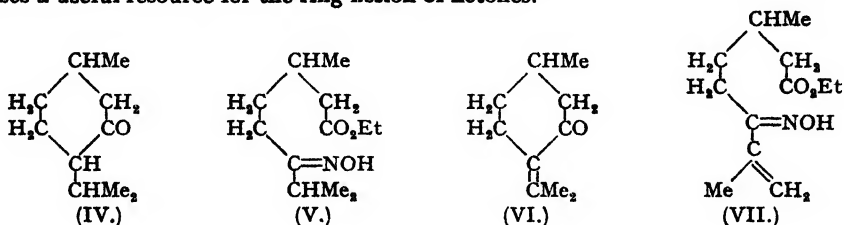

He found (*Proc.*, 1900, 16, 132) that ethyl crotonate condensed with ethyl oxalate in the presence of sodium ethoxide as follows :

The constitution of the product has since been confirmed; this was necessary in view of the possibility of the double bond migration to the $\beta\gamma$ -position, followed by oxylation in the α -position. An extension was made later (*J.*, 1923, 123, 1325).

Lapworth and Wechsler (*J.*, 1907, 91, 1919) noted an anomalous reaction of cyanodihydrocarvone with amyl nitrite in the presence of sodium ethoxide. Further experiments revealed an interesting scission of ketones containing the group —CO—CH— under the same conditions. It may be assumed that a nitroso-derivative is first formed and that this adds the elements of alcohol to yield $\text{—CO·OEt} + \text{HON·C<}$ (*J.*, 1908, 93, 30).

Thus menthone (IV) yields (V) after hydrolysis of the product; pulegone (VI) gives (VII), the process involving the above-mentioned shift of a double bond. A simple model was provided (*J.*, 1911, 99, 1882) by phenyl isopropyl ketone, Ph·CO·CHMe_2 , which was found to be converted by amyl nitrite in alcoholic sodium ethoxide into benzoic ester, $\text{Ph·CO}_2\text{Et}$, and acetoxime, HON=CMe_2 . This reaction has been applied to cinchoninone and affords in this and other cases a useful resource for the ring-fission of ketones.

Another degradation was discovered when bromine was allowed to act on ethyl benzeneazooacetate, $\text{CH}_3\text{·CO·CH(N}_2\text{Ph)·CO}_2\text{Et}$, when the acetyl group was eliminated and a so-called hydrazino-derivative, $\text{CBr(N·NHPh)·CO}_2\text{Et}$, was produced (*J.*, 1905, 87, 1854). When treated with alkalis, two molecules condensed to give ethyl diphenyldihydrotetrazinedicarboxylate,

These novel types of substances have not received much subsequent attention.

An interesting paper on sulphonic esters (*J.*, 1912, 101, 273) describes some new reactions based on the idea that esters and sulphonic esters tend to undergo scission at the dotted line:

$\text{R·CO·}\ddot{\text{O}}\text{—R'}$, $\text{R·SO}_2\text{·}\ddot{\text{O}}\text{—R'}$. It was found that olefins add the elements of sulphurous acid with the production of sulphonic acids (*J.*, 1925, 127, 307). In the simplest case ethylene reacts with sodium hydrogen sulphite with formation of ethanesulphonic acid, which was isolated as the barium salt:

This reaction was rather unexpected; it underlines the abnormality of sulphur and recalls Posner's experiments on the addition of mercaptans to unsaturated substances.

At various times Lapworth paid considerable attention to improvements of preparative methods and to the prescription of satisfactory recipes. For example, he made really pure oleic acid (*Biochem. J.*, 1925, 19, 7) and studied its quantitative oxidation to dihydroxystearic acid (*J.*, 1925, 127, 1628, 1987). This is only one instance of his interest in the chemistry of the fats. He began work on sphingosine and cerebrone (*J.*, 1913, 103, 1029) but never carried it far.

Other illustrations of the improvement of methods are the reductions of emulsified nitro-compounds (*J.*, 1921, 119, 765, 768; 1925, 127, 2970) whereby excellent yields of arylhydroxylamines were obtained, and contributions to *Organic Syntheses* (1927, 7, 20; 1928, 8, 99) based on his earlier work with McRae (*J.*, 1922, 121, 1699, 2741). The details are characteristically elegant. An aldehyde such as benzaldehyde is brought into reaction with sodium cyanoacetate, previously made in the usual way; the addition of hydrocyanic acid and hydrolysis then afford a substituted succinic acid.

An unusual development for Lapworth was a study of natural products, in this case the pungent principles of ginger (*J.*, 1917, 111, 77) and capsicum (*J.*, 1919, 115, 1109). It is curious that E. K. Nelson, and also H. Nomura, published work on gingerol almost simultaneously with that of Lapworth, Pearson, and Royle. The work of Lapworth and his collaborators was the most comprehensive. The oleo-resin of Thresh, and of Garnett and Grier, methylated by means of methyl sulphate and alkali, yields a crystalline compound termed methylgingerol. This is decomposed by heat or alkali into methylzingerone, $\text{C}_{15}\text{H}_{16}\text{O}_2$, and aldehydes, of which the chief is *n*-heptaldehyde. Methylzingerone was proved by analysis and synthesis (*J.*, 1917,

was seen to be divergence, however, in other important respects and the origin of these became clear with the development of translations into the terms of the electronic theory of valency.

The working hypothesis of "labelling" from a key-atom gave rise to some interesting experimental work and an early example is that of Lapworth and Shoesmith (*J.*, 1922, 121, 1391) on the methoxybenzyl bromides.

Thus the *m*- and *p*-isomerides are labelled from oxygen as key-atom :

The behaviour of these substances was found to harmonise with that predicted from the figures. It was known that Br in, for example, $\text{O}=\text{C}^+-\text{Br}^-$ is very readily replaced by OH and that Br in $\text{O}=\text{C}^+-\text{CH}^+-\text{Br}^-$ is unusually readily replaced by H. *p*-Methoxybenzyl bromide was much more easily hydrolysed to the related alcohol than was *m*-methoxybenzyl bromide, and in reductions to the tolyl methyl ethers, the *m*-isomeride was the more reactive.

Nowadays the properties of the *p*-derivative can be readily interpreted on a more precise electronic basis, but the *m*-derivative would be regarded as a benzyl bromide, lacking the special constitutive features of the *p*-type, and differing from benzyl bromide itself only as the result of the general electrical effect of the methoxy-group. In other words, it is the *p*-derivative that exhibits exceptional behaviour, and a comparison of benzyl bromide and *m*-methoxybenzyl bromide is required in order to estimate the significance of the contrast to which Lapworth and Shoesmith drew attention.

About this period (1922—26) an active controversy arose (cf. *J.*, 1925, 127, 1742); this consumed much time and effort but need not be described in detail. Lapworth himself would be the last to desire these ephemeral writings to be resuscitated on account of their purely historical interest. It had at least one useful result in that the theory was more quickly moulded into its present form.

The chief subsequent events have arisen from the applications of quantum mechanics to organic chemical problems. These have provided a new calculus for the electronic theory of valency but have not rendered the older qualitative approach obsolete.

Lapworth's last scientific paper (*J.*, 1931, 1959) was most happily a collaborative effort with Professor C. K. Ingold. It was concerned with the problem of *m*-nitration of toluene. Competitive nitrations of toluene and benzene show that toluene is far more readily attacked than benzene. But in the nitration of toluene, only 4.4% of the *m*-derivative is produced. The question arises—does the methyl group activate the *m*-position, relative to the reactivity of benzene? Careful experiments showed that this is indeed the case, the disparity of toluene and benzene reactivity being sufficient.

There is little doubt that Lapworth would have continued to shed light on these and similar problems but unfortunately signs of his illness made their appearance early in the third decade of the century. He continued for some years to inspire his colleagues and collaborators by discussion and correspondence. Indeed it is true to say that throughout his life, though his publications are highly important, his generous help to others had an almost equal, if not greater, influence on the progress of science.

The world-wide recognition of Lapworth's genius and his abiding scientific reputation increases with the passage of time. It is now seen that his insight into chemical mechanisms, and his insistence on the electrochemical point of view at the molecular level, forged a necessary link in the chain of theory which now connects the most diverse phenomena.

In the laboratory one of his students, Dr. G. N. Burkhardt, gives the following picture. "He was skilful in devising and using the simple methods which he always preferred and, with a home-made cigarette in one corner of his mouth, and his head on one side, he would attack a new substance with reagents and a set of test-tubes. Using traces of material and a number of uncommon devices, he would find as much in a few minutes as might take hours to establish on a larger scale with more elaborate technique. As a teacher, lecturing on three main branches of chemistry in succession, he concerned himself to an unusual degree with the exposition of ideas, methods, and general principles, so that his lectures were most stimulating and valuable to his

better students, though they could be the despair of those whose tastes or abilities required only the easy catalogue of facts."

In his dealings with his fellow men he was selfless, generous to a fault, and completely straightforward and sincere. His scientific work occasionally brought him into controversy with exponents of older views, but this was always conducted with great dignity and the most careful choice of words. Incidentally he possessed an enviable command of language especially noticed in his writing, and a pretty and sometimes caustic wit, entirely free from any suspicion of malice. As administrator of his department and laboratory he showed firmness and wisdom, but this was not his real *métier* and it is a pity that a sense of duty compelled him to undertake responsibilities which turned out to last far too long. As already mentioned, the valuable help of Mrs. Lapworth lightened the load of routine for several years. The loyalty with which Lapworth was served and the undying devotion of all those who collaborated with him whether in teaching or research are the best testimony to his professional work and the University of Manchester owes much to his encouragement of young men of promise and to his guidance of the School of Chemistry during critical years.

A sensitive soul, always sparkling with vitality, all-embracing in his curiosity and interest, it is natural that he had many hobbies.

His father was a pianist and his mother and sister were accomplished singers. He himself played the violin and 'cello and was a lover of music, with sound and individual taste and a wide knowledge of the classics. He had little use for the modern forms. At New Cross he took part, as violinist, in chamber music and played in the College orchestra. When he came to Manchester Perkin asked him to share in his famous musical parties but there were too many violinists and Lapworth learned the viola. For many years he served on the Council of the Royal Manchester College of Music. He was a good dancer, was fond of the theatre, of films, radio, and the gramophone, and, in my time, he was a voracious reader of thrillers. Carpentry and microscopy were just two of his pursuits, and outside his chemistry his main scientific interests were astronomy, geology, and botany. He was an authority on British mosses and made a fine collection of them.

Holidays were spent in mountaineering and later in golfing and fishing. As a boy he started scrambling at St. Andrews and soon accompanied his father on geological expeditions to the mountains. At the age of eighteen he made a solitary ascent of the Petit Dent de Veisivi and later climbed Lliwedd and the Rosenlauri Engelhörner by several routes.

Much affected by the loss of his friend Humphrey Owen Jones and his wife on the Aiguille Blanche de Peteret, he never climbed again.

His fishing ground was chiefly the river Eden near Gosforth, and he was a member of the Yorkshire Anglers Club. Speaking of one of his friends he said: "The keenest angler I know—what a pity that he never catches fish".

The outdoor life consorted well with his interest in nature, and it was K. J. P. Orton who introduced him to the study of birds. Orton, a recognised authority, was good with the field-glasses, but Lapworth's trained and sensitive ear enabled him to surpass his teacher in the recognition of birds by song. Birding with the Ortons was the *raison d'être* of many happy expeditions round Hayes Common, Keston, and in the Bangor district. Many years later the writer found in a St. Andrews "den" that Lapworth had not forgotten his craft.

The breadth of interest and joy in life which Lapworth showed in his recreations were characteristic of the man. In science, too, his temperament might have caused too wide a spread, but he was saved from this by self-discipline and by a dominant theoretical theme.

Lapworth's health, at least in later years, was never robust, and the exceptional strain of carrying the burden of the whole Department of Chemistry eventually broke it down. His long and distressing illness was borne with the greatest fortitude, but, until the very end, he never lost his interest and was able to enjoy the visits of his friends at intervals.

R. ROBINSON.

186. Photochemical Reactions in Sunlight. Part XII. Reactions with Phenanthraquinone, 9-Arylxanthenes, and Diphenyl Triketone.

By ALEXANDER SCHÖNBERG and AHMED MUSTAFA.

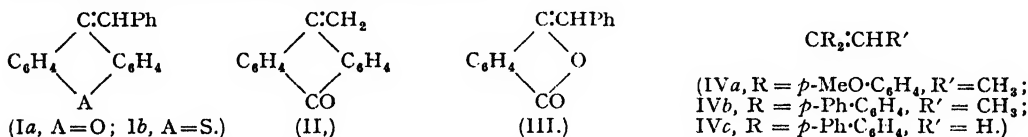

(a) The photochemical addition of phenanthraquinone or retenequinone to various substances containing an olefinic linkage has been carried out. The olefinic compounds include diphenylketen and a number of olefins, (I)–(III), in which one carbon atom of the ethylenic linkage is a member of a five- or six-membered ring system. The photo-products obtained are represented by the formulæ (V)–(VIII).

(b) Reaction scheme (A), which shows the photo-formation of peroxides from 9-arylxanthenes, was carried out in five cases. Some of the arylxanthenes are new and were prepared according to scheme (B). 9-Benzylxanthen was stable in sunlight in the presence of oxygen.

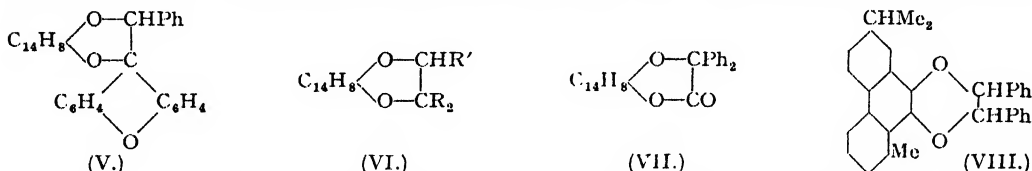

(c) The photo-reaction between phenanthraquinone and aromatic aldehydes was studied in three cases (see C); steric hindrance (ortho-effect) may explain the slow rate of the photo-reaction in the case of 2-methoxy-1-naphthaldehyde.

(d) Diphenyl triketone in sunlight forms benzil.

(a) RECENTLY (J., 1944, 387; 1945, 551) we showed that phenanthraquinone reacted with certain unsaturated compounds to form derivatives of phenanthro-1:4-dioxen. We have now extended this reaction to 9-benzylidene-xanthen and -thioxanthen (I, *a* and *b*), methyleneanthrone (II), benzylidenephthalide (III), 1:1-di-*p*-anisylpropylene (IV*a*), 1:1-dixenylpropylene (IV*b*), *as*-dixenylethylene (IV*c*), and diphenylketen.

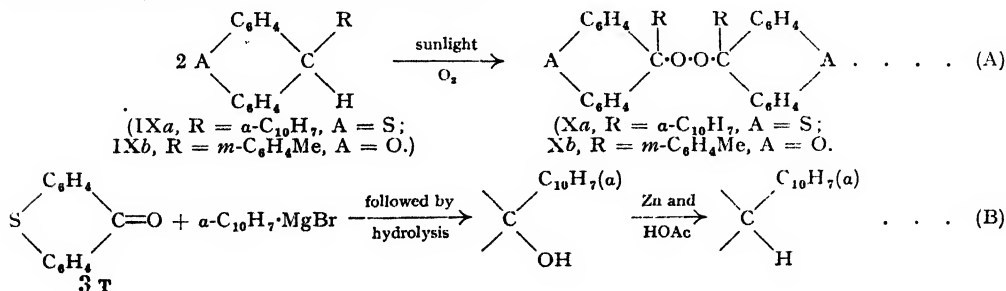

The photo-product obtained from (Ia) has the structure (V), and those from (Ib), (II), and (III) are analogous. Those from (IV, *a*, *b*, and *c*) are of type (VI), in which R and R' are as in the three formulæ. Diphenylketen gives the compound (VII). The condensation product from

retenequinone and stilbene is assigned the structure (VIII). All these products are colourless except (VIII), which is light yellow. On pyrolysis, the compounds were resolved into their generators except that diphenylketen was not obtained from (VII), probably because of its thermolability.

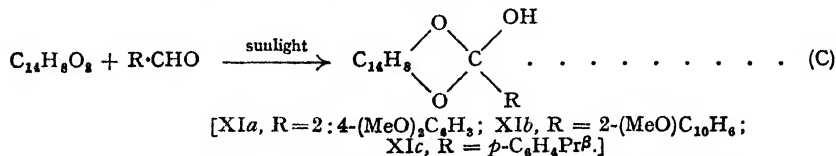

The photo-products from (III) and diphenylketen were insoluble in aqueous sodium hydroxide, but were readily attacked when heated with aqueous-alcoholic sodium hydroxide, a behaviour according with the lactone structure assigned to them; the resulting solutions were orange-coloured.

(b) To the list of triarylmethanes forming peroxides in air and sunlight by route (A) (Schönberg and Mustafa, J., 1945, 657), we now add 9-*α*-naphthylthioxanthen, 9-*m*-tolylxanthen, and 9-*p*-tolyl-, 9-*p*-anisyl-, and 9-*α*-naphthyl-xanthen. The first two are new and were prepared as shown in (B) for the naphthyl compound:

9-Benzylxanthen in benzene was unchanged when exposed to sunlight in presence of oxygen. It seems that an aryl group in position 9 in xanthyl is necessary for the formation of peroxides in sunlight by the action of oxygen.

(c) Schönberg and Moubasher (*J.*, 1939, 1430) described a number of photo-reactions between phenanthraquinone and aromatic aldehydes according to (C). We have carried out similar reactions with 2 : 4-dimethoxybenzaldehyde, 2-methoxy-1-naphthaldehyde, and cuminaldehyde; the first two reactions are much slower than that between benzaldehyde and phenanthraquinone in sunlight : this may be due to steric hindrance (ortho-effect).

(d) Lately, two methods have been described for conversion of diphenyl triketone into benzil by processes in the dark, namely, by the action (i) of aluminium chloride and (ii) of selenium (precipitated) in the presence of oxygen (Schönberg and Azzam, *J.*, 1939, 1430; Schönberg and Moubasher, in the press). It has now been found that the conversion is also effected when a benzene solution of the triketone is exposed to sunlight, but no reaction takes place in the dark in the absence of catalysts.

EXPERIMENTAL.

All substances were in solution unless otherwise stated. The benzene used was free from toluene* and thiophen and had been dried over sodium. The reaction mixtures were placed in a Schlenk tube (Schlenk and Thal, *Ber.*, 1913, 46, 2655; comp. Houben, "Die Methoden der Organischen Chemie", 2nd Edition, Vol. 4, p. 960) of Pyrex glass, and the air was then displaced by dry carbon dioxide and the tube sealed by fusion.

The photo-formation of peroxides was carried out as above, but in the presence of dry air.

Control experiments in the dark, but otherwise under identical conditions, showed no reaction.

(a, i) *Photo-reactions with Phenanthraquinone.*—9-Benzylidenexanthien. Phenanthraquinone (1 g.) and 9-benzylidenexanthien (Ia) (Decker, *Ber.*, 1905, 38, 2493) (1.3 g.) in benzene (50 c.c.) were exposed to sunlight for 4 months (February—June), the phenanthraquinone gradually dissolving completely. The benzene was evaporated off in a vacuum, and the residual dark solid washed with cold acetone and crystallised from benzene—light petroleum (b. p. 30—50°), forming almost colourless crystals, m. p. 241° (red brown melt) (Found : C, 84.8; H, 4.9. C₂₄H₂₂O₃ requires C, 85.3; H, 4.6%). The product (V), when treated with sulphuric acid, gave an olive-green colour; it was soluble in hot benzene and ligroin (b. p. 100—150°).

Thermal decomposition. The foregoing product was heated for ½ hour at about 270° (bath temp.) in a stream of dry carbon dioxide (the height of the decomposition tube being about 25 cm.); red-brown fumes were evolved, and an orange liquid collected on the walls of the tube. After 24 hours, this solidified to a mixture of orange and almost colourless crystals; extraction with hot light petroleum (b. p. 50—60°) left a residue of phenanthraquinone (identified, after recrystallisation from alcohol, by m. p., mixed m. p., and colour reaction with sulphuric acid). The extract was concentrated, and the resulting crystals, recrystallised from ethyl alcohol, proved to be 9-benzylidenexanthien (Ia).

9-Benzylidenethioxanthien. Phenanthraquinone (1 g.) and 9-benzylidenethioxanthien (Ib) (Decker, *loc. cit.*) (1.4 g.) in 30 c.c. of benzene were exposed to sunlight for 3 months (August—November), the phenanthraquinone dissolving as before and the orange colour of the solution fading to pale yellow. The crystals that separated were filtered off, washed several times with hot absolute ethyl alcohol, and recrystallised from benzene, forming colourless crystals, m. p. 245° (orange melt) (Found : C, 82.6; H, 4.6; S, 5.9. C₂₄H₂₂O₂S requires C, 82.6; H, 4.4; S, 6.5%). The product (as V) gave a brown colour with sulphuric acid at room temperature; it was difficultly soluble in cold ethyl alcohol, but soluble in hot benzene; when heated as described above, it yielded its generators, which were separated as above.

Methyleneanthrone. Phenanthraquinone (1 g.) and methyleneanthrone (II) (Clar, *Ber.*, 1936, 69, 1687) (1 g.) in 25 c.c. of benzene were exposed to sunlight for 40 days (February—April); the phenanthraquinone dissolved, and the resulting crystals were filtered off and washed with cold benzene, followed by hot ethyl alcohol; they recrystallised from chlorobenzene, forming almost colourless crystals, m. p. 165° (decomp.; green melt), and gave a bluish-green colour with sulphuric acid. The product (as V) (Found : C, 84.1; H, 4.3. C₂₀H₁₈O₃ requires C, 84.1; H, 4.4%) is difficultly soluble in hot ethyl alcohol, but soluble in benzene; when heated as described above, it yielded its generators, separated as before.

Benzylidenephthalide. Phenanthraquinone (1 g.) and benzylidenephthalide (III) (*Org. Synth.*, Coll. Vol. 2, p. 61) (1.1 g.) in benzene (25 c.c.) were exposed to sunlight for 20 days (May); the quinone dissolved, and the resulting crystals were filtered off and washed with light petroleum (b. p. 50—60°). The product crystallised from xylene in colourless crystals, m. p. 310° (red-brown melt) (Found : C, 80.3; H, 4.1. C₂₂H₁₈O₄ requires C, 80.9; H, 4.2%). It gave no colour with sulphuric acid at room

* Toluene in sunlight acts as a reducing agent; e.g., phenanthraquinone is transformed into 9 : 10-dihydroxyphenanthrene (Benrath and Meyer, *J. pr. Chem.*, 1914, 89, 258).

temperature, but a violet colour at 100°; it was difficultly soluble in cold ethyl alcohol and benzene, but soluble in hot xylene. Its behaviour with alkalis is described on p. 997.

Thermal decomposition was carried out for $\frac{1}{2}$ hour at about 330° (bath temp.) as described above. The resulting mixture was separated as before.

1:1-*Di-p-xenylpropylene*.—Phenanthraquinone (1 g.) and the olefin (IVb) (Pfeiffer and Schneider, *J. pr. Chem.*, 1931, **129**, 129) were exposed to sunlight for 50 days (March—April). The benzene was evaporated off in a vacuum, and the residual dark oil extracted with hot ligroin (b. p. 100—150°). The extract, on slow evaporation in a vacuum, gave crystals, which recrystallised from ethyl alcohol in colourless crystals, m. p. 143° (orange melt) (Found: C, 88.9; H, 5.8. $C_{41}H_{30}O_2$ requires C, 88.8; H, 5.5%). 2:2-*Dixenyl-3-methylphenanthro-9':10'-1:4-dioxen* (as VI) when treated with sulphuric acid gave an olive-green colour after a few minutes at room temperature; it was soluble in benzene and hot ethyl alcohol.

The thermal decomposition was carried out as described above for $\frac{1}{2}$ hour at about 270° (bath temp.); the mixture was separated as before.

Diphenylketen. Phenanthraquinone (1 g.) and diphenylketen (Staudinger, *Ber.*, 1911, **44**, 1622) (2 g.) in 30 c.c. of benzene were exposed to sunlight for 3 months (March—May), the phenanthraquinone dissolving as before and the solution becoming brown. The crystals that separated were filtered off, washed with cold benzene, and recrystallised from hot benzene, forming almost colourless crystals, m. p. 227—230° (decomp.; orange melt) (Found: C, 83.5; H, 4.5. $C_{28}H_{18}O_3$ requires C, 83.6; H, 4.5%). The compound (VII) gave no immediate colour with sulphuric acid, but a dirty-green colour developed after some time; it was difficultly soluble in ligroin (b. p. 90—100°) and ethyl alcohol, but soluble in hot benzene; for its behaviour with alkali, see p. 997.

Thermal decomposition (15 mins. at bath temp. ca. 300°) afforded drops of an orange oil which solidified after 24 hours and were identified as phenanthraquinone.

as.-*Dixenylethylene*. Phenanthraquinone (1 g.) and the ethylene (IVc) (1.6 g.) (Pfeiffer and Schneider, *loc. cit.*) were exposed to sunlight for 3 months (March—June). The separated solid was collected, washed with cold ether and then with hot acetone, and recrystallised from benzene in colourless crystals, m. p. 234° (Found: C, 89.5; H, 5.3. $C_{40}H_{28}O_2$ requires C, 88.9; H, 5.2%). 2:2-*Dixenylphenanthro-9':10'-1:4-dioxen* (as VI), when treated with sulphuric acid, gave a red-brown colour at room temperature; it was soluble in hot benzene and difficultly soluble in ligroin (b. p. 90—100°).

For separation of the products of thermal decomposition (15 minutes at bath temp. ca. 290°), hot ligroin (b. p. 90—100°), in which (IVc) is soluble, was used.

1:1-*Di-p-anisylpropylene*. Phenanthraquinone (1 g.) and the olefin (IVa) (Pfeiffer and Wizinger, *Annalen*, 1928, **461**, 145) (1.1 g.) were exposed to sunlight for 3 months (March—June). The benzene was evaporated off in a vacuum and the brownish oily residue was extracted several times with ligroin (b. p. 70—80°). The extract, on slow evaporation, gave an almost colourless solid residue which recrystallised from benzene-light petroleum (b. p. 50—60°) in colourless crystals, m. p. 181° (orange-brown melt) (Found: C, 80.2; H, 5.6. $C_{31}H_{26}O_4$ requires C, 80.5; H, 5.6%). 2:2-*Di-p-anisyl-3-methylphenanthro-9':10'-1:4-dioxen* (as VI) when treated with sulphuric acid at room temperature gave a dark brown colour changing after a few minutes into olive-green; it was soluble in hot benzene, difficultly soluble in cold ethyl alcohol.

The products of thermal decomposition (bath temp. ca. 270°) were separated as in the preceding case.

(a, ii) *Photo-reaction between Retenequinone and Stilbene*.—Retenequinone (1 g.) and stilbene (0.7 g.) in 25 c.c. of benzene were exposed to sunlight for 21 days (March), the quinone then having dissolved. The benzene was evaporated off in a vacuum, and the solid residue was washed with cold light petroleum (b. p. 80—100°), and crystallised from ethyl alcohol, forming very light yellow crystals, m. p. 224—226° (decomp.; red melt) (Found: C, 86.8; H, 6.5. $C_{32}H_{26}O_2$ requires C, 86.5; H, 6.3%). 5:6-*Diphenyl-(1'-methyl-7'-isopropylphenanthro)-9':10'-1:4-dioxen* (VIII) gave no colour with sulphuric acid at room temperature, but a red colour at 100° and was soluble in hot benzene. At ca. 270° (bath temp.) it decomposed into retenequinone (identified, after recrystallisation from chloroform and ethyl alcohol, by mixed m. p. and colour reaction with sulphuric acid) and stilbene (recrystallised from ethyl alcohol and identified by m. p. and mixed m. p.). (This experiment was carried out with M. Z. Barakat.)

(b) *Action of Oxygen on Triarylmethanes in Sunlight*.—(1) *9- α -Naphthylxanthene*. Reduction of 9- α -naphthylxanthinhydratol (Gomberg and Schoepfle, *J. Amer. Chem. Soc.*, 1917, **39**, 1668) was carried out as described by Ullmann and Engi (*Ber.*, 1904, **37**, 2371) for the phenyl compound, i.e., by means of zinc dust and acetic acid with platinum chloride as a catalyst. 9- α -Naphthylxanthene recrystallised from benzene-light petroleum (b. p. 30—50°), m. p. 184° (Found: C, 89.5; H, 5.1. Calc. for $C_{23}H_{18}O$: C, 89.6; H, 5.2%). Kovache (*Ann. Chim.*, 1918, **10**, 184) gives m. p. 184°. It was soluble in benzene and gave no colour with sulphuric acid.

9- α -Naphthylxanthene was insolated for 5 days (February). The colourless crystals that separated were recrystallised from xylene; m. p. 228° (decomp.; dark melt) (Found: C, 85.3; H, 4.7. Calc. for $C_{40}H_{30}O_2$: C, 85.4; H, 4.7%). For the peroxide, Gomberg and Schoepfle (*loc. cit.*) gave m. p. 228—230°. The peroxide was practically insoluble in light petroleum (b. p. 30—50°) or in cold benzene, but soluble in hot benzene or xylene, and gave a deep red solution with sulphuric acid.

(2) *9- α -Naphthylthioxanthene*. To a Grignard solution of α -naphthylmagnesium bromide (magnesium, 1.2 g.; α -bromonaphthalene, 10.4 g.; dry ether, 50 c.c.), dry benzene (30 c.c.) was added, and the mixture treated gradually with powdered thioxanthone (Davis and Smiles, *J.*, 1910, **97**, 1296) (6 g.). The solution became yellow and a yellow precipitate formed; the mixture was refluxed for one hour, set aside overnight, poured into ice-cold dilute hydrochloric acid, extracted with ether, the extract dried, and the ether-benzene mixture evaporated. The residue, washed with cold ethyl alcohol and recrystallised from hot ethyl alcohol, had m. p. 191—192° (Found: C, 81.1; H, 4.3; S, 8.8. $C_{23}H_{18}OS$ requires C, 81.2; H, 4.7; S, 9.4%). 9- α -Naphthylthioxanthinhydratol was soluble in cold benzene, ether, and hot ethyl alcohol, and gave a red colour with sulphuric acid. It was reduced as in the preceding case, and the colourless 9- α -naphthylthioxanthene crystallised from benzene with one molecule of solvent of crystallisation, m. p. 77° (Found: C, 86.7; H, 5.5; S, 7.9. $C_{23}H_{18}S.C_6H_6$ requires C, 86.5;

H, 5.4; S, 7.9%). It was freely soluble in benzene, but difficultly soluble in ethyl alcohol; it gave no colour with sulphuric acid.

This xanthen was insolated for 4 days (February). The colourless crystals that separated, recrystallised from benzene-light petroleum (b. p. 30–50°), had m. p. 176° (efferv.). 9-*a*-Naphthylthioxanthyl peroxide (Found: C, 81.1; H, 4.4; S, 8.8. $C_{44}H_{30}O_2S_2$ requires C, 81.4; H, 4.5; S, 9.4%) is slightly soluble in hot benzene and soluble in hot xylene and gives a violet colour with sulphuric acid.

(3) 9-*m*-Tolylxanthen. 9-*m*-Tolylxanthhydrol, prepared substantially as for 9-*a*-naphthylthioxanthhydrol but from *m*-tolylmagnesium bromide (magnesium, 1.2 g.; *m*-bromotoluene, 9 g.; dry ether, 30 c.c.; dry benzene, 30 c.c.) and xanthone (5 g.), separated from benzene in colourless crystals, m. p. 149° (Found: C, 82.8; H, 5.6. $C_{30}H_{18}O_2$ requires C, 83.3; H, 5.5%). It was soluble in hot benzene and difficultly soluble in light petroleum (b. p. 30–50°) and gave a red colour with sulphuric acid.

Reduction of 9-*m*-tolylxanthhydrol was carried out as for the naphthyl analogue. The colourless 9-*m*-tolylxanthen, crystallised from ethyl alcohol, had m. p. 98° (Found: C, 88.1; H, 5.5. $C_{30}H_{18}O$ requires C, 88.2; H, 5.9%). It was difficultly soluble in cold ethyl alcohol, but soluble in hot ethyl alcohol or hot benzene; it gave no colour with sulphuric acid.

9-*m*-Tolylxanthen was insolated for 38 days (February–March), during which the benzene solution became yellow. The colourless crystals, obtained by evaporation of the benzene, followed by washing with absolute ethyl alcohol, were recrystallised from benzene-ethyl alcohol and had m. p. 205°. The peroxide (Found: C, 83.2; H, 5.4. $C_{40}H_{30}O_4$ requires C, 83.6; H, 5.2%) was soluble in cold benzene, but insoluble in hot ethyl alcohol; it gave a yellow colour with sulphuric acid.

(4) 9-*p*-Tolylxanthen. Reduction of 9-*p*-tolylxanthhydrol (Gomberg and Cone, *Annalen*, 1909, **370**, 164) was carried out as above. The colourless 9-*p*-tolylxanthen, crystallised from ethyl alcohol, had m. p. 116° (Found: C, 87.7; H, 5.9. Calc. for $C_{30}H_{18}O$: C, 88.2; H, 5.9%) (Kovache, *loc. cit.*, gives m. p. 116°). It gave no colour with sulphuric acid.

9-*p*-Tolylxanthen was insolated for 2 days (April). Colourless crystals, which began to separate after a few hours, were finally recrystallised from benzene; m. p. 217–218° (decomp.) (Found: C, 83.3; H, 5.6. Calc. for $C_{40}H_{30}O_4$: C, 83.6; H, 5.3%). Gomberg and Cone (*loc. cit.*, p. 166) give m. p. 212° (not sharp) for the peroxide. It dissolved with difficulty in light petroleum (b. p. 30–50°) and gave a brownish-red colour with sulphuric acid.

(5) 9-*p*-Methoxyphenylxanthen. Reduction of 9-*p*-methoxyphenylxanthhydrol (Gomberg and West, *J. Amer. Chem. Soc.*, 1912, **34**, 1528) was carried out as for the naphthyl analogue. The colourless xanthen, crystallised from ligroin (b. p. 70–80°), had m. p. 117° (Found: C, 82.9; H, 5.5. Calc. for $C_{30}H_{18}O_2$: C, 83.3; H, 5.5%) (Kovache, *loc. cit.*, gives m. p. 115°). It gave no colour with sulphuric acid.

9-*p*-Methoxyphenylxanthen was insolated for 30 days (February–March). The colourless crystals that separated were recrystallised from xylene, m. p. 205° (decomp.; dark brown melt) (Found: C, 79.1; H, 5.2. Calc. for $C_{40}H_{30}O_6$: C, 79.2; H, 4.9%). Gomberg and West (*loc. cit.*) give m. p. 214° (decomp.) for *p*-methoxyphenylxanthyl peroxide. It was soluble in boiling benzene and toluene, slightly soluble in cold benzene, and insoluble in light petroleum (b. p. 30–50°), and gave a red-brown colour with sulphuric acid.

(6) 9-Benzylxanthen. 9-Benzylxanthen (Decker, *loc. cit.*) (2 g.) was insolated for four months (April–August) in the presence of air. On slow evaporation of the benzene solution, it was recovered practically unchanged.

(c) Photochemical Reaction between Phenanthraquinone and Aromatic Aldehydes.—(i) 2:4-Dimethoxybenzaldehyde. Phenanthraquinone (1 g.) and the aldehyde (0.8 g.) in benzene (30 c.c.) were exposed to sunlight for 10 days (August). The colourless crystals that separated were washed with small amounts of cold benzene and crystallised from benzene, from which the 2:4-dimethoxyphenylhydroxymethylene ether of 9:10-dihydroxyphenanthrene (XIa) separated in colourless needles, m. p. 223° (red brown melt) (Found: C, 73.4; H, 4.8. $C_{23}H_{18}O_6$ requires C, 73.8; H, 4.8%). It was soluble in hot chloroform and benzene and difficultly soluble in hot ethyl alcohol; it gave a green colour with sulphuric acid.

(ii) Cuminaldehyde. Phenanthraquinone (1 g.) and cuminaldehyde (0.7 g.) in benzene (30 c.c.) were exposed to sunlight for 6 days (September). The resulting colourless crystals, recrystallised from ligroin (b. p. 80–90°), had m. p. 168–170° (decomp.; red melt). The benzene solution on concentration, gave a further amount of the cuminyldihydroxymethylene ether of 9:10-dihydroxyphenanthrene (XIc) (Found: C, 80.1; H, 5.3. $C_{24}H_{20}O_6$ requires C, 80.9; H, 5.6%). It was difficultly soluble in cold ethyl alcohol, but soluble in hot benzene; it gave an olive-green colour with sulphuric acid.

(iii) 2-Methoxy-1-naphthaldehyde. Phenanthraquinone (1 g.) and 2-methoxy-1-naphthaldehyde (0.9 g.) in benzene (30 c.c.) were exposed for 10 days (September). The benzene was evaporated in a vacuum, and the residue washed with hot ethyl alcohol and crystallised from ligroin (100–150°), forming colourless crystals, m. p. 190° (orange melt) (Found: C, 79.1; H, 4.6. $C_{26}H_{18}O_4$ requires C, 79.1; H, 4.6%). The 2-methoxy-1-naphthylhydroxymethylene ether of 9:10-dihydroxyphenanthrene (XIb) was soluble in benzene and difficultly soluble in hot ethyl alcohol; it gave a green colour with sulphuric acid.

(d) Action of Sunlight on Diphenyl Triketone.—Diphenyl triketone (2 g.) (*Org. Synth.*, Coll. Vol. 2, p. 244) in benzene (20 c.c.) was exposed to sunlight for 21 days (May). The benzene solution on evaporation in a vacuum, gave a yellow residue. The latter, on crystallisation from ligroin (b. p. 70–80°) gave yellow crystals, m. p. 95°, proved to be benzil (m. p. and mixed m. p.); yield ca. 70%. The dark experiment was negative.

187. *The Crystal Structure of the Orthorhombic Modification of 1 : 2 : 5 : 6-Dibenzanthracene. A Quantitative X-Ray Investigation.*

By J. MONTEATH ROBERTSON and J. G. WHITE.

The crystal and molecular structure of the orthorhombic modification of 1 : 2 : 5 : 6-dibenzanthracene has been determined by quantitative X-ray analysis. The molecular arrangement in the crystal is quite different from that found for other aromatic hydrocarbons (e.g., anthracene, coronene, or pyrene). There are four molecules in the unit cell and these each possess an exact centre of symmetry (space-group *Pcab*). The molecules lie approximately in layers along the 200 planes, to which they are tilted at an angle of about 31° ; 9 out of the 11 carbon atoms are separately resolved in the Fourier maps, and the bond lengths connecting these atoms can be directly measured. These vary from 1.38 to 1.45 Å.

An approximate calculation of the bond distances from the 12 stable valency-bond structures for dibenzanthracene is given, but there is less agreement with the observed values than was found in coronene and pyrene.

Unfortunately, the accuracy is not likely to be quite as high as in the other structures mentioned above. In the central ring of the molecule the resolution is good and here the error should not exceed ± 0.02 Å. In the outer parts of the molecule the bond-length variations (Fig. 3) must be considered rather doubtful. It is shown, however, that the co-ordinates given lead to better structure factor agreements than can be obtained from any regularised model.

RECENT X-ray measurements on coronene and pyrene (Robertson and White, *J.*, 1945, 607; this vol., p. 358) have established that the carbon-carbon bond lengths vary slightly in different parts of these molecules. These variations are small, in fact, not much greater than the possible experimental error under present conditions; nevertheless, the variations do seem to conform to a fairly definite pattern which is capable of at least partial explanation in terms of the more important structures which contribute to the normal states of these molecules.

We have now extended our measurements to 1 : 2 : 5 : 6-dibenzanthracene. This hydrocarbon exists in two distinct crystalline modifications, monoclinic and orthorhombic. Preliminary data for the monoclinic form have been given by Iball and Robertson (*Nature*, 1933, 132, 750). The orthorhombic form, with which we are concerned in the present paper, was first described by Krishnan and Banerjee (*Z. Krist.*, 1935, 91, 170, 173), who studied the magnetic anisotropy of the crystal and from their measurements of the magnetic susceptibilities were able to deduce the approximate orientation of the molecules. Accurate values for the cell dimensions, and a determination of the space-group have been given by Iball (*Nature*, 1936, 137, 361), but detailed atomic positions have not been given by any of these authors.

The crystal structure and molecular arrangement in orthorhombic dibenzanthracene differs from that of both the coronene and the pyrene structures. Like coronene, the molecules are found to display an exact centre of symmetry and to this extent the analysis is simplified. However, the unit cell contains four complete molecules and their mutual arrangement (see Figs. 1 and 2) makes it impossible to obtain resolution of all the atoms in any projection of the structures. In this respect the results obtained from the present two-dimensional analysis resemble the pyrene results, and they should similarly be regarded as a preliminary analysis, carried out with as much accuracy as possible, which must be undertaken before any further refinement by more elaborate three-dimensional methods can be attempted. In the present case the most favourable Fourier projection of the structure (Fig. 1) shows separate resolution of nine out of the eleven crystallographically independent carbon atoms, and direct measurements of these positions can be made. The results indicate certain bond-length variations, as shown in Fig. 3. These figures represent the most probable values, but they are unfortunately subject to certain errors. The accuracy in the central ring should be reasonably high, the errors here probably not exceeding ± 0.02 Å. In the other parts of the molecule the observed bond-length variations must be considered rather doubtful.

Description of the Structure.—*Crystal data.* 1 : 2 : 5 : 6-Dibenzanthracene, $C_{22}H_{14}$; M , 278.3; m. p. 267.5° ; d , calc. 1.294, found 1.282; orthorhombic bipyramidal, $a = 8.22$, $b = 11.39$, $c = 15.14$ Å. (Iball). Absent spectra, $(0kl)$ when l is odd, $(h0l)$ when h is odd, $(hk0)$ when h is odd. Space-group D_{2h}^{15} (or Q_h^{15}) (*Pcab*). Four molecules per unit cell. Molecular symmetry, centre. Volume of the unit cell, 1418 Å^3 . Absorption coefficient for X-rays, $\lambda = 1.54 \text{ Å}$, $\mu = 6.78 \text{ cm}^{-1}$; $\lambda = 0.71 \text{ Å}$, $\mu = 0.86 \text{ cm}^{-1}$. Total number of electrons per unit cell = $F(000) = 584$.

Structure analysis. The space-group *Pcab* with only four molecules in the unit cell requires that the molecules must possess centres of symmetry which coincide with the crystallographic centres of symmetry. The asymmetric unit may therefore be taken as one half of the chemical

FIG. 1(a).

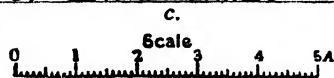

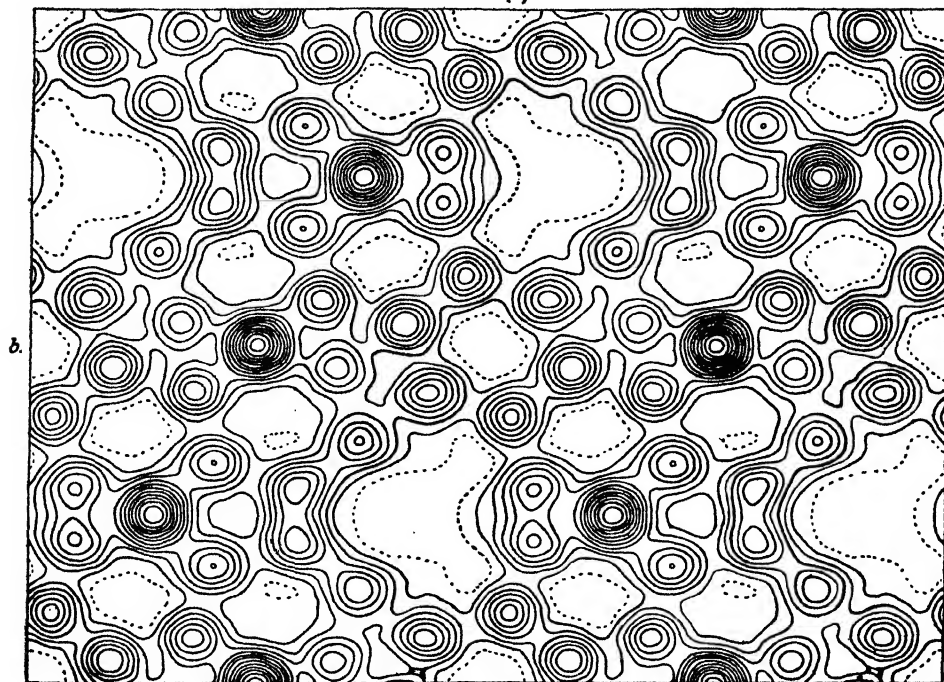

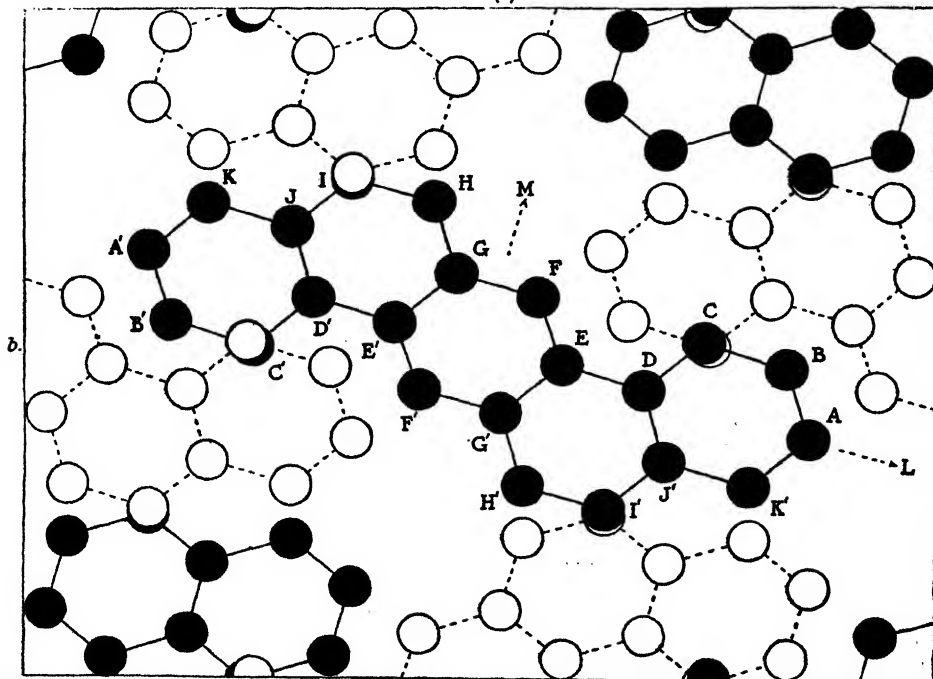

FIG. 1(b).

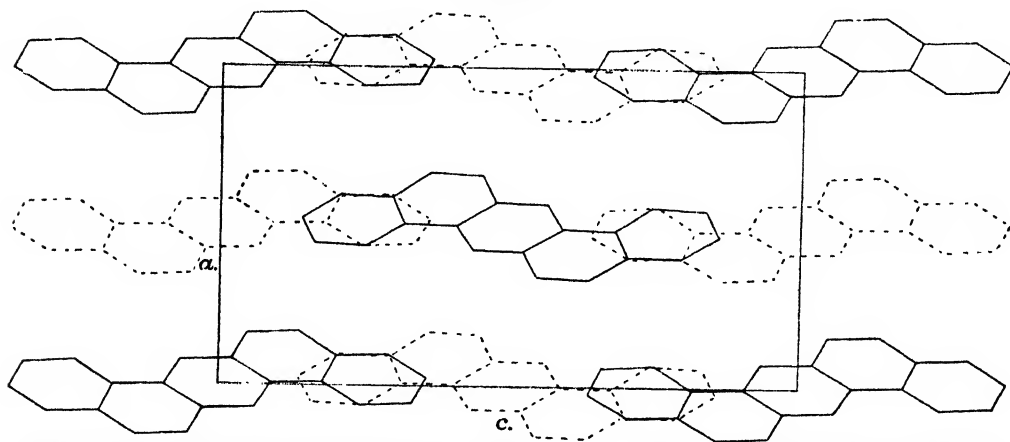

Projection along the *a* axis on the (100) or *bc* plane. The molecules are inclined at about 31° to the projection plane. Each contour line corresponds to a density increment of one electron per \AA^3 , the one-electron

molecule, or eleven carbon atoms, if we neglect the hydrogen atoms. As a first approximation a regular planar structure was assumed, according to the usual chemical formula.

The magnetic measurements of Krishnan and Banerjee (*loc. cit.*) give the tilt of the molecular plane to the *bc* plane as 29° , and these authors predict that the long axis of the molecule (*L* in Fig. 1*b*) probably lies along the *c* axis of the crystal. The first of these observations is probably fairly accurate, but the second can only be an approximation. Now, the strength of the (200) reflection ($F = 153$) suggests that if the molecular plane is inclined at about 30° to the *bc* plane, as the magnetic measurements suggest, then the line of zero tilt in the molecule must be its longest axis, that is, the molecular axis *L* must lie in, or very nearly in, the *bc* plane.

Bearing these factors in mind, only one degree of freedom remains to be fixed, the angle which *L* makes in the *bc* projections with the crystal axis *c* (or *b*). A suitably drawn projection of the molecules may then be pivoted about the centre of symmetry in the *bc* plane and the effect of various positions on the (*0kl*) structure factors may be tested by inspection or simple calculation. In practice the (020) structure factor was used as an index, as its low value ($F = 24$) makes it extremely sensitive. When the molecular axis *L* is made to coincide with the crystal axis *c* the calculated value of this structure factor is much too large, but it can be brought to the correct value by a rotation of about 16° away from the *c* direction. A further small rotation would make

FIG. 2.

View of the molecular arrangement projected on the 010 plane. The dotted molecules are situated half a translation along the *b* axis.

this structure factor pass through zero and assume a negative value, but this possibility can be ruled out by the calculation of certain other structure factors.

Detailed calculations on this basis gave reasonably good agreements between the measured and the calculated values of all the structure factors, and it was possible to proceed immediately to further refinement of the atomic positions by Fourier series methods. Two successive Fourier syntheses of the (*0kl*) zone were carried out, 50 terms being included in the first, and 56, all the reflections which could be observed in this zone, in the second. The results of this final synthesis are given by the contour map of Fig. 1(*a*), from which it can be seen that nine out of the eleven crystallographically independent atoms are resolved. The other two atoms, *C* and *I*, are obscured by the overlapping of related atoms in adjoining molecules as indicated in Fig. 1(*b*).

The *y* and *z* co-ordinates finally adopted were obtained from those actually measured on this map after a correction for incompleteness of the Fourier series due to Booth (*Nature*, 1945, 156, 51). In this method a Fourier synthesis of the same zone is carried out using the calculated instead of the observed values of the structure factors and omitting all terms which are omitted in the final Fourier synthesis. The resulting map was found to give certain small changes in the atomic positions and these shifts were added to the observed co-ordinates but with opposite sign. This led to a slight improvement in the agreements between the measured and the calculated values of the structure factors, as described below (Experimental Section).

The *x* co-ordinates of the atoms cannot be obtained directly, as the other possible projections would give little information because of overlapping effects. These co-ordinates can only be calculated on the assumption that the molecule is planar, but this assumption is well supported

by the agreements obtained between the calculated and the observed values of the structure factors for the other two zones.

A complete picture of the crystal symmetry may be obtained by considering Fig. 1 in conjunction with Fig. 2, which shows diagrammatically the projection along the b axis.

Orientation, co-ordinates, and dimensions. By assuming a planar molecule and averaging certain distances as described more fully in the Experimental Section, it is possible to calculate the orientation of the molecule. The results are given in Table I, where χ , ψ , and ω are the angles which the molecular axes L and M [Fig. 1 (b)] and their perpendicular, N , make with the a , b , and c crystallographic axes. These results give the inclination of the molecular plane to the (100) plane, expressed by χ_N , as 31.3° in reasonably good agreement with the value of 29° predicted by Krishnan and Banerjee (*loc. cit.*).

TABLE I.

Orientation of the molecule in the crystal.

$\chi_L = 92.1^\circ$	$\cos \chi_L = -0.0374$	$\chi_M = 58.8^\circ$	$\cos \chi_M = 0.5180$
$\psi_L = 106.1^\circ$	$\cos \psi_L = -0.2771$	$\psi_M = 35.3^\circ$	$\cos \psi_M = 0.8162$
$\omega_L = -16.2^\circ$	$\cos \omega_L = 0.9601$	$\omega_M = 75.2^\circ$	$\cos \omega_M = 0.2558$
	$\chi_N = 31.3^\circ$	$\cos \chi_N = 0.8545$	
	$\psi_N = 120.5^\circ$	$\cos \psi_N = -0.5069$	
	$\omega_N = 96.5^\circ$	$\cos \omega_N = -0.1130$	

The co-ordinates with respect to the crystal axes are collected in Table II; y_1 and z_1 are the co-ordinates of the resolved atoms measured directly from the Fourier projection, while y_2 and z_2 are the values finally adopted after correction for the incompleteness of the Fourier series. It will be seen that the difference is small. The co-ordinates of the two atoms C and I which cannot be directly measured are those which the atoms would have in a regular hexagonal molecule in the above orientation. These positions are in agreement with the appearance of the double peaks shown in Fig. 1(a) but the centres cannot be assigned with any great certainty.

Table II lists the co-ordinates (x, y, z) for the eleven carbon atoms in the asymmetric crystal unit; the co-ordinates of all the other atoms in the unit cell may be obtained from these by the relations appropriate to the space-group $Pcab$, viz.,

$$\pm (x, y, z; 1/2 + x, 1/2 - y, z; x, 1/2 + y, 1/2 - z; 1/2 - x, y, 1/2 + z)$$

TABLE II.

Co-ordinates. Centre of symmetry as origin; y_1 and z_1 are co-ordinates measured directly, y_2 and z_2 co-ordinates adopted after correction.

The molecular dimensions and bond lengths may be calculated from these co-ordinates and are shown graphically in Fig. 3. The ringed atoms are those separately resolved in Fig. 1, and the bond distances between these atoms are the only ones which can be obtained directly.

From the orientation of the molecule and the co-ordinates given in Table II the molecular co-ordinates of the atoms may be calculated and these are collected in Table III.

Intermolecular distances. The closest distance of approach between atoms of different molecules occurs between the standard molecule and the reflected molecule at $(1/2 - x, y, 1/2 + z)$. Between C on the standard molecule and J on this reflected molecule the distance is 3.54 A., while between F and A' the atoms are 3.56 A. apart. Other distances in this direction are $CD' 3.76$ A., $CK 3.71$ A., $EB' 3.87$ A., and $FK 3.78$ A. The distances are not quite so close between the first molecule and the reflected molecule at $1/2 + x, 1/2 - y, z$, where the atom I on the standard molecule is 3.59 A. from D' on the reflected molecule, 3.75 A. from J , and 3.82 A.

TABLE III.

from E'. All other pairs of atoms are more than 4 Å. apart, and the distances given above are just about the same as the usual intermolecular distances encountered in hydrocarbon structures.

It will be noted that in the dibenzanthracene structures all the primitive translations are greater than 8 Å., and we do not encounter pairs of molecules which directly overlie one another as in the phthalocyanine, coronene, or pyrene structures. It is therefore not profitable to discuss the normal projections of pairs of parallel molecules in this case, because they are widely separated and interleaved with parts of other differently oriented molecules.

FIG. 3.

*Dimensions of the molecule of 1 : 2 : 5 : 6-dibenzanthracene.*

Discussion of Results.—The bond-length measurements given in Fig. 3 vary from 1.38 to 1.45 Å., a slightly larger range than that found in coronene, and about the same as that found in pyrene (Robertson and White, *loc. cit.*). Unfortunately, the accuracy obtained in the present investigation is not likely to be quite as high as in these other structures. The unusually large values found for *GH*, *JK*, and *KA'* are very difficult to assess, as the atoms *H* and *K* are so distorted by their proximity to the corresponding atoms in the reflected molecule that their centres are rather more uncertain than those of the other resolved atoms. These bond lengths must therefore be considered as rather doubtful. The central ring, however, is quite free from any such distorting effects, and here the maximum error in the bond lengths should not be greater than ± 0.03 Å., and probably does not exceed ± 0.02 Å. The bond *GE* is, therefore, probably longer than the other two independent bonds in this ring, which are both very close to the benzene value of 1.39 Å.

Beyond this fairly definite conclusion little can be said with certainty. It will be noted that the dibenzanthracene molecule contains no symmetry element apart from the centre that can be used to average the bond lengths into any system of groups, as was done for coronene. However, the measurements recorded in Fig. 3 do receive a measure of general support from the very satisfactory agreements obtained between the observed and calculated values of the structure factors (Table IV). These agreements are better than can be obtained from any regular model placed in the same orientation.

For comparison with the results obtained for coronene and pyrene (Robertson and White,

is little agreement. The widest divergence is in the bond $K'A$, which is calculated as rather shorter than the benzene value and found experimentally longer than the graphite distance. As stated above, the position of K is rather uncertain, and under such conditions agreement could not be expected.

Structures (I) and (II) each contain four benzenoid rings, (III) and (IV) each contain three, and (V) and (VI) each contain only two, the remaining rings being quinonoid in type. If we attempt to apply the Fries rule, by preferring those structures which contain the largest number of benzenoid rings, the effect on the above calculations is disappointing. The bond lengths in the central ring tend to become equalised at the benzene value of 1.39 Å., and in the other parts of the molecule more extreme values are obtained, which are not in agreement with the observations.

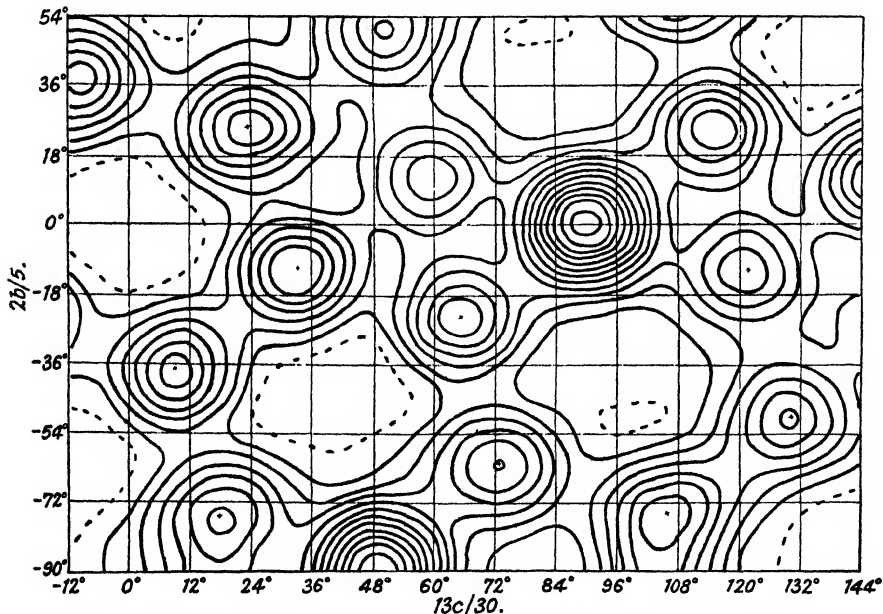

While lack of agreement in the outlying parts of the molecule may be due to experimental error to some extent, it should be noted that no rigorous theoretical derivation of bond lengths in a molecule of this shape has yet been made. It is possible that the excited structures (completely neglected in the above treatments) may play an appreciable part in such an asymmetric molecule, while in more symmetric molecules of the coronene type they may be relatively less important.

The calculated average value for the bond lengths in (VIII) is 1.41 Å., while the experimental average is 1.42 Å. The latter figure is, surprisingly, rather larger than that usually found in polycyclic aromatic hydrocarbons. It would, however, be necessary to determine the primitive translations of the crystal with greater accuracy before attaching undue importance to this average figure.

EXPERIMENTAL.

X-Ray Measurements.—Most of the X-ray work was carried out photographically with Cu- $K\alpha$ radiation ($\lambda = 1.54$), using rotation, oscillation, and moving-film methods. In addition, certain absolute measurements were made on the ionisation spectrometer, using monochromatic copper and molybdenum radiation.

FIG. 4.

Co-ordinates assigned to the resolved atoms in the bc projection of dibenzanthracene.

Some very beautifully formed specimens of the crystals were supplied by Dr. Iball, crystallised from ethyl acetate. These crystals appear to be remarkably stable and are little affected by exposure to X-rays; we have used some of them for many years as sub-standards for calibration purposes in absolute intensity work.

For the present investigation the intensity work was carried out mainly on three different specimens, which weighed 0.116, 0.081, and 0.0665 mg., respectively. These specimens were selected so that on rotation the path of the X-ray beam in the crystal did not vary by more than about 0.2 mm., and relative

absorption corrections for different reflections in the same zone were neglected. Most of the intensities were measured from calibrated films, using an integrating photometer of the type described by Robinson (*J. Sci. Instr.*, 1933, 10, 233). Only a few of the weakest reflections were estimated visually.

The absolute measurements were made directly on the ionisation spectrometer, with monochromatic rays, and also by means of sub-standards, employing the photographic technique (Robertson, *ibid.*, 1943, 20, 175). The usual formulae and correction factors for mosaic crystal specimens were employed.

Fourier Analysis.—Using the phase constants obtained initially from the trial structures and the measured values of *F*, a double Fourier series was set up according to the usual formulae. The electron density was computed at 450 points on the asymmetric unit, the *b* axis being divided into 60 parts (intervals of 0.190 Å.) and the *c* axis into 60 parts (intervals of 0.252 Å.). The summations were carried out by means of three-figure strips (Robertson, *Phil. Mag.*, 1936, 21, 176). The positions of the contour lines were obtained by graphical interpolation from the summation totals, by making sections of both the rows and columns. The resulting contour map is shown in Fig. 1, the whole unit cell being included.

Orientation of the molecule and co-ordinates. From an inspection of the observed lengths in projection of *ED* and parallel distances, which can be only very slightly tilted, it was found that the best average radius of the hexagons is 1.42 Å. With this average value and the assumptions that *L* and *M* are at right angles and that the molecule is planar, it was possible to calculate the orientation of the molecule with respect to the crystallographic axes.

The distances *FG'*, *EH'*, and *BK'* as measured from the projection given in Fig. 1 are 2.102 ± 0.040 Å., and from the assumed mean radius of the hexagons (1.42 Å.) the angle χ_M which *M* makes with the *a* crystal axis is obtained as 58.8° . The inclination of *L* cannot be derived in this way because it is very near to 90° . The calculation may, however, be made from the observed angle between *L* and *M* in the projection. The projected lines *ADE*, *BF*, and *K'J'G'* are inclined at a mean angle of $-16.1^\circ \pm 0.6^\circ$ to the *c* axis, and the lines *BK'*, *EH'*, and *FG'* make the mean angle of $72.6^\circ \pm 0.3^\circ$ with *c*. From these figures the complete orientation of the assumed regular planar molecule may be obtained by relations similar to those already given for the coronene analysis (Robertson and White, *loc. cit.*).

The next step consists of assigning the most probable positions to the centres of the resolved atoms, without the aid of any regularised model. The positions finally adopted after the Booth corrections for incompleteness of the Fourier series, etc., are shown by small crosses in Fig. 4. From these positions and the orientation now calculated, the actual molecular co-ordinates may be obtained (Table III), and the interatomic distances readily follow. The crystal co-ordinates are given in Table II.

The structure factors of the (*0kl*) zone have been recalculated on various assumptions, and the mean discrepancy, expressed as

$$\frac{\sum (|F_{\text{meas.}}| - |F_{\text{calc.}}|)}{\sum F_{\text{meas.}}}$$

has been evaluated with the following results. For a regular hexagonal model with a constant carbon-carbon distance of 1.42 Å. placed in the best orientation, the discrepancy is 16.1%. For the co-ordinates obtained directly from the contour maps (Figs. 1 and 4) without any assumptions about regularity (y_1 , z_1 in Table II), the discrepancy is reduced to 15.0%. After the Booth corrections, the final values for the co-ordinates, which are used for calculating the bond lengths (y_2 , z_2 in Table II), give a discrepancy of 13.8%. The differences between these figures are small, and their significance is difficult to estimate, but they do seem to justify the use of our final co-ordinates as being preferable to any set of regularised co-ordinates.

In calculating the structure factors the scattering curve formerly used for hydrocarbons (Robertson, *Proc. Roy. Soc.*, 1935, A, **150**, 110) was found to be rather unsuitable, as the calculated values for small spacing planes were consistently higher than the observed values. For the large spacing planes the tendency was for the observed structure factors to be larger than the calculated. In order to keep the upper part of the scattering curve at the usual values, all the absolute F 's were multiplied by a scale correction factor of 0.84 and then an empirical scattering curve was drawn for $\sin \theta = 0.5$ —0.9. The values used for this range are given below (max. $f_e = 100$).

$\sin \theta$ ($\lambda = 1.54$)	0.5	0.6	0.7	0.8	0.9
f_e	23.5	15.0	9.5	7.0	4.5

The general agreements calculated from the final co-ordinates are quite as good as are usually found in this type of analysis. The discrepancies are 13.8% for the (0kl) zone, 12.0% for the (hk0) zone, and 13.2% for the (h0l) zone. For all structure factors the mean discrepancy is 12.6%. The measured and calculated values of the structure factors are collected in Table IV.

We thank Professor J. W. Cook, F.R.S., and Dr. J. Iball for pure specimens of material used in this work, and Dr. Iball for much valuable preliminary data. We are also indebted to the Royal Society for a grant which defrayed the cost of some of the apparatus employed.

UNIVERSITY OF GLASGOW.

[Received, November 4th, 1946.]

188. The Chemistry of Plutonium.

By B. G. HARVEY, H. G. HEAL, A. G. MADDOCK, and (Miss) E. L. ROWLEY.

A survey of some of the chemical and electrochemical properties of plutonium has been made. Valency states of 3, 4, and 6 have been established.

Oxidation and reduction reactions between the different valency states have been investigated. The reactions of plutonium ions with some of the commoner organic reagents are described.

PLUTONIUM was discovered late in 1940 by Seaborg, McMillan, Kennedy, and Wahl (*Physical Rev.*, 1946, **69**, 366; see also Seaborg, Wahl, and Kennedy, *ibid.*, p. 367). The investigations now reported were carried out with about 5 mg. of ^{239}Pu extracted from neutron-irradiated uranium. Experiments were carried out either with the plutonium in tracer concentrations, or else, by microchemical methods, with plutonium concentrations of the order of 1 mg. per ml.

^{239}Pu is an α -active nucleus with a half-life of 2.4×10^4 years (Seaborg, *Chem. Eng. News*, 1945, **23**, 2190).

I. *The Valencies of Plutonium.*—Plutonium was investigated in each of three well-defined valency states. It appears to be more stable to both mild oxidation and reduction when it is in the middle valency state of the three; in this condition, it was shown to be quadrivalent (see Experimental, A).

Polarographic experiments in plutonium solutions showed the presence of a wave at a half-wave potential of + 0.7 volt on the hydrogen scale. It was already known that plutonium could be oxidised to a valency state higher than 4, but the observed wave did not appear to be sufficiently positive to correspond to this process. It was therefore suspected that the wave corresponded to the reduction of plutonium to a state with a valency lower than 4. The existence of such a state was immediately confirmed chemically, and its valency was shown to be 3 by two methods (Experimental, B, i and ii), and that of plutonium in its highest oxidation state was shown to be 6 by the experiment described under B, iii.

II. *The Electrochemistry of Plutonium.*—Plutonium, like uranium, is a base metal and a transition element. Electrochemical studies were therefore mainly concerned with the processes of oxidation and reduction between the various valency states, and with complex formation. Evidence for complex formation is presented elsewhere (Sect. IV).

The potential of the Pu–Pu(III) couple. No indication of the potential of this couple has been obtained. The corresponding couple U–U(III) has a potential which has been estimated at – 1.5 volts (European sign convention) (Heal, unpublished work), and it is probable that the value for plutonium is not very different from this.

The potential of the couple Pu(III)–Pu(IV). The potential was determined both by direct measurement and polarographically (see C and D). The best characterised waves obtained are shown in Figs. 3a, 3b, and 3c. In all cases the diffusion current was lower for Pu(IV) than for Pu(III) solutions. The explanation of this phenomenon remains obscure.

The estimates of the molal oxidation–reduction potential given below were taken from the

direct determination in the case of sulphuric acid, and from the half-wave potentials in the other two cases :

In $1N-H_2SO_4$, + 0.72 volt at 23°. In $1N-HCl$, + 0.99 volt at 30°. In $1N-HClO_4$, + 0.86 volt at 23°.

These results show that the tervalent plutonium ion is a much less powerful reducing agent than the tervalent uranium ion (which liberates hydrogen from water). Indeed, the quadrivalent plutonium ion may be reduced to the tervalent state by the quadrivalent uranium ion. This reaction was studied polarographically at 30°, with the results recorded in E (Experimental).

III. *The Reactions of Plutonium.*—(a) *Oxidation-reduction reactions.* (i) In aqueous solutions, Pu(IV) may be reduced to Pu(III) by sulphur dioxide, hydroxylamine hydrochloride, the uranous ion, hydrazine hydrochloride, the iodide ion, electrolytically at a platinum cathode, or by shaking with mercury in chloride solutions.

The reaction with sulphur dioxide is slow at room temperature, but in hot solutions it goes to completion in about 5 minutes. The reduction of Pu(IV) by the iodide ion is also somewhat slow at room temperature in both sulphate and chloride solutions. The titration of the liberated iodine does not appear to be a useful method for the routine determination of plutonium.

(ii) Oxidation of Pu(III) by atmospheric oxygen is fairly rapid, and solutions of Pu(III) salts are completely oxidised to Pu(IV) on two or three evaporations to dryness in an open vessel in air. However, Pu(III) solutions are stable in an inert atmosphere. Permanganate oxidises Pu(III) quantitatively to Pu(IV) at room temperature in acid solutions. At 60°, the plutonium is oxidised to the hexavalent state.

(iii) In tracer concentrations of plutonium, the following oxidising agents were found to oxidise the Pu(IV) ion to the hexavalent state: hot potassium permanganate, potassium dichromate, argentic salts (including sodium perdisulphate in the presence of silver ions), and ceric ions. The conditions found to give satisfactory oxidation with perdisulphate and silver ions in these experiments are set out in section F (Experimental).

In concentrations of about 1 mg. per ml., Pu(IV) was oxidised to the hexavalent state by the following reagents: potassium permanganate in hot acid solution, hot sodium perdisulphate, argentic nitrate at room temperature, or hot bromate solutions containing nitric acid.

(iv) Pu(VI) is reduced to the ter- or quadri-valent state by sulphur dioxide, ferrocyanide ions, and hydrogen peroxide. The last reaction is complicated by a subsequent reaction between the hydrogen peroxide and the Pu(IV) ion to give a precipitate of a plutonium peroxide (see p. 1012).

(b) *Compounds of tervalent plutonium.* Solutions of tervalent plutonium salts are bright blue. The sulphate, chloride, and perchlorate are readily soluble in dilute acids. On addition of an excess of ammonium hydroxide a dirty blue precipitate of plutonium hydroxide is obtained. It may readily be redissolved in dilute acids to give solutions of Pu(III) salts.

The fluoride is insoluble in dilute acids, and tracer amounts of tervalent plutonium may be removed from solution by coprecipitation with lanthanum fluoride in the presence of hydrofluoric acid.

In the presence of hydroxylamine hydrochloride (to keep the plutonium in the reduced state), Pu(III) can be precipitated on a carrier of lanthanum oxalate. The removal of plutonium from the solution, however, was only 75% complete. The plutonium could be removed from the lanthanum oxalate carrier by washing with hot ammonium oxalate solution. It was not removed by ammonium oxalate solution at room temperature.

In acetate buffers at pH's of 3.6 and 5.6 it was found that Pu(IV) was much more completely removed from solution on a precipitate of bismuth oxychloride than was Pu(III); Pu(IV) ions therefore appear to be much more readily hydrolysed in solution than Pu(III) ions. To prevent losses of plutonium by adsorption on to glass, it is always necessary to work in acid solutions: $pH < 1$ is normally safe.

Pu(III) cannot be removed from acid solutions by coprecipitation with zirconium and one of the typical reagents for quadrivalent ions such as phenylarsonic acid or *m*-nitrobenzoic acid. Since Pu(IV) may readily be precipitated under these conditions, this enables a separation of Pu(III) from Pu(IV) to be carried out (see p. 1013).

(c) *Compounds of quadrivalent plutonium.* Solutions of the quadrivalent salts of plutonium are pale pink, with the exception of the nitrate, whose solutions are green.

Oxide, PuO_2 . Ignition of the nitrate, iodate, or hydroxide of quadrivalent plutonium at about 500–600° yields a dark brown oxide PuO_2 . In thin layers, the oxide appears to be yellow. If prepared by gentle ignition, it may easily be redissolved in hot concentrated

sulphuric or nitric acid. If ignited to a bright red heat, it dissolves readily only in potassium hydrogen sulphate at a dull red heat.

Hydroxide. The hydroxide is precipitated on the addition of ammonium hydroxide to solutions of Pu(IV) salts. It is a pale green gelatinous substance which can be centrifuged very readily. Precipitation of this hydroxide is one of the most convenient ways of removing plutonium from solution.

After being washed with dilute ammonium hydroxide and dried at 100°, the hydroxide dissolves readily in 1N-mineral acids, but decidedly more readily in nitric than in sulphuric or hydrochloric acid.

Peroxide. When hydrogen peroxide is added to an acid solution of a quadrivalent plutonium salt, a red-brown colour develops, and a bulky green precipitate of doubtful composition is slowly deposited. Precipitation of the plutonium is most complete in the pH range 3–4.5. The presence of sulphate ion appears to favour the reaction.

A precipitate of the same nature is obtained by adding hydrogen peroxide to solutions containing sexavalent plutonium, but it is formed less readily than from Pu(IV) solutions. It is therefore probable that the peroxide is a compound of quadrivalent plutonium, and that hydrogen peroxide reduces Pu(VI) to Pu(IV). The peroxide of plutonium is therefore quite different from uranium peroxide (peruranic acid). It is insoluble in sodium hydroxide solutions, and is presumably not a per-acid.

The peroxide dissolves in concentrated nitric acid with evolution of oxygen, to give a bright blue solution. When this solution is warmed, more oxygen is lost, and the blue solution fades to the pale green of Pu(IV) nitrate solutions. The peroxide may also be dissolved in 6% sulphurous acid solution.

The ratio of plutonium to peroxidic oxygen in the peroxide was determined by permanganate titration as described in the Experimental (G, i); if the permanganate reacted with the peroxidic oxygen in the same way as it does with hydrogen peroxide, the titration indicates that the ratio of atoms plutonium to atoms peroxidic oxygen is 2 to 3 (see G, ii). If the 0.335 mg. not accounted for is expressed as oxygen, the data give the following atomic ratios: Pu, 1; SO₄, 0.30; O (peroxidic and non-peroxidic), 2.93. The peroxide could therefore be written as PuO₃· $\frac{1}{3}$ SO₄. It is possible that the dried peroxide is different in composition from the original precipitate. Thorium, for example, forms two peroxides, Th₂O₇ (or Th₂O₇·SO₄) and ThO₃. The latter form is more stable than the former, and is obtained when the former is allowed to decompose (Pascal, "Traité de Chimie Minérale," Vol. 11, p. 289).

Fluoride. The fluoride of Pu(IV) coprecipitates very well with lanthanum fluoride. Experiments (see H) were carried out to determine the weight of lanthanum which must be precipitated as fluoride in order to obtain efficient carrying of the plutonium. Precipitation of plutonium on a lanthanum fluoride carrier under these conditions appears to be substantially complete when the weight of lanthanum precipitated is greater than about 0.1 mg. per ml. of plutonium solution.

The precipitation of plutonium fluoride in the absence of a carrier was uncertain: 0.35 mg. of Pu(IV) in 2 ml. of 1N-perchloric acid was not precipitated by the addition of 48% hydrofluoric acid. In higher concentrations of plutonium, a gelatinous precipitate was obtained which quickly collapsed to a dense yellowish powder, difficult to centrifuge off on account of its lack of coherence. The precipitation of an equal weight of lanthanum fluoride was found to bind the precipitate and eliminate this difficulty.

Sulphate, Pu(SO₄)₂. Evaporation of Pu(IV) solutions, prepared from the hydroxide and sulphuric acid or from the peroxide and sulphurous acid in the presence of sulphuric acid, followed by gentle ignition to remove the sulphuric acid, gives anhydrous *plutonium sulphate* as a light pink powder. The same compound is obtained when the oxide PuO₂ is fumed down to dryness with sulphuric acid. The anhydrous salt may be weighed in air. It is soluble in dilute mineral acids to give pale pink solutions. Dilute sulphuric acid solutions appear to be metastable, and sometimes a deposit of red-brown crystals is obtained on standing (Experimental, I).

Nitrate. Solutions of the nitrate in nitric acid are green. A sample of the hydrated solid nitrate was readily soluble in nitromethane.

Iodate, Pu(IO₃)₄. The iodate is obtained as a voluminous, very pale pink precipitate on addition of iodic acid or an iodate solution to solutions of Pu(IV) salts. It dissolves readily in 6% sulphurous acid solution, giving a solution containing tervalent plutonium.

Phenylarsonate. Pu(IV) is coprecipitated very efficiently from acid solutions on a precipitate of zirconium phenylarsonate, and the best pH range for this coprecipitation was investigated (Experimental, J), even strongly acid solutions being suitable.

In the presence of reducing agents (SO_2 or hydroxylamine hydrochloride), it was found that plutonium was not carried down at all by zirconium phenylarsonate. It was therefore concluded that the phenylarsonate of Pu(III) is soluble.

m-Nitrobenzoate. Pu(IV) may be precipitated on zirconium *m*-nitrobenzoate. The effect of pH on the completeness of the precipitation was investigated in the same way as with phenylarsonic acid (Experimental, K). In the presence of reducing agents, plutonium was not carried down on the precipitate of zirconium *m*-nitrobenzoate. It was therefore concluded that the *m*-nitrobenzoate of Pu(III) is soluble.

(d) *Compounds of sexavalent plutonium.* Ammonium plutonate. This salt may be prepared by adding ammonium hydroxide to a hot solution of a plutonium salt which has been oxidised to the sexavalent state with argentic nitrate; it is thereby obtained as a brownish-yellow precipitate which may be filtered off after it has cooled and stood until coagulated. The composition of ammonium plutonate has not been determined.

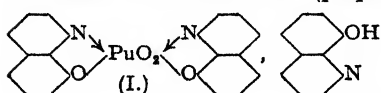

On account of the similarity between the chemistry of uranium and of plutonium in their sexavalent states, the terms "plutonate" and "plutonyl" have been used in the present paper to describe the sexavalent compounds of plutonium.

Plutonyl fluoride. Sexavalent plutonium is not precipitated on a lanthanum fluoride carrier in the presence of an excess of hydrofluoric acid. By this method, plutonium can readily be separated from lanthanum.

Plutonyl nitrate. Ammonium plutonate dissolves readily in nitric acid to give an orange solution, which, by analogy with uranium, is believed to contain plutonyl nitrate, $\text{PuO}_2(\text{NO}_3)_2$. At low pH values, the solution appears pink, and as the pH is increased, the colour becomes progressively more orange.

Ethyl ether and nitromethane extracted plutonyl nitrate from its aqueous solutions saturated with ammonium nitrate.

Sodium plutonyl acetate. Addition of sodium acetate solutions to a mixed plutonyl and ammonium nitrate solution (prepared by dissolving ammonium plutonate in nitric acid) slowly

precipitates crystals similar in appearance to those of sodium uranyl acetate, but pale mauve in colour. The compound is presumably sodium plutonyl acetate.

Plutonyl "oxinate." 8-Hydroxyquinoline ("oxine") precipitates plutonyl ions quantitatively in the pH range 3.5–9. The plutonium content of this oxinate was determined as described in Experimental (L). The weight of the complex obtained agreed with the structure (I) for the oxinate, which therefore appears to be the analogue of the corresponding uranyl complex.

IV. *Complex Formation by Plutonium.*—(a) *Inorganic complex ions.* The oxidation-reduction potentials for the Pu(III)–Pu(IV) couple are about +0.72 volt in 1N-sulphuric acid, +0.99 volt in 1N-hydrochloric acid, and +0.86 volt in 1N-perchloric acid. This variation indicates that there must be a tendency towards complex formation with the anion in at least two of the three acids, but the electrochemical evidence does not indicate in which acids this occurs. The presence of a high concentration of chloride ions inhibited the coprecipitation of Pu(III) on a lanthanum fluoride carrier, whereas the sulphate ion showed no real effect. This indicates that Pu(III) ions probably form complexes in chloride solutions. Similarly, ammonium thiocyanate completely inhibited the coprecipitation of Pu(IV) on a carrier of zirconium phenylarsonate or *m*-nitrobenzoate, thus indicating that Pu(IV) ions probably form complexes with the thiocyanate ion.

The presence of alkali carbonates interfered with the extraction of the acetylacetone complex of Pu(IV) into benzene. Experiments with visible quantities of plutonium showed that Pu(IV) salts, including the fluoride, dissolve completely in excess of ammonium carbonate.

Experiments with tracer amounts of plutonium showed that Pu(IV) coprecipitated with lanthanum oxalate could be washed off the lanthanum precipitate with hot or cold ammonium oxalate solution much more readily than could Pu(III). The solubility of Pu(IV) oxalate in ammonium oxalate was confirmed by using visible quantities of plutonium. Pu(IV) fluoride was also found to be readily soluble in ammonium oxalate solution.

(b) *Organic complexes of plutonium.* A brief survey of the behaviour of Pu(III), Pu(IV), and Pu(VI) towards some of the commoner organic complexing reagents was made. The results are contained in Experimental (M). In some cases, the reaction between the plutonium ion and the organic reagent was studied in more detail, using tracer concentrations of plutonium.

Diketone complexes. The extraction coefficient (defined as the ratio of the concentrations

of plutonium in the solvent and the aqueous layer) was measured at various pH's for the systems Pu(IV), water, benzene, and acetylacetone, trifluoroacetylacetone, or benzoylacetone. With the first two diketones, the extraction coefficient rose from 0.5 at pH 1 to an almost constant value of 80 at pH's of greater than 5 for acetylacetone and greater than 4 for trifluoroacetylacetone. The benzoylacetone gave a maximum extraction coefficient of 8 at a pH of 4. At higher pH's, the extraction coefficient decreased.

Salicylate complex. The extraction coefficient was measured for the system Pu(IV), amyl acetate, salicylic acid, and water at different concentrations of salicylic acid and at two different pH's. The detailed results are given in Experimental (N). In general, the extraction coefficient increased with increasing salicylate concentration in the aqueous layer, but at the higher pH, it was lower for a given salicylate concentration than for the same salicylate concentration at the lower pH. The irregularity of some of the results is believed to be due to the fact that a considerable proportion of the plutonium adhered to the glass walls of the vessels at the pH's used.

EXPERIMENTAL.

General Methods.—(a) *Preparation and purification of plutonium compounds.* During the present work, several methods were used for the initial purification of plutonium and for its recovery from the residues of previous experiments. The most useful method was found to be the one already described by Seaborg *et al.* (*loc. cit.*, p. 367) in which plutonium is precipitated with a carrier of lanthanum fluoride, and then separated from the lanthanum fluoride by making use of the solubility of the fluoride of hexavalent plutonium.

The plutonium in the ter- or quadri-valent state is precipitated on a carrier of lanthanum fluoride by the method described above. The precipitate is then dissolved by fuming with sulphuric or perchloric acid, and the solution is diluted with water. The plutonium is then oxidised to the hexavalent state: potassium permanganate in hot solution was found to be the most convenient oxidising agent for this purpose. The lanthanum is then precipitated by the addition of hydrofluoric acid, leaving the plutonium in solution.

The final purification of the plutonium may be carried out by evaporating the solution to fuming to eliminate the excess of hydrofluoric acid, reducing the plutonium to the tervalent state by warming with an excess of 6% sulphurous acid solution, and then precipitating the plutonium as Pu(OH)₃ by the addition of ammonium hydroxide.

The Pu(OH)₃ may then be dissolved in sulphuric acid, the plutonium converted to the quadrivalent state by evaporating the solution to dryness in air, and then successively precipitated as peroxide and iodate until the desired degree of purity has been reached.

(b) *Methods of determining plutonium.* Counting of α -particles provides a rapid method for carrying out determinations of relative amounts of plutonium when working with tracer quantities of the element. The half-life of ²³⁹Pu is 2.4×10^4 years (Seaborg, *loc. cit.*). This corresponds to the production of 138×10^6 α -particles/min./mg. Pu.

Plutonium may be weighed as Pu(SO₄)₂, PuO₂, or Pu(IO₃)₄. The sulphate is particularly convenient, since it may be prepared by fuming many plutonium compounds to dryness with sulphuric acid. The iodate is a useful form in which to weigh small amounts of Pu since it contains only 25.46% of Pu.

It has already been mentioned that permanganate titration of Pu(III) or Pu(IV) may be carried out in hot acid solutions. Titration of the iodine liberated in sulphate solution by the oxidation of iodide ions by Pu(IV) ions is not a convenient method for routine estimation of plutonium because the reaction is rather slow. In chloride solutions, the reaction is faster, but the titration is still not satisfactory.

(A) About 1 mg. of plutonium was purified and precipitated from sulphate solution as its insoluble iodate by addition of a solution of iodic acid. The precipitate was dried at 100° and weighed in a platinum crucible. It was then ignited to constant weight at a dull red heat in air. 3.532 Mg. of iodate gave a plutonium compound weighing 1.021 mg. after ignition. The loss of weight agrees well with the reaction $\text{Pu}(\text{IO}_3)_4 \rightarrow \text{PuO}_2 + 5\text{O}_2 + 2\text{I}_2$. The weights of iodate and oxide correspond to a valency of 3.92 for the middle oxidation state of plutonium. The 1.021 mg. of dioxide formed in this experiment was converted into sulphate by fuming to dryness three times with sulphuric acid. The sulphate weighed 1.616 mg.; *i.e.*, the sulphate contains 63.2% of PuO₂ [Pu(SO₄)₂ requires PuO₂, 62.9%].

(B) (i) During a determination of the oxidation-reduction potential of the Pu(IV)-Pu(IV-*n*) couple, it was found that a plot of the potential of a platinum electrode against the logarithm of the concentration ratio of Pu(IV) to Pu(IV-*n*) gave a straight line of slope 0.048 volt at 23°. This corresponds most nearly to the theoretical value of 0.059 volt for a single-electron transfer.

(ii) It was found that in sulphate solutions, the Pu(IV) ion will oxidise the iodide ion to iodine. The iodine which was liberated by 2.206 mg. of Pu(SO₄)₂ gave a titre of 0.47 ml. of 0.0103N-sodium thiosulphate. This corresponds to a valency difference of 0.95 between the middle and the lower state of plutonium.

(iii) 0.814 Mg. of Pu(SO₄)₂ was titrated in 1N-sulphuric acid solution with approximately 0.005N-potassium permanganate. Reaction was very slow at room temperature, but proceeded rapidly at 60°. After completion of the titration, the plutonium was reduced to the tervalent state by warming with sulphurous acid solution. The excess of sulphur dioxide was driven off by evaporating the solution to a very small volume in a stream of purified carbon dioxide. The tervalent plutonium was then titrated at room temperature to the quadrivalent state with the same permanganate solution. The end-point was quite definite and stable. On warming the solution to 60°, the pink colour of the end-

point faded, and a further quantity of permanganate reacted as the plutonium was oxidised to the highest valency state.

In four such cycles, the average volume of permanganate required to oxidise the Pu(III) to Pu(IV) was 0.37 ml. The volume required to oxidise the Pu(IV) to the highest valency state was almost exactly twice as much, *viz.*, 0.72 ml.

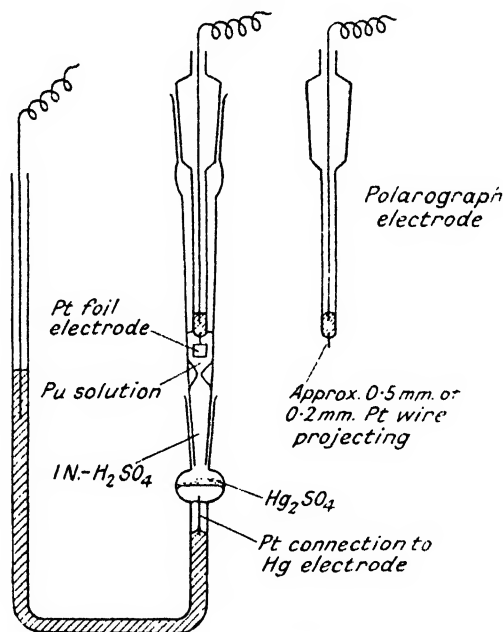

(C) Potentials of the cell

were measured. The cell is shown in Fig. 1.

The ratio of c_1 to c_2 was varied by mixing in various proportions stock solutions of Pu(IV) sulphate and of Pu(III) sulphate, both in 1N-H₂SO₄. The Pu(III) solution was made as and when required by both electrolytic reduction at a platinum cathode of a Pu(IV) solution.

FIG. 1.

Cell used for polarography and for E_0 measurements (half actual size).

The potentials were determined at 23°. They became steady within 5 mins. after insertion of the platinum electrode into the cell. The values are recorded below :

Potentials of the couple Pu(III)-Pu(IV).

Concn. of Pu(III) in solution, M.	Concn. of Pu(IV) in solution, M.	Potential, volt.	Concn. of Pu(III) in solution, M.	Concn. of Pu(IV) in solution, M.	Potential, volt.
0.00404	0.00058	0.0289	0.00152	0.00354	0.0825
0.00354	0.00118	0.0420	0.00101	0.00412	0.0931
0.00304	0.00177	0.0548	0.00051	0.00471	0.1050
0.00227	0.00265	0.0581			

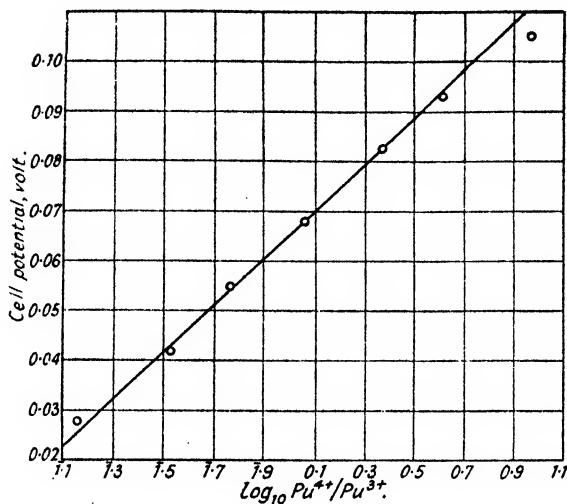

The molar concentrations were estimated by diluting a small volume of each of the stock solutions, and α -counting aliquots of the dilute solutions. There may thus be errors of up to 15% in the absolute concentration values, but as the same counter and counting technique were used for both of the solutions, the relative concentrations are believed to be correct to $\pm 5\%$.

Fig. 2 shows the linear variation of the potential with $\log_{10} c_2/c_1$. The potential when $c_2 = c_1$ was + 0.064 volt, with the platinum electrode positive. Assuming that the potential of the mercurous sulphate electrode is + 0.66 volt on the hydrogen scale, this gives a value of + 0.72 volt for the couple with equal concentrations. The molal standard potential is therefore in the region of + 0.72 volt.

Similar experiments designed to measure the potential of the same couple in 1N-hydrochloric acid and 1N-perchloric acid failed, because in several trials with different lots of plutonium the potentials drifted badly. However, the observed values of the equimolar potentials were always close to the potentials of the polarographic waves in the same solutions (see p. 1018).

(D) Polarographic experiments were carried out in 1*N*-sulphuric, -perchloric, and -hydrochloric acids (see Figs. 3, *a*, *b*, and *c*).

FIG. 2.

A small platinum wire micro-electrode replaced the foil electrode of the cell in Fig. 1, and a sintered-glass plug was substituted for the constriction. A dropping-mercury electrode could not be used because mercury dissolves anodically in the range of potentials studied. For polarograms in hydrochloric acid, a normal calomel reference electrode was used. For perchloric acid solutions, the reference electrode was Hg|Hg₂Cl₂(s) + 0.1*N*-HCl + 1*N*-HClO₄ with a bridge solution of 1*N*-HClO₄. In sulphuric acid, the reference electrode was Hg|Hg₂SO₄(s) + 1*N*-H₂SO₄.

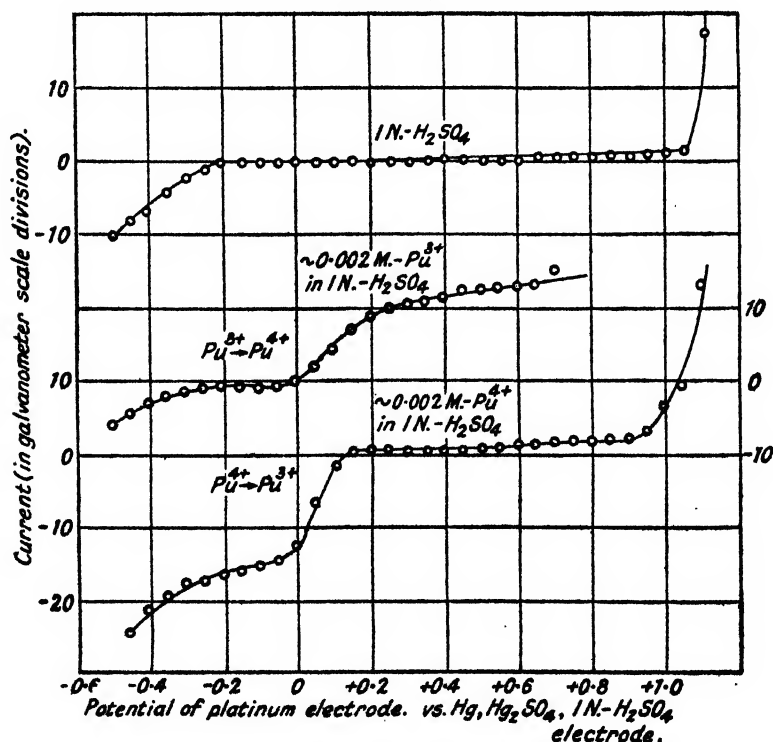

FIG. 3 (*a*).

FIG. 3 (b).

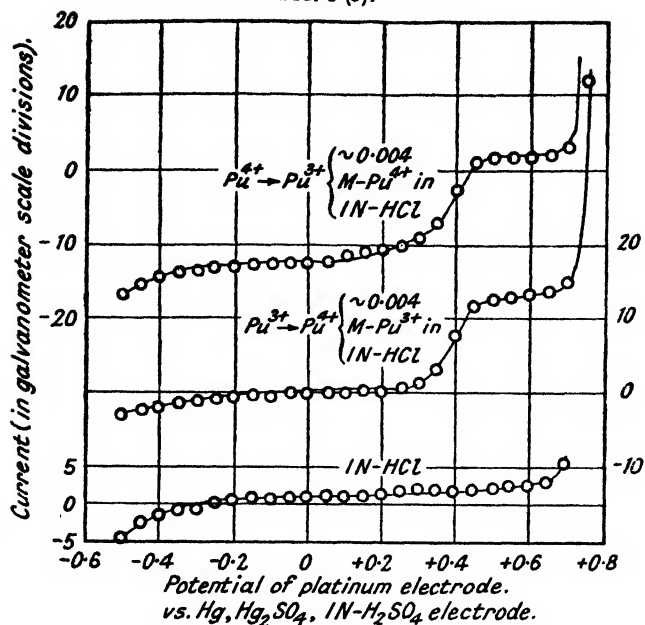

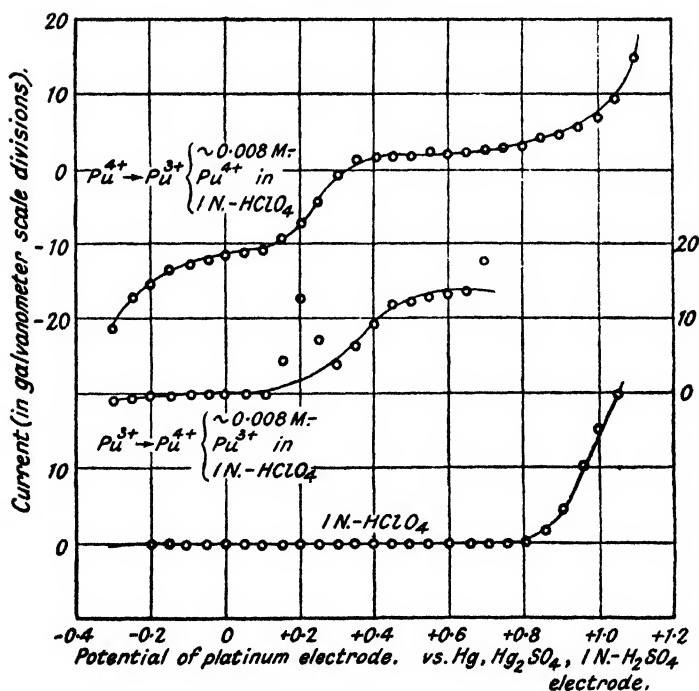

FIG. 3 (c).

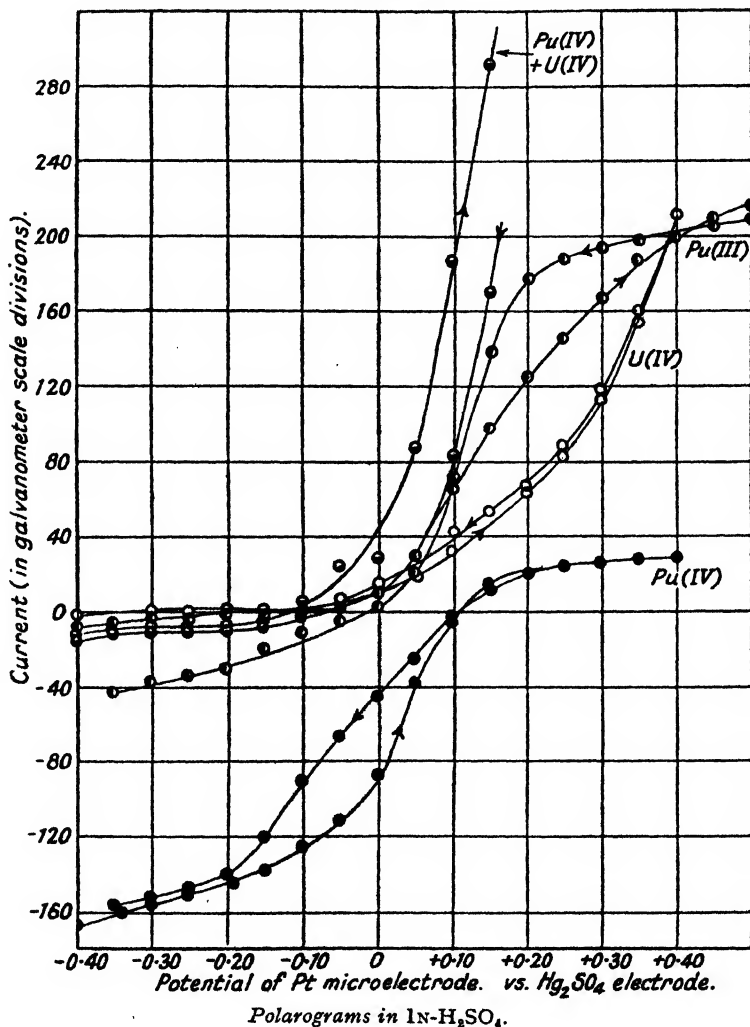

The polarograms in perchloric acid solution were carried out at 23°. In all other cases, the cell was held at 30° in a vibration-free thermostat.

(E) Small volumes of concentrated uranous sulphate and uranous chloride in their respective 1N-acids were added to solutions of Pu(IV) in 1N-sulphuric and hydrochloric acids. In both cases the Pu(IV) reduction wave disappeared within 2 or 3 minutes of the addition and was replaced by a wave starting

in the same place as the Pu(III) wave in the same solution (Figs. 4 and 5). The concentrations of Pu(IV) in these experiments were chosen so that after addition of the U(IV) solution, the Pu concentrations were equal to those used in plotting the polarograms for pure Pu(III) solutions given in the same diagram.

U(IV) in sulphuric and hydrochloric acids does not give an oxidation wave in this range of potentials. The great height of the oxidation wave in the Pu-U mixtures must be due to the oxidation of U(IV) at the electrodes in the presence of Pu(III), which acts as an electron carrier. (The uranium concentration was about 5 times the plutonium concentration.)

FIG. 4.

(F) Experiments were carried out in which the Pu(IV) ion was oxidised by the perdisulphate ion in the presence of silver ions. Different concentrations of reagents were tried, and the fraction of the plutonium which had been oxidised in the experiment was estimated by precipitating the remaining Pu(IV) on a carrier of lanthanum fluoride (the fluoride of sexavalent plutonium remains in solution under these conditions). The plutonium on the lanthanum fluoride carrier was then estimated by α -counting.

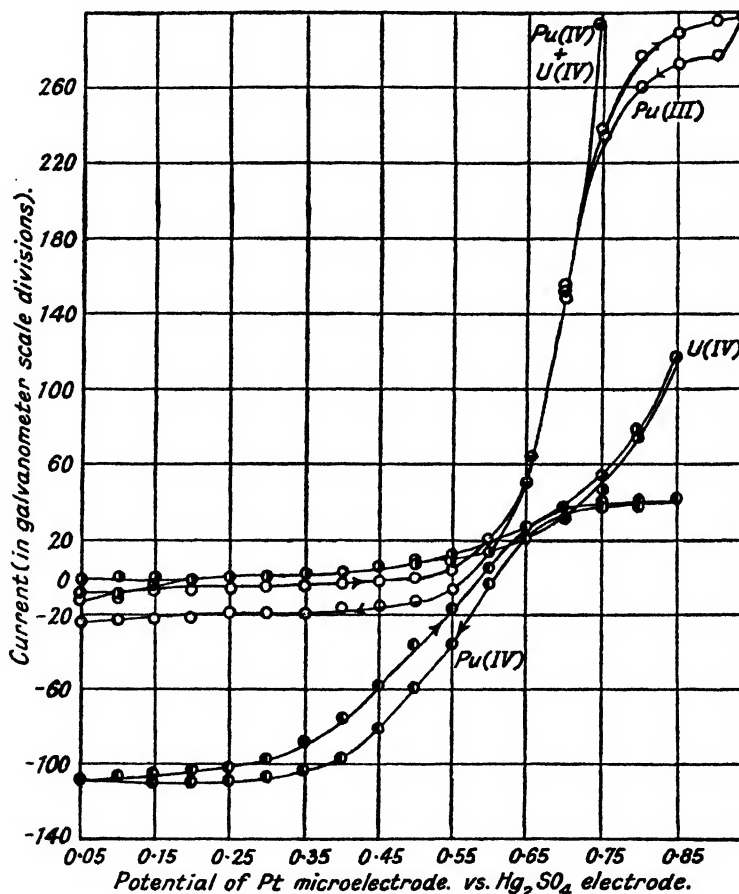

Concentrations of 0.2 mg. per ml. of silver ion and 2 mg. per ml. of perdisulphate ion were found to be sufficient. Oxidation of the plutonium took place when the solutions were heated to 80° and then allowed to cool and stand for 20 minutes. The presence of nitrate ions (about 0.5M) appeared to be advantageous. Perchloric acid up to 2M was without influence of the reaction.

(G) (i) A sample of plutonium peroxide precipitated from sulphate solution was washed free from excess of hydrogen peroxide, suspended in 1N-sulphuric acid, and titrated with potassium permanganate. It was found that on warming the solution very slightly, a reaction took place and the per-

oxide went into solution. After 0.71 ml. of permanganate had been used, the peroxide appeared to have dissolved completely, and further permanganate only reacted at a somewhat higher temperature. The volume of permanganate required at this higher temperature was 0.47 ml.

The second half of this titration was believed to represent the oxidation of Pu(IV) to Pu(VI). This was confirmed by reducing the plutonium to Pu(III) with sulphur dioxide, and evaporating the solution to fuming in air to remove the excess sulphur dioxide and convert the Pu(III) into Pu(IV). The same volume (0.47 ml.) of permanganate was used when the Pu(IV) obtained in this way was titrated to Pu(VI).

FIG. 5.

Polarograms in 1N-HCl.

(ii) A second sample of the peroxide, precipitated from sulphuric acid solution, washed three times with water, and dried to constant weight over silica gel at room temperature, was dissolved in concentrated nitric acid. The sulphate ion present in the solution was determined by precipitating it as barium sulphate. The plutonium was then precipitated from the solution as hydroxide and weighed as PuO_2 . The following results were obtained:

Wt. of peroxide, mg.	2.255
Wt. SO_4 , mg.	0.216
Wt. Pu, mg.	1.704
Total, mg.	1.920
Remainder, mg.	0.335

(H) A small weight of lanthanum nitrate in aqueous solution was added to a dilute perchloric acid solution containing a tracer quantity of quadrivalent plutonium; 48% hydrofluoric acid was then added until its concentration in the Pu-La solution was 12%. The precipitate of lanthanum fluoride was allowed to settle, and a further quantity of lanthanum nitrate, equal to the first amount, was then slowly added with good stirring.

After standing for about 80 minutes with occasional stirring, the solution was centrifuged to separate the fluoride precipitate. The supernatant solution was removed, and the precipitate washed several times with dilute hydrofluoric acid. The lanthanum fluoride was then spread on a sample tray, and the plutonium estimated by α -counting. The results are given below:

Precipitation of Pu(IV) on lanthanum fluoride.

Total wt. of La used, mg./ml. of Pu soln.	0.35	0.093	0.034	0.017
% Pu remaining in solution	1.49	1.94	6.11	10.4

(I) A sample of sulphate crystals (see p. 1012) was separated from the solution, washed with acetone, dried at room temperature and weighed. The sample was then converted into the anhydrous salt by fuming to dryness with sulphuric acid. The crystals were found to be the *tetrahydrate* [Found: $\text{Pu}(\text{SO}_4)_2$, 85.8. $\text{Pu}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$ requires $\text{Pu}(\text{SO}_4)_2$, 85.6%].

(J) Experiments were carried out to discover over what pH range zirconium phenylarsonate could be used as a carrier for tracer quantities of plutonium. Zirconyl nitrate solutions were added to dilute perchloric acid solutions containing tracer quantities of plutonium. The pH's of the solutions were then adjusted to various values by the addition of either more perchloric acid or ammonia. An excess of saturated aqueous phenylarsonic acid solution was then added, and the precipitate of zirconium phenylarsonate was removed by centrifuging, and its plutonium content estimated by α -counting. The results are shown herewith.

The precipitation of Pu(IV) on zirconium phenylarsonate.

pH	0.1	0.19	0.33	1.45	1.90	3.95
% Pu precipitated by 0.2 mg./ml. of Zr	87.6	88.5	93.9	93.7	90.0	93.2

(K) Precipitation of Pu(IV) on zirconium m-nitrobenzoate.

pH	0.39	1.46	1.88	3.80
% Pu precipitated by 0.2 mg./ml. of Zr	5.1 *	91.0	95.4	93.3

* Zr not completely precipitated.

(L) 9.457 Mg. of $\text{Pu}(\text{SO}_4)_2$ were dissolved in sulphuric acid and oxidised by heating for several hours at 90° on a steam-bath with an excess of sodium perdisulphate. The pH of the solution was then adjusted to about 5, and about 5 equivs. of oxine dissolved in acetic acid were added. The precipitate was coagulated by heating on the steam-bath, filtered off, washed with hot water, dried at 130°, and weighed. The *oxinate* weighed 15.713 mg. [Found: Pu, 33.4. $\text{PuO}_2(\text{C}_9\text{H}_6\text{ON})_2 \cdot \text{C}_9\text{H}_7\text{OH}$ requires Pu, 33.9%].

This work was carried out for the National Research Council of Canada, Atomic Energy Division, at Montreal, Que., and Chalk River, Ont. Two of the authors (B. G. H. and A. G. M.) were on leave from Messrs. Imperial Chemical Industries, Ltd. The authors are indebted to Mr. A. J. Cruikshank for help with some sections of the work

CHALK RIVER, ONTARIO.

[Received, March 6th, 1947.]

189. Production of Antibiotics by Fungi. Part III. Javanicin. An Antibacterial Pigment from *Fusarium javanicum*.

By H. R. V. ARNSTEIN and A. H. COOK.

The isolation and characterisation of *javanicin* is described. It is regarded as a 5 : 8-dihydroxy-6-acetonyl-1 : 4-naphthaquinone carrying additional β -methyl and β -methoxyl groupings.

It was observed (Arnstein, Cook, and Lacey, *Nature*, 1946, **157**, 333; see also Part I, Cook and Lacey, *Brit. J. Exp. Path.*, 1945, **26**, 404) that certain metabolism solutions obtained from *Fusarium javanicum* inhibited the growth of *Staphylococcus aureus* at a dilution of 1 : 100 and were also very active against the acid-fast *Mycobacterium phlei*. In view of the possibility of the active principle or principles having a useful inhibitory action against *M. tuberculosis* their nature

was studied more closely. Their production under various conditions and some biological properties are described elsewhere (Part II, Arnstein, Cook, and Lacey, *Brit. J. Exp. Path.*, 1946, 27, 349) and the present communication records experiments on their chemical nature.

The materials of the present study were only produced under selected conditions; the most notable requirement was the presence of "Bactotryptone" in addition to mineral salts and glucose in the fermenting solution. Bactotryptone could be replaced by some but not all similar preparations, though the characteristic essential for the production of antibacterial activity could not be distinguished. Under the selected conditions the active solutions were heavily pigmented, resembling red ink in colour. The activity could be completely removed from slightly acid solutions by extraction with solvents such as ether, and the crude recovered pigment accounted for the whole of the activity of the original solutions. After preliminary experiments had shown that the antibacterial activity was insensitive to heat, acid, alkali, and solvents, attempts were made to purify the active principles, for example, by the ordinary methods of chromatography but without success. It was found that the active principle could be removed from the crude ethereal extract by shaking with sodium carbonate but not by sodium hydrogen carbonate, and that it could be returned from aqueous sodium carbonate to ether by neutralising the solution. The final solution was still strongly coloured (red-orange) and, as inactive pigment fractions were rejected at each point, it was apparent that several probably chemically similar pigments were initially present. The active solution on concentration gave a pigment which could be crystallised. The behaviour of the crystalline material varied from batch to batch. One compound, m. p. 207.5–208° (decomp.), was invariably obtained and sometimes another compound, m. p. 213–214° (decomp.), formed a second component. Occasionally a product, m. p. 178–179°, was obtained which was analytically intermediate between the two compounds, and as the m. p. behaviour was reproduced by an equimolecular mixture of the two it seems not unlikely that the third product was a molecular compound of the other two. Both compounds were very active antibacterial agents (see Arnstein, Cook, and Lacey, *loc. cit.*) and there was no reason to doubt that the whole of the activity of the original solutions was due to these two crystalline pigments. They were very similar in character but detailed attention could be given only to the compound, m. p. 207.5–208°, which, as it does not appear to have been isolated previously, is conveniently termed *javanicin*; the compound, m. p. 213–214°, contained one oxygen atom more than *javanicin* and is therefore termed *oxyjavanicin*.

The pigments produced by *Fusaria* are known to be very variable and delicately dependent on the conditions of growth (Brown and Horne, *Ann. Bot.*, 1924, 38, 379; Brown, *ibid.*, 1925, 39, 373; Sideris, *J. Agric. Res.*, 1925, 30, 1011); probably for this reason there have been few occasions when *Fusarium* pigments have been isolated in pure condition and studied chemically. Ashley, Hobbs, and Raistrick (*Biochem. J.*, 1937, 31, 388) isolated two pigments, rubrofusarin and aurofusarin, from *F. culmorum*. Aurofusarin is so different from the present pigments that it can hardly be confused with them, whilst the distinctive nature of rubrofusarin is made clear below. *Javanicin* and *oxyjavanicin* differ from the earlier pigments in diffusing into and being isolated from the medium instead of from the mycelium; the mycelium of *F. javanicum* although coloured did not yield any remarkable quantity of antibacterial pigment. Solid media on which *F. javanicum* was grown also became deeply pigmented; on the other hand, those on which *F. culmorum* was grown were scarcely coloured although the mycelia were very bright (Brown and Horne, *loc. cit.*). Mull and Nord (*Arch. Biochem.*, 1944, 4, 422) mention diffusing *Fusaria* pigments and the experiments of Sideris (*loc. cit.*) particularly clearly demonstrate their formation, so the production of *javanicin* and *oxyjavanicin* is possibly not restricted to *F. javanicum*, and other species may produce nearly related pigments.

Javanicin contained only carbon, hydrogen, and oxygen. It apparently contained no easily hydrolysed groupings and could be heated in an autoclave without significant loss of activity, though very dilute solutions on prolonged exposure to light lost both colour and antibacterial activity, presumably as a result of photochemical oxidation.

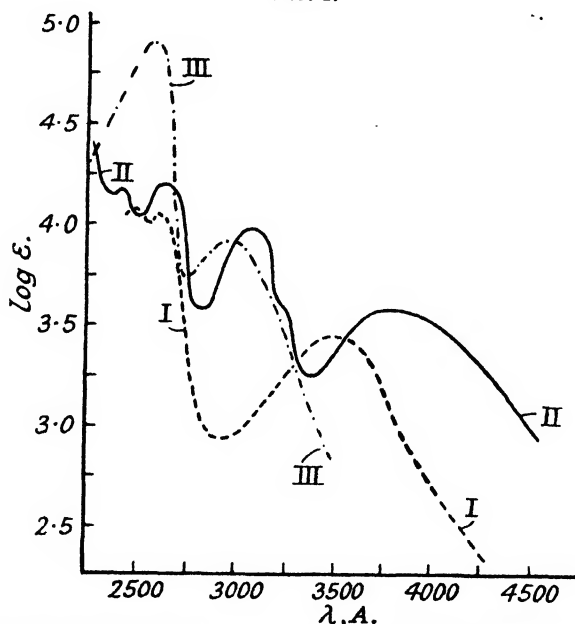

Analyses and determinations of molecular weight on different samples of *javanicin* from several batches indicated the formula $C_{15}H_{14}O_6$. Of the six oxygen atoms one was present as a methoxyl group. The molecule contained three active hydrogen atoms, but on acetylation in presence of concentrated sulphuric acid it yielded a yellow compound of the empirical and molecular formula, $C_{17}H_{14}O_6$, i.e., a monoacetyl derivative of a hitherto unknown anhydro*javanicin*. This *monoacetylanhydrojavanicin* contained one methoxyl group.

The reality of the dehydration of *javanicin* during acetylation was confirmed by the behaviour of the pigment itself. *Javanicin* showed signs of undergoing dehydration in sulphuric acid solution and under other conditions, but reaction was most satisfactory with ethereal hydrogen

chloride containing zinc chloride. Under these conditions javanicin smoothly lost 1 mol. of water to give *anhydrojavanicin*, $C_{18}H_{12}O_8$, which on acetylation passed into the acetyl compound previously obtained directly. Anhydrojavanicin was chemically and physically quite distinct from the parent pigment, and contained only one active hydrogen atom in agreement with structure (III) ($R = H$) developed below. Two more oxygen atoms were revealed as a quinone grouping, for on reductive acetylation anhydrojavanicin was converted into a *leucoanhydrotriacetate*, $C_{21}H_{20}O_8$.

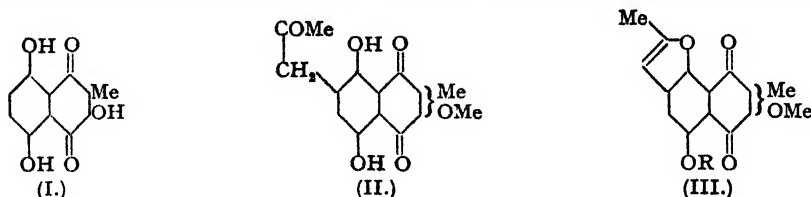

Javanicin anhydromonoacetate and leucoanhydrotriacetate showed spectra which indicated them to be α -naphthaquinone and naphthalene derivatives respectively (Fig. 1). It is known that if the hydroxyl groups of a hydroxynaphthaquinone be acylated, the spectrum loses any features peculiar to the tautomeric hydroxynaphthaquinone structure and reverts to that of a simple naphthaquinone (Macbeth, Price, and Winzor, *J.*, 1935, 325). Incidentally, consideration of the spectra of javanicin and its derivatives excluded the possibility of their being benzoquinone or anthraquinone derivatives; it was moreover impossible to accommodate a summation of other facts noted below on these formulations. Rubrofusarin, $C_{18}H_{12}O_8$, a pigment from

FIG. 1.

I. *Hydroxydroserone triacetate*.II. *Javanicin anhydromonoacetate*.III. *Javanicin leucoanhydrotriacetate*.

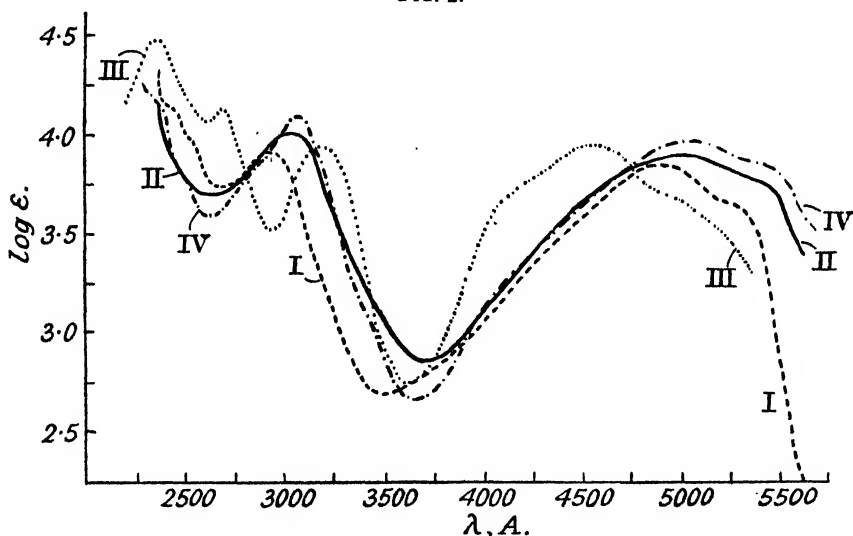

F. culmorum (Ashley, Hobbs, and Raistrick, *loc. cit.*) appears formally closely related to javanicin, but rubrofusarin behaves quite differently especially towards alkalis, with which it gives only a yellow colour, gives derivatives which are clearly distinct from those of javanicin, and is also spectrally quite distinct from javanicin (cf. Mull and Nord, *loc. cit.*). Javanicin gave a deep violet solution with 10% sodium hydroxide, purple solutions with concentrated ammonia or 2*N*-sodium carbonate, but no colour with sodium hydrogen carbonate. It was decolorised by bromine water or aqueous sodium hydrogen sulphite. The formulation of javanicin as a naphthaquinone derivative was supported by its colour reaction with lead acetate in methanol. Javanicin gave a violet solution; methyl-naphthazarin also gave a violet solution, whilst hydroxydroserone (see below) gave a violet precipitate, and Kuhn and Wallenfels (*Ber.*, 1939, 72, 1411) record that 5 : 8-dihydroxy- and 2 : 5 : 8-trihydroxy-naphthaquinone, echinochrome A, and its trimethyl ether all give violet solutions or precipitates. The formation of a coloured solution rather than a precipitate indicated the absence of any β -hydroxyl group (cf. Kuhn and Wallenfels, *loc. cit.*; see also below). Reaction of javanicin with diazomethane was complex, presumably because of reaction with the side chain, but anhydrojavanicin failed to react under normal conditions. As anhydrojavanicin is regarded as having the angular structure (III), and as only β -hydroxyl

groups in naphthaquinones are methylated under the normal conditions by diazomethane (Kuhn and Wallenfels, *loc. cit.*), this behaviour provides further though indirect evidence of the methoxyl group occupying a β -position. Comparison of the absorption spectrum of javanicin with that of representative hydroxynaphthaquinones revealed that its spectrum was practically

coincident with that of hydroxydroserone (Macbeth, Price, and Winzor, *loc. cit.*) (Fig. 2) (3:5:8-trihydroxy-2-methyl-1:4-naphthaquinone, I) and the sequel shows that javanicin is indeed closely related structurally to hydroxydroserone, which also gives a magnificent violet colour with alkali (Rennie, *J.*, 1887, 51, 374).

FIG. 2.

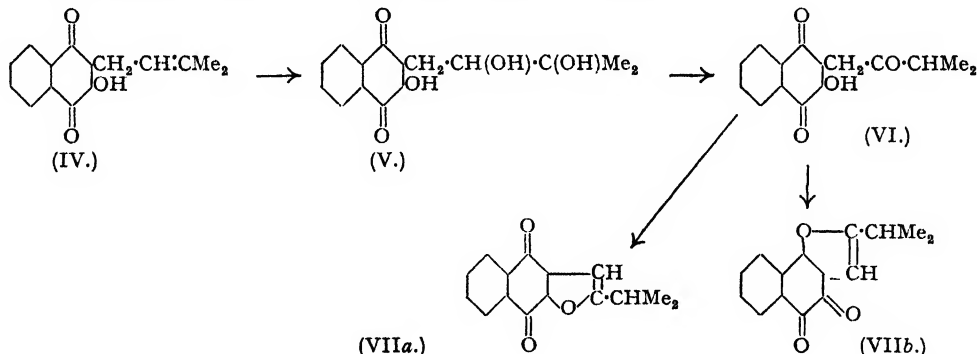

I. Hydroxydroserone. II. Javanicin. III. Anhydrojavanicin. IV. Oxyjavanicin.

These facts suggested then that javanicin was a dihydroxylated naphthaquinone carrying in addition to a β -methoxyl group a substituent which was able to undergo dehydration (cyclisation) by interaction with a neighbouring hydroxyl group. In view of the magnificent colour of javanicin in alkali and its acidity, the hydroxyls were believed to be in the *peri*-positions. Attempts were made to confirm this analytically by the formation of a boric acid complex (Macbeth and Winzor, *J.*, 1935, 334) but under conditions which precluded anhydride formation a stable complex proved unobtainable. That two hydroxyls were indeed present was shown by the behaviour of javanicin towards acylating agents under milder conditions than were used in the original experiments described above. When it was acetylated with acetic anhydride in pyridine diacetyljavanicin, $C_{18}H_{18}O_8$, was formed, and treatment with benzoyl chloride in pyridine afforded dibenzoyljavanicin, $C_{26}H_{26}O_8$. The acylation of a number of hydroxylated naphthaquinones has been described in the literature and no difficulty seems to have been encountered in fully acylating these compounds, so it was concluded that javanicin contained no more than two hydroxyl groups together with a β -methoxyl group.

On oxidation by the Kuhn-Roth method, javanicin gave two molecules of volatile fatty acid indicating two substituents, so the structure could be written in the form $C_{10}HO_2(OH)_2(OMe)RR'$, where $R + R' = C_4H_8O$. For the following reasons the four carbon atoms could only be distributed so that R contained C_1 and R' contained C_3 . The oxygen atom in the grouping C_4H_8O could not be placed on a terminal carbon atom for the side chain could not then have afforded a molecule of volatile fatty acid. If therefore there had been a

C_8, C_8 distribution the substituents would have been Et and COMe [or possibly $CH(OH)Me$], but these would not reasonably permit cyclisation. The remaining possibilities therefore for R, R' are Me and $CH_2 \cdot COMe$, or less likely, in view of the analytical results, Me and $CH_2 \cdot CH(OH)Me$. When javanicin was oxidised with sodium hypiodite or hypobromite, considerable yields of iodoform or bromoform were obtained. Moreover, when javanicin was treated with 2:4-dinitrophenylhydrazine a *mono-2:4-dinitrophenylhydrazone* was formed. Under the same conditions hydroxydroserone failed to react with dinitrophenylhydrazine and it was concluded that javanicin contained the substituents Me and $CH_2 \cdot COMe$. This conclusion was in agreement with the finding that javanicin had no observable optical activity, and that hydrogenation afforded no evidence of an ethylenic linkage. Catalytic hydrogenation resulted in rapid uptake of 1 mol. of hydrogen with disappearance of the colour, which was quickly regenerated in presence of air. From the recovered coloured solution the original pigment could be isolated, and obviously hydrogenation to this extent resulted only in formation of a leuco-compound. A second mol. of hydrogen was slowly absorbed, and further hydrogenation was very slow indeed; this stage corresponds supposedly to reduction of the ketone grouping followed by progressive reduction of the naphthalene nucleus, but no pure hydro-compounds were isolated. This suggested the partial structures (II) and (III) ($R = COMe$) for javanicin and its anhydromonoacetate respectively. These structures leave one unsubstituted position in the naphthalene nucleus; accordingly, after anhydrojavanicin was treated with bromine under very mild conditions a *monobromoanhydrojavanicin* was isolated. Furthermore, rather prolonged treatment of javanicin or anhydromonoacetyljavanicin with acetic anhydride gave an *acetoxo*-derivative of anhydroacetyljavanicin, $C_{18}H_{16}O_8$. Highly substituted naphthaquinones are known to undergo Thiele-Winter acetylation by this treatment, though with some difficulty.

The ready cyclodehydration of javanicin and its derivatives as pictured above is perhaps paralleled by the behaviour of lapachol (IV). Dihydroxylapachol (V) on dehydration gives, among other products, hydroxyisalapachol (VI), which on further dehydration affords two products formulated by Hooker (*J.*, 1896, 69, 1360) as (VIIa) and (VIIb).

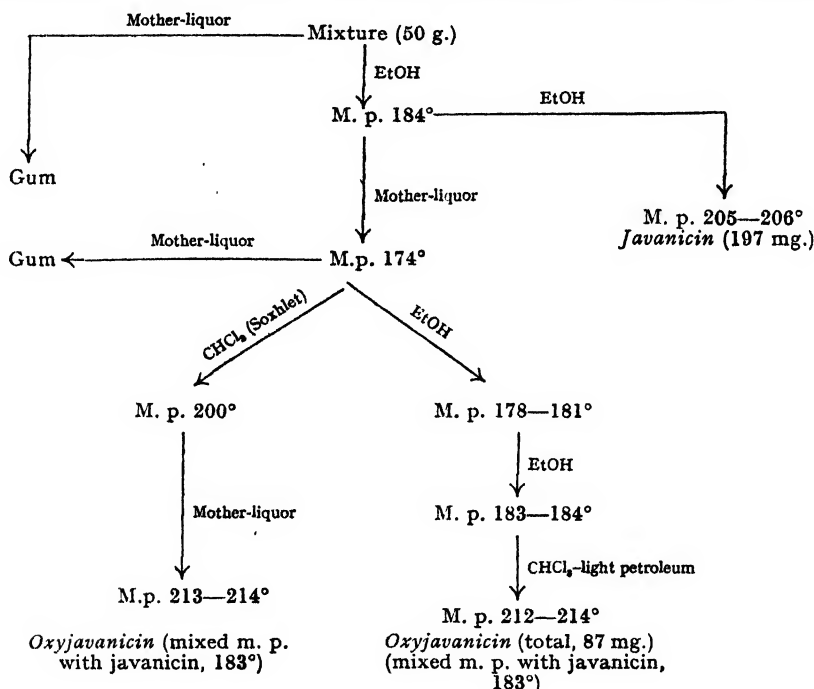

It may be pointed out that quinones of various kinds have been frequently observed to have strong antibacterial actions, and that the action of javanicin (and oxyjavanicin) is undoubtedly due in large measure to the quinone nature. Like that of other quinones, for example, its action is inhibited, though with some difficulty, by compounds containing thiol groupings. On the other hand, it seems equally certain that specific structural effects are exerted. Thus, comparison of javanicin with the nearly related hydroxydroserone showed that the activity of the latter especially towards *Myco. phlei* was surprisingly small (Arnstein, Cook, and Lacey, *Brit. J. Exp. Path.*, 1946, 27, 349).

EXPERIMENTAL.

Production of Javanicin and Oxyjavanicin.—Stock slope cultures of *F. javanicum* were grown on a medium containing Kepler's malt extract (3%) and agar (2%) in $6'' \times 1''$ test-tubes. The mycelium of a single slope was pulped with sterile water (50 c.c.), and the suspension (2—3 c.c.) used to inoculate bottles of liquid medium. This technique was adopted to ensure even and prompt growth. The liquid medium contained: Sodium nitrate, 20 g.; potassium chloride, 5 g.; anhydrous magnesium sulphate, 2.5 g.; dipotassium hydrogen phosphate, 10 g.; ferrous sulphate heptahydrate, 0.1 g.; glucose, 400 g.; "Bactotryptone" (Difco) or "Eupepton" (No. 2) (Allen and Hanbury, Ltd.), 50 g.; distilled water to 10 l. The inorganic salts were dissolved separately in small portions of hot distilled water and added to distilled water (ca. 8 l.). Glucose in water (1 l.) and bactotryptone or eupepton in water (500 c.c.) were

added, and the volume made up. The medium, which was at pH 6.8–7.0 without further adjustment was distributed into quart-size milk bottles, each containing 400 c.c., furnished with cotton-wool plugs and sterilised at 15 lb. for 15 minutes. The inoculated bottles were incubated, stacked in an almost horizontal position at 25–28° for 10–14 days. The mycelium covered the surface only sparsely; it was highly pigmented (red) from the beginning and the medium became distinctly red after about 7 days. The antibiotic activity and colour of the medium increased to a maximum after about 10 days, the medium then having pH 3. All bio-assays were carried out by the serial dilution method, as plate assays were unreliable, especially on partly purified material. Before assay the solutions were adjusted to pH 7 and sterilised by heat; Seitz filtration resulted in the pigment and antibacterial principles being retained on the filter. (a) In a typical batch the filtered metabolism solution (11 l.), which inhibited the growth of *Staph. aureus* at a dilution of 1:100, was extracted twice with ether (2.5 l.) previously freed from peroxides. The ethereal solution was twice extracted with saturated aqueous sodium hydrogen carbonate, which removed a mixture of apparently at least several antibacterially inactive pigment components. The remaining ethereal solution was extracted with *N*-sodium carbonate (4 × 500 c.c.), which removed all the activity. By adjusting the aqueous solution to pH 7 and again extracting with ether (2 l.), the activity and pigment were returned to the organic solvent. The dried ethereal solution was evaporated to 50 c.c., whereupon most of the pigment separated; the mother-liquor yielded only a small quantity of gummy solid, which was rejected. The solid pigment (0.509 g.) had m. p. ca. 168° and inhibited the growth of *Staph. aureus* at a dilution of 1:200,000. The mixture was crystallised according to the following scheme:

(b) In another batch of metabolism medium (20 l.) the mycelium was filtered off, yielding 31 g. of dry material after drying at 100° for several hours. The finely powdered mycelium (20 g.) was extracted (Soxhlet) with light petroleum for 6 hours, no more red pigment then appearing to be extracted. On concentration to small volume (50 c.c.) and cooling, a small quantity of red solid (20 mg.), m. p. 200°, was obtained. One recrystallisation from hot acetone-ethanol (1:1) (5 c.c.) afforded pure crystalline material (laths), m. p. 207° (decomp.) alone or mixed with javanicin obtained from the filtrate (see below). (c) The filtrate from (b) (20 l.) was extracted with ether-benzene (1:1) (4 l.). After being extracted once with saturated aqueous sodium hydrogen carbonate solution (1 l.) and washed with water (1 l.), the organic solvent was shaken with 1% sodium hydroxide (1 l.). The deep violet-purple aqueous layer was separated, and the pigment re-extracted into benzene (1 l.) by acidifying with 10% phosphoric acid. The benzene layer was washed once with water (500 c.c.), dried, and evaporated to dryness under reduced pressure. The solid residue was extracted (Soxhlet) with acetone-ethanol (1:1) (50 c.c.). On cooling, almost pure javanicin, m. p. 200° (450 mg.), separated. One recrystallisation from hot acetone-ethanol (1:1) (50 c.c.) yielded pure javanicin, m. p. 207–208° (decomp.). Method (c) was more convenient than (a) and gave consistent yields provided spore suspensions had been used for inoculating the medium. When inoculation was carried out by using a platinum loop, the yields were very variable, as shown below:

Vol. of filtered metabolism solution (l.)	20	20	20	40
Yield of pure pigment { Mg.	430	325	433	950
{ Mg./l.	21.5	16.3	21.7	23.8

Javanicin when crystallised repeatedly from ethanol separated in red laths with a coppery lustre, m. p. 207.5–208° (decomp.). Analyses were carried out on different samples from several batches [Found: C, 62.1, 62.9, 61.8, 62.0, 62.4, 61.7; H, 4.95, 5.11, 4.92, 5.04, 5.11, 4.90. OMe, 10.4; side-chain Me (Kuhn–Roth), 9.2; active H, 0.98. $C_{18}H_{14}O_8$ requires C, 62.1; H, 4.86; 1 OMe, 10.7; 2 Me, 10.3; 3 H, 1.03%]. Light absorption in ethanol: λ_{\max} 3030, 5050 Å., $\log \epsilon$ 3.97, 3.90; in chloroform, λ_{\max} 3070, 5100 Å., $\log \epsilon$ 3.99, 3.86. Optical activity: A solution of javanicin (24.5 mg.) in acetone (50 ml.) in a 1-dm. tube showed no observable rotation.

Oxyjavanicin separated from chloroform or chloroform–light petroleum in clusters of red needles with a coppery lustre, m. p. 213–214° (decomp.; preheated bath) (Found: C, 58.6, 58.5; H, 4.65, 4.60; OMe, 9.9; side-chain Me, 5.3; active H, 0.79. $C_{18}H_{14}O_8$ requires C, 58.5; H, 4.61; OMe, 10.1; 1 Me, 5.56; 2 H, 0.66%). Light absorption: in chloroform, λ_{\max} 3030, 5050 Å., $\log \epsilon$ 4.08, 3.96.

Monoacetylanhydrojavanicin.—(a) *From javanicin*. Javanicin (38 mg.) was dissolved in redistilled acetic anhydride (2.5 c.c.), and a trace of concentrated sulphuric acid added. There was an immediate darkening, and the mixture was heated at 100° for a few seconds till most of the red colour had disappeared, then poured into ice-cold distilled water (10 c.c.) and set aside for $\frac{1}{2}$ hour; a yellow solid separated (yield, after drying in a vacuum, 26.3 mg.), m. p. 229–238° (decomp.). After two recrystallisations from ethanol the product formed long needles, m. p. 247–248° (decomp.) [Found, on different samples: C, 64.3, 65.05; H, 4.7, 4.6; OMe, 8.2, 9.3; *M* (cryoscopic in camphor), 317. $C_{18}H_{14}O_8(OMe)$ requires C, 64.9; H, 4.6, OMe, 9.85%; *M*, 314]. Light absorption: in ethanol, λ_{\max} 2420, 2650, 3080, 3730 Å., $\log \epsilon$ 4.16, 4.20, 3.97, 3.59.

(b) *From anhydrojavanicin*. Anhydrojavanicin (29 mg.) was suspended in acetic anhydride (1 c.c.) containing a trace of concentrated sulphuric acid. On heating to 100° the colour changed to yellow. After 2 minutes the solution was poured on crushed ice (5 g.) and set aside for $\frac{1}{2}$ hour, the yellow product separating in clusters of needles (28 mg.). After one crystallisation from ethanol, the m. p. was 249–250° (decomp.) alone and when mixed with javanicin anhydromonoacetate obtained above.

Anhydrojavanicin.—Javanicin (200 mg.) was suspended in dry ether (250 c.c.). Saturated ethereal hydrogen chloride (250 c.c.) was added, followed by anhydrous zinc chloride (0.5 g.). The mixture was shaken in a stoppered bottle for 3 hours, the colour having then changed to orange. The ethereal solution was washed several times with water till free from acid. The aqueous layer was washed with benzene (3 × 150 c.c.) to remove all the pigment. The benzene layer was combined with the ethereal solution, again washed with water (2 × 100 c.c.), and dried (Na_2SO_4). After removal of solvent, the solid residue was crystallised twice from acetone, from which it separated in clusters of needles, m. p. 244–245° (decomp.) (Found: C, 66.4; H, 4.50; active H, 0.53. $C_{18}H_{12}O_8$ requires C, 66.2; H, 4.42; one active H, 0.37%). Light absorption: in ethanol, λ_{\max} 2300, 2640, 3160, 4500 Å., $\log \epsilon$ 4.49, 4.12, 3.95, 3.95. Javanicin (17 mg.) and concentrated sulphuric acid (1 c.c.) were heated together at 100° for 90 seconds. The solution was poured on crushed ice (10 g.), and a brown solid separated (20 mg.). The solid gave a violet coloration with 10% sodium hydroxide. It was dissolved in ethanol and reprecipitated by adding water, and then had m. p. 229–233° (decomp.). Repetition of this treatment yielded 1.3 mg. of a product which showed the following light absorption, in ethanol: λ_{\max} 2350, 3160, 3240, 4560 Å.; $\log \epsilon$ (calculated for *M* = 284) 4.61, 3.92, 3.92, 3.91.

Javanicin Leucoanhydrotriacetate.—Anhydrojavanicin (250 mg.) in pyridine (20 c.c.) was warmed with acetic anhydride (2.5 c.c.). Zinc dust (1 g.) was added, and the reaction allowed to proceed for 5 minutes, the supernatant liquid then having become pale yellow. The solution was filtered and evaporated to small bulk. After a short time an almost colourless solid separated in rhombic prisms, m. p. 256–257° (decomp.) (321 mg., 87%). One recrystallisation from acetone–benzene afforded the pure *leucoanhydrotriacetate*, m. p. 258° (decomp.) (Found: C, 63.05; H, 5.10; CH_3CO , 34.1. $C_{22}H_{20}O_8$ requires C, 63.0; H, 5.0; CH_3CO , 32.25%). Light absorption in dioxan: λ_{\max} 2610 Å., $\log \epsilon$ 4.92. Optical activity: A solution of 17.3 mg. in 2 ml. of chloroform in a 1-dm. tube showed no observable rotation.

Diacetyljavanicin.—Javanicin (50 mg.) was dissolved in pyridine (3 c.c.) and mixed with acetic anhydride (0.2 c.c.) in pyridine (2 c.c.). The solution was heated at 70° for 1 hour and kept at room temperature for a further 48 hours. After concentration to 1 c.c., a little ice was added which precipitated some gummy material. The supernatant liquid was decanted and further diluted with water (10 c.c.) and a yellow solid separated on cooling. The solid was crystallised from ethanol containing a little acetone. A second crystallisation from aqueous acetone yielded the pure *compound* (6.5 mg.) in clusters of needles, m. p. 207–208° (decomp.) (Found: C, 61.05; H, 4.95. $C_{18}H_{14}O_8$ requires C, 61.0; H, 4.81%). Light absorption, in ethanol: λ_{\max} 2210, 2900, 4260 Å., $\log \epsilon$ 4.57, 4.17, 3.79.

Dibenzoyl javanicin.—Javanicin (70 mg.), dissolved in pyridine (4 c.c.), was treated with benzoyl chloride (250 mg.). After about 10 minutes the red colour of the solution had changed to yellow. After a further 16 hours at room temperature, the solution was evaporated to dryness and the solid residue dissolved in ether–benzene (1 : 1) (25 c.c.). The solution was well washed with dilute hydrochloric acid (3 × 20 c.c.), followed by saturated aqueous sodium hydrogen carbonate (3 × 20 c.c.) and distilled water (20 c.c.). After drying (Na_2SO_4) the solvent was evaporated. The yellow residue was dissolved in ethanol (5 c.c.). On dilution with water (15 c.c.) some crystallisation took place, but most of the material was precipitated as a gum. On washing with cold ethanol, a pale yellow solid (47 mg.) was obtained. The *product* crystallised from hot ethanol–acetone (1 : 1) in bunches of needles, m. p. 216–217° (decomp.; preheated bath) (Found: C, 69.8; H, 4.41. $C_{20}H_{18}O_8$ requires C, 69.9; H, 4.42%). Light absorption in ethanol: λ_{\max} 2290, 2600, 3650 Å., $\log \epsilon$ 4.63, 4.44, 3.52. Optical activity: A solution of 6.7 mg. in 2 ml. of chloroform in a 1-dm. tube showed no observable rotation.

Javanicin (29 mg.) was dissolved in *N*-sodium hydroxide (5 c.c.) and treated with sufficient iodine in potassium iodide to decolorise the solution completely. The solution had a strong smell of iodoform, and after standing at 0° overnight the precipitated iodoform was collected and dried (P_2O_5); yield 12.6 mg., m. p. 121–122° (decomp.) alone and when mixed with authentic iodoform.

Javanicin Mono-2 : 4-dinitrophenylhydrazine.—A hot solution of javanicin (25 mg.) in ethanol (3 c.c.) and ethyl acetate (1 c.c.) was added to a cold solution of 2 : 4-dinitrophenylhydrazine, prepared by warming 2 : 4-dinitrophenylhydrazine (50 mg., 3 equivs.) with concentrated sulphuric acid (0.1 c.c.) till completely

dissolved, and diluting the cold solution with ethanol (1 c.c.). A red solid was immediately precipitated. The solution was warmed (100°) for a few seconds and cooled in ice. The solid was filtered off; yield 34 mg. (82%), m. p. 252—254° (decomp.; darkening at 249°). Recrystallisation from pyridine by adding ethanol yielded pure *javanicin mono-2:4-dinitrophenylhydrazone*, separating in needles, m. p. 255—256° (decomp.) (Found: C, 54.2, 53.4; H, 3.9, 3.7; N, 11.9. $C_{21}H_{11}O_8N_4$ requires C, 53.6; H, 3.83; N, 11.9%).

Monobromoanhydrojavanicin.—Anhydrojavanicin (50 mg.) was dissolved in chloroform (10 c.c.) and treated with excess of bromine in chloroform. The mixture was kept for 20 minutes at room temperature and evaporated to dryness. After being washed with a little ethanol, the residual solid was crystallised from benzene, from which it separated as tapered laths, m. p. 259—260° (decomp.) (yield 14 mg.). One recrystallisation from benzene-ethanol gave the pure *product*, m. p. 259—260° (decomp.) (Found: C, 51.35; H, 3.76. $C_{18}H_{11}O_8Br$ requires C, 51.3; H, 3.14%).

Acetoxyanhydroacetyljavanicin.—Javanicin (50 mg.) was refluxed for 15 minutes with acetic anhydride (5 c.c.) and anhydrous sodium acetate (50 mg.). The solution was poured on crushed ice, and the yellow solid filtered off after $\frac{1}{2}$ hour. The solid was dissolved in acetone and reprecipitated with water; yield 14 mg. One recrystallisation from acetone-ethanol afforded the pure *compound*, m. p. 265° (extensive decomp.; darkening at 250°) (Found: C, 63.6; H, 4.8. $C_{18}H_{14}O_7$ requires C, 64.0; H, 4.5%).

We thank Sir Ian M. Heilbron, D.S.O., F.R.S., for his interest and encouragement, Dr. M. S. Lacey for bacteriological results, and the Medical Research Council and Rockefeller Foundation for financial assistance.

190. The Course of Cyclisation in the Formation of Alicyclic Rings. Part I. Effect of Alkyl Groups on the Cyclisation of Esters of Polycarboxylic Acids.

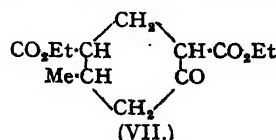

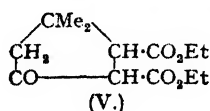

By R. N. CHAKRAVARTI.

The Dieckmann condensation of a simple or substituted β -alkyl-adipic or -pimelic ester leads to a ketonic ester in which the reactive methylene group nearer to the alkyl radical remains unaffected by preference when there is an alternative way of ring formation.

A DIFFICULTY often experienced in the synthesis of hydroaromatic ring systems is the determination of the structure of the ketonic esters obtained by the sodium condensation of esters of unsymmetrical polycarboxylic acids having two reactive methylene groups. A well-known example of this type is afforded by the sodium condensation of ethyl 2-methylbutane-1:2:4-tricarboxylate (I), which, on the basis of certain oxidative degradations, was found to lead to the keto-ester (II) (Baker, *J.*, 1931, 1548; cf. Banerjee, *J. Indian Chem. Soc.*, 1940, 17, 423). More critical examination, however, revealed that the product of the condensation should be represented as ethyl 4-methylcyclopentanone-2:4-dicarboxylate (III) (Chakravarti, *J. Indian Chem. Soc.*, 1943, 20, 173, 189, 243, 247, 399), and not (II) as was found by Baker (*loc. cit.*).

The cyclisation of the analogously constituted ethyl 2:2-dimethylbutane-1:3:4-tricarboxylate (IV) led to the keto-ester (V) (Perkin and Thorpe, *J.*, 1906, 89, 781). Also, only (VII) was isolated in the cyclisation of ethyl 2-methylpentane-1:3:5-tricarboxylate (VI) (Chakravarti, *J. Indian Chem. Soc.*, 1944, 21, 322).*

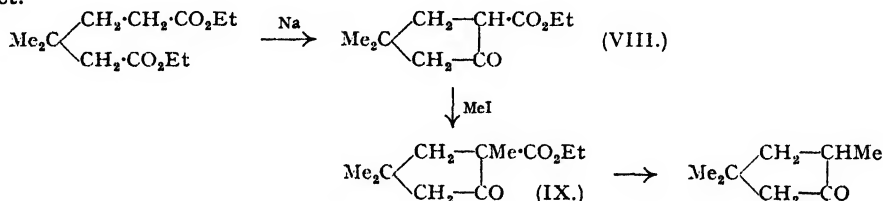

The above results definitely lead one to believe that the methyl groups in (I), (IV), and (VI) exert some steric influence on the reactive methylene groups marked (*), which accounts for

* Since this paper was communicated, another interesting case has been discussed elsewhere (Chakravarti, *Experientia*, 1947, 3, 149).

their lesser reactivity. This effect may be due to the positive character of the alkyl group, and if this be true it can be concluded that the positive character of a methyl group is much more pronounced than the negative character of a carbethoxyl group (cf. the first example cited above).

In the present instance, while devising a suitable method for the synthesis of 4:4-dimethylcyclopentanone-2-acetic acid required in connection with another work, it became necessary to investigate the action of sodium on ethyl $\beta\beta$ -dimethyladipate. For this purpose, the product of the sodium condensation was heated with excess of methyl iodide and the resulting methylated keto-ester hydrolysed with dilute aqueous alkali to give a neutral ketone, b. p. 160°. It gave a crystalline semicarbazone, m. p. 168°, which proved to be identical with that of 2:4:4-trimethylcyclopentanone (Wallach, *Annalen*, 1918, 414, 331; Qudrat-i-Khuda, *Nature*, 1933, 132, 210; Dey and Linstead, *J.*, 1935, 1063). No evidence of the presence, in the hydrolysed product, of the isomeric ketone, 2:3:3-trimethylcyclopentanone (von Kregten, *Rec. Trav. chim.*, 36, 78; Noyes, *Ber.*, 1899, 32, 2291), b. p. 167–169° (semicarbazone, m. p. 222°), could be detected, thus indicating that in this cyclisation the keto-ester (VIII) is the only product.

The result obtained above confirms the view already postulated that the reactivity of a methylene group is reduced considerably by its closer proximity to a methyl group (or any other alkyl group). Thus the action of sodium on the ester of a substituted β -alkyl-adipic or -pimelic acid (having two alternatives for cyclisation) may be expected to lead to a ketonic ester in which the reactive methylene group, nearer to the alkyl radical, remains unaffected by preference. The other isomer in such a case, if produced at all, can only be in much smaller amount. This view is also in line with the results obtained by the cyclisation of ethyl β -methyl-adipate (Dieckmann and Groeneveld, *Ber.*, 1900, 33, 595) and -pimelate (Einhorn and Klages, *ibid.*, 1901, 34, 3793).

EXPERIMENTAL.

$\beta\beta$ -Dimethyladipic acid, required for this work, was prepared by the improved method of Rydon (*J.*, 1936, 594; 1937, 1341).

Ethyl 2:4:4-Trimethylcyclopentanone-2-carboxylate (IX).—Ethyl $\beta\beta$ -dimethyladipate (20 g.) was heated on the water-bath with a fine suspension of sodium (3.9 g.) in anhydrous benzene (50 c.c.). The heating was continued for about 6 hours till the whole of the sodium had passed into solution. The product was then cooled in ice, treated with excess of methyl iodide (20 c.c.), and kept overnight. The methylation was completed by heating the reaction mixture on the water-bath for 5–6 hours. The product at this stage should not give any coloration with alcoholic ferric chloride. Sufficient water was added to dissolve the sodium iodide, and the benzene layer was separated. It was washed thoroughly with water and dried (CaCl_2), and the solvent evaporated. The residual liquid on distillation under reduced pressure gave the ester as a colourless mobile oil (12 g.) with a characteristic odour, b. p. 88°/4 mm. (Found: C, 66.5; H, 9.1. $\text{C}_{11}\text{H}_{18}\text{O}_3$ requires C, 66.7; H, 9.1%).

2:4:4-Trimethylcyclopentanone.—The above ketonic ester (11.5 g.) was heated on a sand-bath for 6 hours with a solution of potassium hydroxide (12 g.) in water (150 c.c.). When cold, the product was taken up in ether, washed well with water, and dried (Na_2SO_4), and the ether removed. The liquid remaining was then distilled; with the exception of a little high boiling residue, it came over constantly at 160°, as a colourless liquid (6.8 g.) with a peppermint-like smell (Found: C, 75.9; H, 11.2. Calc. for $\text{C}_8\text{H}_{14}\text{O}$: C, 76.2; H, 11.1%). With semicarbazide acetate in aqueous alcohol it readily gave a semicarbazone, which crystallised from spirit in colourless shining laminae, m. p. 168°, undepressed in admixture with an authentic specimen of the semicarbazone of 2:4:4-trimethylcyclopentanone (Found: C, 59.2; H, 9.4. Calc. for $\text{C}_8\text{H}_{11}\text{ON}_3$: C, 59.0; H, 9.3%).

Further work with 4:4-dimethylcyclopentanone-2-acetic acid is in progress.

My best thanks are due to Prof. J. C. Bardhan for encouragement and to Mr. J. Chakraverti for facilities.

191. Olefinic Acids. Part II. The Reactivity of α -Bromoacrylic Acid and Some Related Compounds.

By L. N. OWEN and H. M. BABATUNDE SOMADE.

α -Bromoacrylic acid reacts with alkoxides to give α -bromo- β -alkoxy-propionic acids which, by further action, are converted into β -alkoxy-acrylic and $\alpha\beta$ -dialkoxy-propionic acids, the proportion of β -alkoxy-acid being greater when the higher alkoxides are used. In contrast with the results obtained in the crotonic series (Part I), no α -alkoxy-acrylic acids are formed. Towards thioacetic acid, benzylthiol, diazomethane, and methyl diazoacetate, the order of decreasing reactivity is, as would be anticipated, α -bromoacrylic acid, α -bromocrotonic acid, α -bromo- $\beta\beta$ -dimethylacrylic acid; the products obtained by these addition reactions have been investigated and identified.

The absorption spectra of several α - and β -alkoxy-acrylic acids are recorded.

THE investigations described in Part I (Owen, *J.*, 1945, 385) established that α -bromocrotonic acid (I; R = Me) reacted with alkoxides (or the appropriate alcoholic alkali) to give α - and β -alkoxy-crotonic acids, (II; R = Me) and (III; R = Me), the proportion of the latter being greater with the higher alkoxides, but attempts to isolate either of the possible intermediates (IV) or (V) were unsuccessful.

Baker (*J.*, 1942, 520) in the course of attempts to prepare α -alkoxy-acrylic acids, has shown that $\alpha\beta$ -dibromopropionic acid, on treatment with boiling methanolic sodium methoxide, yields $\alpha\beta$ -dimethoxypropionic acid, not by direct substitution, but probably *via* α -bromoacrylic acid. The presence of other products was indicated by the unsaturated nature of the crude halogen-free acids isolated from the reaction mixture, but these were not identified, and the exact mechanism of the reaction was not established. It has now been found that β -methoxyacrylic acid is formed under these conditions; on cold acid hydrolysis it gives malonic semi-aldehyde (VI; R = H) (2:4-dinitrophenylhydrazone, m. p. 136°).

The reaction has been more closely studied by using α -bromoacrylic acid (I; R = H) as starting material, particularly with a view to comparing its behaviour with that of α -bromocrotonic acid. When boiled with methanolic sodium methoxide for 3 hours, the main product was α -bromo- β -methoxypropionic acid (V; R = H, R' = Me), which was isolated as its methyl ester, purified from unsaturated compounds by cautious treatment with aqueous permanganate, and characterised as the amide, m. p. 83°. The presence also of a small amount of β -methoxyacrylic acid (III; R = H, R' = Me) was demonstrated by the formation of malonic semi-aldehyde by acid hydrolysis of a portion of the reaction products. No α -methoxyacrylic acid could be detected, but, clearly, if it had been formed it might well have been converted by subsequent reaction with methanol into $\alpha\beta$ -dimethoxypropionic acid. This, however, has been shown not to be the case, since, by saponification of methyl α -methoxyacrylate, crystalline α -methoxyacrylic acid, m. p. 52°, was obtained,* which was recovered unchanged after treatment with boiling methanolic sodium methoxide; β -methoxyacrylic acid, treated similarly, was likewise unaffected.

It is evident, therefore, that α -bromoacrylic acid, in marked contrast to α -bromocrotonic acid, undergoes addition, rather than substitution, and gives the bromomethoxy-acid (V; R = H, R' = Me), the bromine atom in which is then either eliminated as hydrogen bromide, forming β -methoxyacrylic acid (III; R = H, R' = Me), or replaced to give $\alpha\beta$ -dimethoxypropionic acid (VII; R = H, R' = Me).

It was not possible to interrupt the reaction of α -bromoacrylic acid with ethanolic alkali at the bromo-ethoxy-acid stage, probably owing to the heterogeneous nature of the reaction mixture resulting from the reduced solubility of the salts in ethanol, but on taking the reaction to com-

* Allpress and Haworth (*J.*, 1924, 125, 1233) tentatively ascribed this structure to an unsaturated liquid acid, b. p. 65–75°/12 mm., obtained by the action of methyl chloroformate on fructose; it is possible that their product was an impure form of α -methoxyacrylic acid, although no other properties were given in support of the proposed constitution.

pletion β -ethoxyacrylic acid was obtained, together with $\alpha\beta$ -diethoxypropionic acid, isolated as the *ethyl* ester. Treatment of α -bromoacrylic acid with potassium *isopropoxide* gave a liquid product, containing 88% of β -*isopropoxyacrylic acid* with 12% of $\alpha\beta$ -*diisopropoxypropionic acid*, which could not be separated, whilst with potassium *tert.*-butoxide the only product isolated was crystalline β -*tert.*-*butoxyacrylic acid*. This progressive increase in the proportion of the β -alkoxy-acid as the higher alkoxides are used is similar to that observed in the case of α -bromocrotonic acid; in the present reactions, however, the increase is at the expense of dialkoxypropionic acid, whilst in the crotonic series it is accompanied by a diminution in the amount of α -alkoxy-acid.

The absorption data for the α - and β -alkoxy-acrylic acids are shown in the table. As was observed in the crotonic series (Owen, *loc. cit.*) the β -compounds absorb more strongly than their α -isomerides, but in contrast, not at appreciably different wave-lengths.

‡ Corrected value.

The greater ease of addition to α -halogeno-acrylic, as compared with α -halogeno-crotonic, acids has also been demonstrated in their reactions with a number of other reagents. α -Bromoacrylic acid reacted readily with thioacetic acid to give α -bromo- β -(*acetylthio*)propionic acid (VIII); the corresponding *chloro*-acid was obtained similarly. α -Bromocrotonic acid failed to undergo addition of the reagent, thus indicating that diminution of ethenoid activity is brought about not only by the methyl group in the β -position, but also by the halogen atom, since crotonic acid undergoes the reaction (Holmberg and Schjanberg, *Arkiv Kemi, Min. Geol.*, 1940, **14** A, No. 7, 22).

With benzylthiol in pyridine solution, α -bromoacrylic acid gave β -(*benzylthio*)acrylic acid (IX), presumably *via* the intermediate compound (X); α -bromocrotonic acid could not be induced to react with the reagent.

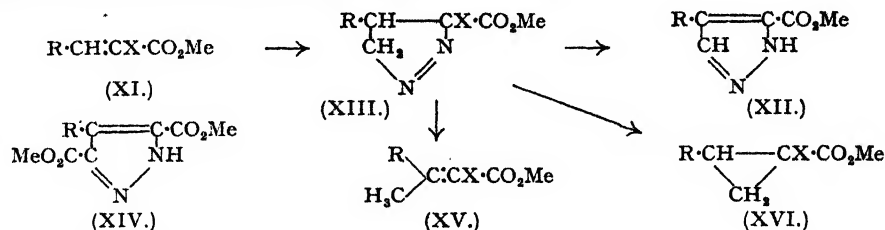

Auwers and König (*Annalen*, 1932, **496**, 31) reported that methyl α -chlorocrotonate (XI; R = Me, X = Cl) reacted with diazomethane to give methyl 4-methylpyrazole-3-carboxylate (XII; R = Me), hydrogen chloride being spontaneously evolved by the unstable intermediate (XIII; R = Me, X = Cl). It has now been shown that α -chloro- and α -bromoacrylic acids, on treatment with diazomethane, give methyl pyrazole-3-carboxylate (XII; R = H), whilst α -bromocrotonic acid gives (XII; R = Me). α -Bromo- $\beta\beta$ -dimethylacrylic acid, on the contrary, was merely converted into its *methyl* ester (*amide*, m. p. 129°) and did not undergo addition, the extra methyl group in the β -position being sufficient to inhibit the reaction.

Buchner and Papandieck (*Annalen*, 1893, **273**, 246), by treatment of methyl $\alpha\beta$ -dibromopropionate with methyl diazoacetate, obtained dimethyl pyrazole-3 : 5-dicarboxylate (XIV; R = H), but did not isolate any of the intermediates. Both methyl α -bromo- and α -chloroacrylate have now been found to give this product under these conditions, whilst methyl α -bromo- and α -chloro-crotonates reacted much less readily, and gave a small yield of *methyl* 4-methylpyrazole-3 : 5-dicarboxylate (XIV; R = Me). Methyl α -bromo- $\beta\beta$ -dimethylacrylate was unaffected by methyl diazoacetate.

In the reaction of diazomethane with α -substituted acrylic or crotonic esters (XI), provided that the intermediate pyrazoline (XIII) does not tend to lose HX and form pyrazoles (cf. above), it may lose nitrogen to give either a higher homologue (XV) of the ester (XI) or a cyclopropane derivative (XVI). The composition of the product depends on the nature of the substituent X; if it is methyl, both (XV) and (XVI) are obtained, whilst if X is a cyano- or carbalkoxy-group the sole product is (XV) (Auwers and König, *Annalen*, 1932, **496**, 252; Young, Andrews, Lindenbaum, and Cristol, *J. Amer. Chem. Soc.*, 1944, **66**, 810). It was therefore not unexpected to find that methyl α -methoxyacrylate (XI; R = H, X = OMe) on reaction with diazomethane

gave a product which contained methyl 1-methoxycyclopropane-1-carboxylate (XVI; R = H, X = OMe), characterised as the *amide*, m. p. 117°. This +T effect of the methoxyl group in the α -position was also shown by the observation that although, as mentioned above, methyl α -methoxyacrylate was unaffected by methanolic sodium methoxide, it reacted with methanolic hydrogen chloride to give methyl α -dimethoxypropionate.

EXPERIMENTAL.

Action of Sodium Methoxide on $\alpha\beta$ -Dibromopropionic Acid.—To the acid (24 g.) in warm methanol (20 c.c.) was added methanolic sodium methoxide (110 c.c., 3.76 N). After the vigorous reaction had subsided, the mixture was refluxed for 7 hours, during which the suspension of potassium α -bromoacrylate disappeared and was replaced by a granular precipitate of potassium bromide. After removal of solvent, the residue was dissolved in water and acidified with hydrochloric acid, with ice-cooling. Extraction with ether gave a syrup, which partly crystallised on standing. The solid β -methoxyacrylic acid (1.1 g.) was dried on porous tile; it recrystallised from water in plates, m. p. 102° (Found: C, 47.2; H, 5.9; equiv., 102. $\text{C}_4\text{H}_6\text{O}_3$ requires C, 47.1; H, 5.9%; equiv., 102). Light absorption: see Table. On treatment with a cold solution of 2:4-dinitrophenylhydrazine sulphate in 5N-sulphuric acid for 2 hours it gave the 2:4-dinitrophenylhydrazone of malonic semi-aldehyde, which crystallised from warm ethyl acetate-light petroleum (b. p. 40–60°) in lemon-yellow nodules, m. p. 136° (decomp.), and gave a deep red solution in aqueous sodium hydroxide (Found: C, 40.0; H, 3.3; N, 20.6. $\text{C}_8\text{H}_6\text{O}_8\text{N}_4$ requires C, 40.3; H, 3.0; N, 20.9%).

α -Bromoacrylic Acid.— $\alpha\beta$ -Dibromopropionic acid (90 g.) was dissolved in water and neutralised with N-sodium hydroxide at 0°. An equal volume of N-sodium hydroxide was then added and the solution left at room temperature for 1 hour. After acidification with a slight excess of concentrated hydrochloric acid (Congo-red), ether extraction yielded α -bromoacrylic acid, which after recrystallisation from light petroleum (b. p. 60–80°) formed colourless prisms (51 g., 87%), m. p. 72° (lit. 70°). This improved procedure gives a product which, unlike less pure material, shows no sign of decomposition after being kept for several months.

Reaction of α -Bromoacrylic Acid with Alkoxides.—(i) A solution of the acid (15 g.) in methanol (40 c.c.) was treated with methanolic sodium methoxide (35 c.c., 3.67N) and refluxed for 3 hours, after which it was evaporated to dryness, and the residue dissolved in water, acidified with hydrochloric acid, and extracted with ether. The liquid acid so obtained contained a small amount of β -methoxyacrylic acid, since a portion, on treatment with aqueous 2:4-dinitrophenylhydrazine sulphate, gave the 2:4-dinitrophenylhydrazone of malonic semi-aldehyde, m. p. 135°. The remainder (7 g.) was dissolved in methyl iodide (5 c.c.) and diluted with ether (10 c.c.), and silver oxide (15 g.) was added in small portions during $\frac{1}{2}$ hour. After refluxing for $\frac{1}{2}$ hour, the solution was filtered and evaporated to an oil, which on distillation furnished a main fraction (6.1 g.), b. p. 70–78°/15 mm. This was unsaturated towards alkaline permanganate, and gave a positive reaction on standing with aqueous 2:4-dinitrophenylhydrazine sulphate. It was therefore suspended in dilute sodium carbonate solution and treated with a slight excess of 2% aqueous potassium permanganate at 0°, with vigorous stirring. The recovered saturated ester (3.0 g.), b. p. 78°/15 mm., n_D^{20} 1.4510, was mainly methyl α -bromo- β -methoxypropionate, probably containing a small amount of methyl $\alpha\beta$ -dimethoxypropionate (Found: C, 33.4; H, 5.7. Calc. for $\text{C}_5\text{H}_8\text{O}_3\text{Br}$: C, 30.5; H, 4.6. Calc. for $\text{C}_6\text{H}_{10}\text{O}_4$: C, 48.6; H, 8.2%). On treatment with aqueous ammonia (d 0.880) it gave α -bromo- β -methoxypropionamide, m. p. 83° (Found: C, 26.2; H, 4.5. Calc. for $\text{C}_4\text{H}_8\text{O}_3\text{NBr}$: C, 26.4; H, 4.4%).

(ii) Ethanolic sodium ethoxide (45 c.c., 2N) was added to α -bromoacrylic acid (10 g.) in ethanol (10 c.c.) and the mixture was refluxed for 20 hours. The residue, after removal of solvent, was dissolved in water and acidified with hydrochloric acid, precipitating β -ethoxyacrylic acid (1.0 g.), which crystallised from warm water in plates, m. p. 109°. Light absorption: see Table. Ether extraction of the residual aqueous portion gave a liquid halogen-free acid (5.1 g.), which was esterified in the usual way in ethereal solution with ethyl iodide and silver oxide. The crude ester was then purified by treatment with 2% potassium permanganate, as already described, and on distillation gave methyl $\alpha\beta$ -diethoxypropionate (1.5 g.), b. p. 87°/11 mm., n_D^{20} 1.4130 (Found: C, 56.8; H, 9.8. $\text{C}_6\text{H}_{10}\text{O}_4$ requires C, 56.8; H, 9.5%).

(iii) α -Bromoacrylic acid (7.5 g.), dissolved in isopropanol (60 c.c.), was treated with a solution of potassium (5 g.) in isopropanol (60 c.c.), and the semi-solid mass was refluxed for 24 hours on the steam-bath. The solvent was then removed, and the residue dissolved in water and acidified with hydrochloric acid; an oil separated, but since it could not be induced to crystallise, the whole was extracted with ether. The liquid acid so obtained (7 g.), b. p. 55°/0.001 mm., n_D^{20} 1.4425, contained no halogen and was highly unsaturated. Light absorption: λ_{max} 2340 Å. (ϵ 12,300) (Found: equiv., 137. $\text{C}_5\text{H}_8\text{O}_3$ requires equiv., 130. $\text{C}_6\text{H}_{10}\text{O}_4$ requires equiv., 190). On treatment with aqueous 2:4-dinitrophenylhydrazine sulphate it gave the 2:4-dinitrophenylhydrazone of malonic semi-aldehyde, m. p. 129° (decomp.) after recrystallisation from dioxan, and was therefore mainly β -isopropoxyacrylic acid, probably containing

ca. 12% α -diisopropoxyacrylic acid. Attempts to isolate either component in a pure state were unsuccessful.

(iv) To a warm solution of potassium (10 g.) in *tert.*-butanol (200 c.c.) was added α -bromoacrylic acid (15.2 g.) in *tert.*-butanol (20 c.c.), and the semi-solid mass refluxed for 24 hours on the steam-bath. Water (100 c.c.) was then added and the *tert.*-butanol removed under reduced pressure. The residual aqueous solution was acidified to Congo-red with hydrochloric acid, which precipitated β -*tert.*-butoxyacrylic acid (3.2 g.); this was collected, and a further quantity (1.7 g.) obtained by extraction of the filtrate with ether. On recrystallisation from light petroleum (b. p. 60–80°) it formed long flat needles, m. p. 86.5° (Found: C, 58.6; H, 8.5; equiv., 144. $C_7H_{12}O_3$ requires C, 58.3; H, 8.4%; equiv., 144). Light absorption: see Table. On standing with aqueous 2:4-dinitrophenylhydrazine sulphate it gave the 2:4-dinitrophenylhydrazone of malonic semi-aldehyde, m. p. 131°. No other acidic products could be detected.

α -Methoxyacrylic Acid.—Methyl α -methoxyacrylate, b. p. 58–60°/15 mm., λ_{\max} . 2280 Å. (ϵ 7300), λ_{\min} . 2360 Å. (ϵ 6400), was prepared by the method of Baker (*loc. cit.*). The ester (2.1 g.) was heated at 100° with aqueous sodium hydroxide (15 c.c., 2N) for 1½ hours, and the solution then cooled, acidified with 2N-hydrochloric acid (15 c.c.), and extracted with ether. Evaporation of the dried extract gave α -methoxyacrylic acid (1.2 g.), which crystallised from light petroleum (b. p. 40–60°) in needles, m. p. 52° (Found: C, 46.8; H, 5.7. $C_4H_6O_3$ requires C, 47.0; H, 5.9%). Light absorption: see Table. On standing with aqueous 2:4-dinitrophenylhydrazine sulphate it gave the 2:4-dinitrophenylhydrazone of pyruvic acid, m. p. 218°.

Action of Sodium Methoxide on α -Methoxy- and β -Ethoxy-acrylic Acids.— α -Methoxyacrylic acid (0.2 g.) was refluxed with methanolic sodium methoxide (3 c.c., N) for 6 hours. After evaporation, acidification of the residue with hydrochloric acid and extraction with ether, the acid (0.17 g.), m. p. and mixed m. p. 50°, was recovered unchanged. β -Ethoxyacrylic acid (0.25 g.), treated similarly, was also recovered (0.21 g.), m. p. and mixed m. p. 108°.

α -Bromo- β -(acetylthio)propionic Acid.— α -Bromoacrylic acid (5 g.) was added in small portions to thioacetic acid (5 c.c.) in a flask cooled in ice. After the vigorous reaction had subsided, the solution was heated on the steam-bath for 15 minutes, and the excess of thioacetic acid then removed under reduced pressure. The solid acid obtained on cooling was recrystallised from carbon tetrachloride, from which it formed colourless prisms (6.9 g.), m. p. 85–86° (Found: C, 26.1; H, 3.2. $C_5H_6O_3SBr$ requires C, 26.4; H, 3.1%). Similar treatment of α -chloroacrylic acid (2 g.) afforded α -chloro- β -(acetylthio)propionic acid (3 g.), m. p. 75°, after recrystallisation from carbon tetrachloride (Found: C, 32.8; H, 3.75. $C_5H_6O_3ClS$ requires C, 32.9; H, 3.9%). Under the same conditions, α -bromocrotonic acid was recovered unchanged.

Action of Benzylthiol on α -Bromoacrylic Acid.—The acid (0.5 g.), pyridine (0.5 c.c.), and benzylthiol (1 c.c.) were heated on a steam-bath for 15 minutes. The solid which separated on cooling was freed from adhering oil on porous tile, dissolved in dilute hydrochloric acid, and extracted with ether. Removal of solvent yielded β -(benzylthio)acrylic acid, which crystallised from carbon tetrachloride in colourless plates, m. p. 162–163° (Found: C, 61.45; H, 5.3. $C_{10}H_{10}O_2S$ requires C, 61.8; H, 5.2%). Light absorption: λ_{\max} . 2740 Å. (ϵ 15,500). Similar experiments, in which traces of hydrochloric acid or benzoyl peroxide were used in place of pyridine, resulted only in the recovery of unchanged bromo-acid.

Reactions of α -Halogeno- α -olefinic Acids with Diazomethane.—(i) α -Bromoacrylic acid (2 g.) was dissolved in excess of ethereal diazomethane and left at 20° for 5 days. After removal of solvent, the liquid residue was warmed to 60°, whereupon there was a vigorous evolution of hydrogen bromide and the formation of methyl pyrazole-3-carboxylate, which crystallised from water in colourless prisms (0.9 g.), m. p. 141° (Found: C, 47.6; H, 4.7; N, 22.3. Calc. for $C_5H_6O_2N_2$: C, 47.6; H, 4.8; N, 22.2%). α -Chloroacrylic acid under identical conditions gave the same product, m. p. 141°.

(ii) α -Bromocrotonic acid (1 g.) treated similarly, gave methyl 4-methylpyrazole-3-carboxylate (0.51 g.), colourless prisms from water, m. p. 170° (Found: C, 51.2; H, 5.75; N, 19.8. Calc. for $C_6H_8O_2N_2$: C, 51.05; H, 5.7; N, 19.85%).

(iii) α -Bromo- β -dimethylacrylic acid (2 g.) was dissolved in excess of ethereal diazomethane and the solution kept at 20° for 12 days. Removal of solvent afforded a nitrogen-free product (1.8 g.), b. p. 98°/33 mm., which was identical with methyl α -bromo- β -dimethylacrylate, b. p. 76°/9 mm., n_D^{20} 1.4909 (Found: C, 37.8; H, 4.8. $C_6H_8O_2Br$ requires C, 37.3; H, 4.7%), prepared by esterification of the bromo-acid with methanol and sulphuric acid, since both specimens with aqueous ammonia (d 0.880) gave α -bromo- β -dimethylacrylamide, needles from light petroleum (b. p. 60–80°), m. p. and mixed m. p. 129° (Found: C, 34.0; H, 4.7; N, 7.5. C_6H_8ONBr requires C, 33.7; H, 4.5; N, 7.9%).

Reactions of Methyl α -Bromo- α -olefinic Esters with Methyl Diazoacetate.—(i) A solution of methyl α -bromoacrylate (1 g.) and methyl diazoacetate (2 g.) in light petroleum (b. p. 80–100°) (50 c.c.) was refluxed for 15 hours (during which the intensity of the deep yellow colour was much reduced) and then evaporated to dryness under reduced pressure. The solid residue of methyl pyrazole-3:5-dicarboxylate (1.3 g.) crystallised from water in colourless prisms, m. p. 152° (Found: N, 15.3. Calc. for $C_7H_8O_4N_2$: N, 15.2%). The same product (0.6 g.), m. p. 152°, was also obtained from methyl α -chloroacrylate (1 g.).

(ii) A solution of methyl α -bromocrotonate (1 g.) and methyl diazoacetate (1 g.) in light petroleum (b. p. 80–100°) (25 c.c.) after refluxing for 24 hours was still deeply coloured, in spite of the use of the excess of bromo-ester. Evaporation under reduced pressure gave a small residue of methyl 4-methylpyrazole-3:5-dicarboxylate, colourless prisms (0.15 g.) from water, m. p. 128–129° (Found: C, 48.85; H, 5.2; N, 14.0. $C_8H_{10}O_4N_2$ requires C, 48.5; H, 5.1; N, 14.1%), which was also obtained, in similar yield, from methyl α -chlorocrotonate under the same conditions.

(iii) A solution of methyl α -bromo- β -dimethylacrylate (1 g.) and methyl diazoacetate (1 g.) in light petroleum (b. p. 80–100°) (20 c.c.) was refluxed for 4 days, after which the solvent and diazo-ester were removed under reduced pressure. The residual nitrogen-free liquid, b. p. 70°/6 mm., was unchanged bromo-ester, identified by conversion into the amide, m. p. and mixed m. p. 128°.

Action of Diazomethane on Methyl α -Methoxyacrylate.—The methoxy-ester (1 g.) was treated with

excess of ethereal diazomethane at 20° for 4 days. Removal of solvent gave a liquid, b. p. ca. 135°, which by treatment with aqueous ammonia (*d* 0.880) was converted into 1-methoxycyclopropane-1-carboxamide; this crystallised from light petroleum (b. p. 40–60°) in colourless needles, m. p. 117°, which showed no unsaturation towards alkaline permanganate (Found: C, 52.2; H, 8.0; N, 11.9. $C_5H_9O_2N$ requires C, 52.2; H, 7.9; N, 12.2%).

Action of Methanolic Hydrogen Chloride on Methyl Methoxyacrylate.—The methoxy-ester (1 g.) was dissolved in methanol (5 c.c.) and saturated with dry hydrogen chloride at 0°. After $\frac{1}{2}$ hour, the hydrogen chloride was removed by aeration and finally by neutralisation with barium carbonate. Evaporation of the solvent and extraction of the residue with ether gave methyl α -dimethoxypropionate, b. p. 67°/20 mm., which on treatment with methanolic 2:4-dinitrophenylhydrazine sulphate gave the 2:4-dinitrophenylhydrazone of methyl pyruvate, m. p. 186–187°; it was also characterised by conversion, with aqueous ammonia, into α -dimethoxypropionamide, m. p. 117° (Found: N, 10.5. Calc. for $C_5H_{11}O_3N$: N, 10.5%).

The authors thank Dr. E. A. Braude for the determinations of absorption spectra.

192. Tetrahydroacridones and Related Compounds as Antimalarials.

By (Miss) J. M. L. STEPHEN, (Miss) I. M. TONKIN, and JAMES WALKER.

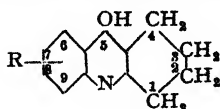

Tetrahydroacridones, 12-hydroxydihydro- β -quinindenes, and 2- and 4-hydroxyquinolines have been examined for antimalarial activity. Marked prophylactic action has been found against *P. gallinaceum* infections in chicks and the structural requirements for activity are outlined. The experimental conditions for the Conrad-Limpach ring-closure of β -arylaminod $\Delta^2\beta$ -unsaturated esters are discussed.

THERE are two approaches to the chemotherapy of malaria. The prophylactic approach aims at rendering the bite of the mosquito ineffective in producing an infection and the therapeutic approach aims at the eradication of an established infection; the former is directed at the sporozoites injected by the mosquito and the subsequent (primary) tissue phase development, while the latter aims at control during the later erythrocytic stages in the developmental cycle of the parasite. Quinine, mepacrine, and pamaquin, to which paludrine and several 4-dialkylaminoalkylaminoquinolines may now be added, are well-established examples of drugs possessing the latter type of action but, until recently, there have been few reports of drugs exhibiting causal prophylactic activity. Pamaquin has a slight prophylactic action (Kikuth and Mudrow, *Z. Immun-Forsch.*, 1939, 95, 285; Mudrow, *Arch. Schiffs- u. Tropen-Hygiene*, 1940, 44, 257). Certain sulphonamides (Sinton, Hutton, and Shute, *Ann. Trop. Med. Parasit.*, 1939, 33, 37; Coatney and Cooper, *Publ. Hlth. Rep., Wash.*, 1944, 59, 1455; Coggeshall, Porter, and Laird, *Proc. Soc. Exp. Biol. Med.*, 1944, 57, 286; Freire and Paraense, *Rev. Brasil. Biol.*, 1944, 4, 27) have a marked causal prophylactic action, as does paludrine (Curd, Davey, and Rose, *Ann. Trop. Med. Parasit.*, 1945, 39, 208), while *p*-methylsulphonylbenzamidine (Fuller, Tonkin, and Walker, *J.*, 1945, 633) and some arylguanidines (King and Tonkin, *J.*, 1946, 1063) have a slight effect. When the war in Europe ended, reports came to hand (Fitch, *Pharm. J.*, 1945, 155, 182; *Combined Intelligence Objectives Sub-Committee*, 1945, Item No. 24, File No. XXIII-12; *idem*, File No. XXIV-20; *idem*, File No. XXV-54) that German workers had encountered causal prophylactic activity in certain 4-hydroxyquinolines, notably 4-hydroxy-7-methoxy-3-*n*-heptylquinaldine (I) (endochin), and the present authors at once recorded, in a preliminary way, similar observations with a chemically related series (*Nature*, 1945, 156, 629); the present paper describes this work in detail.

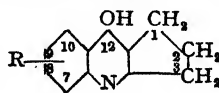

An examination of a number of tetrahydroacridones (II), 12-hydroxy-2:3-dihydro- β -quinindenes (III) (for numbering, see Blount, Perkin, and Plant, *J.*, 1929, 1976), and 2- and 4-hydroxyquinolines for causal prophylactic activity in *Plasmodium gallinaceum* infections in chicks revealed definite activity in compounds conforming to type (IV), of which (I), (II), and

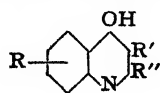

(I.)

(II.)

(III.)

(IV.)

(III) are representative, R' and R'' being saturated hydrocarbon residues. For example, 3-methoxyacridone showed no activity while its tetrahydro-derivative, 7-methoxy-1:2:3:4-

tetrahydroacridone (V), was the most active substance encountered, being, on a weight basis, about twice as active as sulphadiazine and four times as active as endochin (I), our investigations being ultimately extended to include comparison with this substance. Access to compounds of types (II), (III), and (IV) was obtained by condensation of the appropriate aromatic primary amines and β -keto-esters, followed by thermal cyclization of the resulting β -arylamino- $\Delta^{\alpha\beta}$ -unsaturated esters. This reaction was described first for ethyl acetoacetate by Conrad and Limpach (*Ber.*, 1887, 20, 944) who simply heated the intermediate products to about 250° and rarely obtained yields greater than 30%. The reaction was used by numerous workers in the interval and many years elapsed before Limpach (*Ber.*, 1931, 64, 969; D.R.-P. 455,387) made the significant improvement of effecting ring-closure by adding the intermediate products to liquid paraffin preheated to 250—280° and claimed yields of over 90%. Our own experience has been that decomposition is frequently excessive under Limpach's conditions as the products separate on the walls of the reaction vessel and there become overheated, and the yields are not as good as those claimed; other criticisms have been advanced by Maurin (*Ann. Chim.*, 1935, 4, 309). Ashley *et al.* (*Proc. Roy. Soc.*, 1933, B, 113, 295) used molten paraffin wax which was subsequently removed by a solvent. It was obvious to us that the best thermal control and mixing could be obtained by using a vigorously boiling inert solvent of suitable boiling point. For several years, therefore, we have used vigorously boiling diphenyl (b. p. 255°) for this purpose and have obtained clean products in good yield thereby; American workers (Price and Roberts, *J. Amer. Chem. Soc.*, 1946, 68, 1204; Steck, Hallock, and Holland, *ibid.*, p. 1241) have recently described the use of diphenyl ether and the eutectic of diphenyl and diphenyl ether (Dowtherm A) for this purpose, the latter having the advantage of being liquid at room temperature. Other high boiling inert solvents should be equally suitable, quinoline, for example, having been applied for this purpose (Dr. F. H. S. Curd, private communication).

With *o*- and *p*-substituted amines the constitutions of the products formed in the Conrad-Limpach reaction are unequivocal. With *m*-substituted amines, however, two products may be obtained since ring-closure may take place at either the 2- or the 6-position of the arylamino-group; both were isolated in the ring-closures of ethyl 2-*m*-anisidinocyclohex-1-enecarboxylate, which yielded 8- (VI) and 6-methoxy-1 : 2 : 3 : 4-tetrahydroacridone (VII), and ethyl β -*m*-anisidino- α -*n*-heptylcrotonate, which yielded endochin (I), m. p. 213—214°, and the isomeric 4-hydroxy-5-methoxy-3-*n*-heptylquinaldine (VIII), m. p. 219—220°. Leonard, Herbrandson, and Van Heyningen (*J. Amer. Chem. Soc.*, 1946, 68, 1279) have recently studied the latter ring-closure but do not record the isolation of (VIII) and claim, on the basis of analytical data, to have isolated the demethylated substance, 4 : 5-dihydroxy-3-*n*-heptylquinaldine, m. p. 218—218.5° (corr.), in addition to (I), m. p. 218.5—219.5° (corr.). In both these cases ring-closure at the position para to the methoxyl group greatly preponderated, in contrast with the purely aromatic series where approximately equal proportions of 2- and 4-methoxyacridones are formed in the ring-closure of *N*-*m*-anisylantranilic acid (Lehmstedt and Schrader, *Ber.*, 1937, 70, 838). An authentic specimen of (VI) was obtained by applying the Niementowski-Borsche-Tiedtke reaction to 4-methoxyanthranilic acid and cyclohexanone, but the yield was poor because of the ease with which this particular anthranilic acid undergoes decarboxylation. The melting points of 7-methoxy- (V) and 7-ethoxy-1 : 2 : 3 : 4-tetrahydroacridone (X) recorded here differ from those recorded in the literature (see pp. 1036, 1037), but we have carefully repeated these preparations and have fully confirmed our own observations.

Tests for causal prophylactic activity in *P. gallinaceum* infections in 10-day old chicks were carried out using the technique previously outlined (Fuller, Tonkin, and Walker, *loc. cit.*; King and Tonkin, *loc. cit.*) and the results are recorded in the Table. The minimal effective doses are those, given orally twice daily for the first four days and commencing two hours before infection, which gave definite indications of activity in comparison with untreated controls. In some cases no parasites were observed in the blood during the period of observation; sub-inoculations into clean chicks from such birds were carried out in a few cases and, if no infection resulted in the recipients, the donors were considered as having been sterilized of their infections (S). Where no sub-inoculations were carried out the result is recorded as presumably sterilized (? S). These observations (S and ? S) were, of course, made on higher dosages than those recorded as minimal. In a number of cases tests for therapeutic activity were carried out and the results are recorded in the Table; + denotes definite action, +— slight action, and — no action. The following substances, prepared by known methods, were also examined for prophylactic action and found to be inactive: 2 : 4-dihydroxyquinoline, 4-hydroxyquinaldine, 4-hydroxy-6-methoxyquinaldine, 4-hydroxy-8-methoxyquinaldine, 2-hydroxy-6-methoxy-lepidine, 1 : 2 : 3 : 4-tetrahydroacridone, and 3-methoxyacridone. From an inspection of the

Table and the preceding list, it is obvious that activity was only to be found in substances conforming to type (IV), as mentioned above. The necessity for the presence of a substituent in the benzene ring is clearly indicated by the inactivity of the simple 1:2:3:4-tetrahydroacridone and, of the substituents examined, methoxyl was more favourable than chloro-, which was more favourable than the ethoxyl group as indicated by the order of activities, (V) > (XI) > (X), and (XXIV) = (XXVI) > (XXV). The effect of the position of the methoxyl group in the benzene ring was marked, the position corresponding to the 7-position of quinoline being as a rule favourable as indicated by endochin (I), in which R' and R'' of (IV) are of unequal size, but where R' and R'' are of equal size as in (V), (VI), and (IX) the position corresponding to the 6-position of quinoline appeared to be most favourable, and weighting the alicyclic ring had a dystherapeutic effect.

EXPERIMENTAL.

General Method for the Synthesis of 1:2:3:4-Tetrahydroacridones, 12-Hydroxy-2:3-dihydro- β -quinindenes, and 4-Hydroxyquinolines.—Equimolecular amounts, usually 0.1 g.-mol., of the appropriate aromatic primary amine and β -keto-ester were mixed—with warming, if necessary, in the case of solid amines—and the mixture, treated with one drop of concentrated hydrochloric acid (Coffey, Thomson, and Wilson, *J.*, 1936, 856), was set aside in a partly evacuated desiccator for several days at 37°. The crude β -arylamino- Δ^{β} -unsaturated esters were cyclized by being added slowly to a weight of boiling diphenyl four times that of the combined starting materials. Evolution of alcohol took place readily and the boiling solutions were refluxed for 15 minutes after the end of the addition. On cooling, the products usually crystallised when the temperature fell to about 100°. When cold, the diphenyl was removed with ether, and the crude products, usually cream-coloured, were crystallised from suitable

Antimalarial Activity in P. gallinaceum Infections.

solvents. Diphenyl was used in the same arbitrarily selected proportion throughout, but recent work (Price and Roberts, *loc. cit.*) indicates that there may be an optimal concentration for each particular ring-closure.

7-Methoxy-1:2:3:4-tetrahydroacridone (V).—Obtained in an overall yield of 86% from *p*-anisidine and ethyl cyclohexanone-2-carboxylate, the compound crystallised from alcohol or, better, pyridine in flat rectangular plates, m. p. 313° (Found: C, 73.6; H, 6.6; N, 6.3. Calc. for $C_{14}H_{15}O_2N$: C, 73.4; H, 6.6; N, 6.1%). Basu and Das Gupta (*J. Indian Chem. Soc.*, 1937, 14, 468) record m. p. 295°; Hughes and Lions (*J. Proc. Roy. Soc., New South Wales*, 1938, 71, 458) record m. p. 284°; Bukhsh and Desai (*Proc. Indian Acad. Sci.*, 1939, A, 10, 262) record m. p. 285–286°. The intermediate ethyl 2-*p*-anisidino-cyclohex-1-enecarboxylate separated from methyl alcohol in prisms, m. p. 70° (Found: C, 66.7; H, 7.7;

N, 5.4. Calc. for $C_{14}H_{15}O_2N$: C, 69.9; H, 7.6; N, 5.1%. Hughes and Lions (*loc. cit.*) record m. p. 71°; Bukhsh and Desai (*loc. cit.*) record m. p. 71–72°.

8-Methoxy-1 : 2 : 3 : 4-tetrahydroacridone (VI).—(a) 4-Methoxyanthranilic acid (4 g.) (preparation below) and cyclohexanone (4 g.) were mixed and heated to 220° fairly rapidly and the mixture was kept at 220–230° for an hour. The mixture was cooled and treated with ether to remove *m*-anisidine, arising from decarboxylation, and unreacted cyclohexanone. The insoluble 8-methoxytetrahydroacridone (0.3 g.; 5%) separated from spirit in small hexagonal plates, m. p. 309° (Found: C, 73.0; H, 6.5; N, 6.3. $C_{14}H_{15}O_2N$ requires C, 73.4; H, 6.6; N, 6.1%). The *m*-anisidine, arising as a by-product, was characterised as the acetyl derivative, m. p. and mixed m. p. 80°.

(b) The crude cyclization product obtained in 72% yield from *m*-anisidine and ethyl cyclohexanone-2-carboxylate was a mixture of the 8- and 6-methoxy-compounds which could not be separated satisfactorily by crystallisation. The mixture (17 g.) was therefore dissolved in twice its weight of warm glacial acetic acid and then treated with 1½ volumes of concentrated hydrochloric acid. The hydrochloride, which separated on cooling in the ice-chest, was collected and drained thoroughly. The base (10.7 g.), regenerated from the solid hydrochloride with aqueous ammonia, then separated from spirit in hexagonal plates, m. p. and mixed m. p. 309° (Found: C, 73.1; H, 6.5; N, 6.3%).

6-Methoxy-1 : 2 : 3 : 4-tetrahydroacridone (VII).—The acetic-hydrochloric acid mother liquors from the above experiment, on evaporation to dryness and treatment with aqueous ammonia, afforded the crude 6-methoxy-isomer (5.9 g.) which separated from spirit in flattened needles (1.4 g.), m. p. 326°, depressed to 284° on admixture with the 8-methoxy-compound formed in the same reaction (Found: C, 73.5; H, 6.5; N, 6.1. $C_{14}H_{15}O_2N$ requires C, 73.4; H, 6.6; N, 6.1%).

9-Methoxy-1 : 2 : 3 : 4-tetrahydroacridone (IX).—Obtained in 60% yield from *o*-anisidine and ethyl cyclohexanone-2-carboxylate, the compound separated from *n*-butyl alcohol in plates, m. p. 286–288° (Found: C, 73.5; H, 6.6; N, 6.4. Calc. for $C_{14}H_{15}O_2N$: C, 73.4; H, 6.6; N, 6.1%). Hughes and Lions (*loc. cit.*) record m. p. 278°; Bukhsh and Desai (*loc. cit.*) record m. p. 277–279°.

7-Ethoxy-1 : 2 : 3 : 4-tetrahydroacridone (X).—Obtained in 87% yield from *p*-phenetidine and ethyl cyclohexanone-2-carboxylate, the compound separated from pyridine in needles or from alcohol in prisms, m. p. 292–293° (Found: C, 74.1; H, 7.1; N, 5.8. Calc. for $C_{15}H_{17}O_2N$: C, 74.1; H, 7.0; N, 5.8%). Hughes and Lions (*loc. cit.*) record m. p. > 300°; Bukhsh and Desai (*loc. cit.*) record m. p. > 350°. The intermediate ethyl 2-*p*-phenetidino-cyclohex-1-enecarboxylate separated from alcohol in long prisms, m. p. 87° (Found: C, 70.0; H, 8.0; N, 4.9. Calc. for $C_{17}H_{23}O_3N$: C, 70.6; H, 8.0; N, 4.9%). Hughes and Lions (*loc. cit.*) record m. p. 87°; Bukhsh and Desai (*loc. cit.*) record m. p. 88°.

7-Chloro-1 : 2 : 3 : 4-tetrahydroacridone (XI).—Obtained in 74% yield from *p*-chloroaniline and ethyl cyclohexanone-2-carboxylate, the compound crystallised from alcohol in microscopic prisms, m. p. > 330° (Found: C, 67.0; H, 5.3; N, 6.2. Calc. for $C_{13}H_{12}ONCl$: C, 66.9; H, 5.1; N, 6.0%). Basu and Das Gupta (*loc. cit.*) record m. p. 380°. The intermediate ethyl 2-*p*-chloroanilino-cyclohex-1-enecarboxylate separated from aqueous alcohol in short prisms, m. p. 67°, whereas Basu and Das Gupta (*loc. cit.*) record m. p. 90° (Found: C, 64.7; H, 6.7; N, 5.2. Calc. for $C_{15}H_{18}O_2NCl$: C, 64.4; H, 6.4; N, 5.0%).

7-Methyl-1 : 2 : 3 : 4-tetrahydroacridone (XII).—Obtained in 40% yield from *p*-toluidine and ethyl cyclohexanone-2-carboxylate, the compound separated from aqueous acetic acid in thin laths, m. p. > 330° (Found: C, 78.9; H, 7.1; N, 6.8. Calc. for $C_{14}H_{15}ON$: C, 78.9; H, 7.0; N, 6.6%). Sen and Basu (*J. Indian Chem. Soc.*, 1930, 7, 435) record m. p. 340°; Reed (*J.*, 1944, 425) records m. p. 374°.

7 : 8-Dimethoxy-1 : 2 : 3 : 4-tetrahydroacridone (XIII).—Obtained in 65% yield from 4-aminoveratrole and ethyl cyclohexanone-2-carboxylate, the compound separated from aqueous alcohol in microscopic plates, m. p. > 330° (Found: C, 69.9; H, 6.6; N, 5.6. Calc. for $C_{15}H_{17}O_3N$: C, 69.5; H, 6.6; N, 5.4%). Lions (*ibid.*, p. 242) records m. p. > 300°.

12-Hydroxy-9-methoxy-2 : 3-dihydro- β -quinindene (XXIV).—Obtained in 59% yield from *p*-anisidine and ethyl cyclopentanone-2-carboxylate, the compound separated from alcohol in fine needles, m. p. > 330° with prior darkening (Found: C, 72.7; H, 6.3; N, 6.7. $C_{13}H_{13}O_2N$ requires C, 72.6; H, 6.1; N, 6.5%). The intermediate ethyl 2-*p*-anisidinocyclopent-1-enecarboxylate separated from aqueous alcohol in short needles, m. p. 54–55° (Found: C, 69.0; H, 7.3. $C_{15}H_{19}O_3N$ requires C, 68.9; H, 7.3%).

12-Hydroxy-9-ethoxy-2 : 3-dihydro- β -quinindene (XXV).—Obtained in 59% yield from *p*-phenetidine and ethyl cyclopentanone-2-carboxylate, the compound crystallised from alcohol in aggregates of irregular plates, m. p. approx. 300° with previous darkening (Found: C, 73.4; H, 6.1; N, 6.2. $C_{14}H_{15}O_2N$ requires C, 73.4; H, 6.6; N, 6.1%). The intermediate ethyl 2-*p*-phenetidino-cyclopent-1-enecarboxylate separated from spirit in short prisms, m. p. 53° (Found: C, 70.0; H, 7.7; N, 5.1. $C_{16}H_{21}O_3N$ requires C, 69.9; H, 7.6; N, 5.1%).

9-Chloro-12-hydroxy-2 : 3-dihydro- β -quinindene (XXVI).—Obtained in 60% yield from *p*-chloroaniline and ethyl cyclopentanone-2-carboxylate, the compound crystallised from aqueous acetic acid in long needles, m. p. approx. 330° with prior darkening (Found: C, 65.8; H, 4.5; N, 6.6. $C_{12}H_{10}ONCl$ requires C, 65.8; H, 4.6; N, 6.4%).

7-Methoxy-3-methyl-1 : 2 : 3 : 4-tetrahydroacridone (XIV).—Obtained in 40% yield from *p*-anisidine and ethyl 4-methylcyclohexanone-2-carboxylate, the compound separated from 50% alcohol or aqueous pyridine in microscopic rectangular plates, m. p. 346–347° (Found: C, 73.9; H, 7.1; N, 6.1. Calc. for $C_{15}H_{17}O_2N$: C, 74.1; H, 7.0; N, 5.8%). Basu and Das Gupta (*loc. cit.*) record m. p. 335°.

8-Methoxy-3-methyl-1 : 2 : 3 : 4-tetrahydroacridone (XV).—Presumably contaminated initially with the 6-methoxy-isomer in the reaction product obtained in 56% yield from *m*-anisidine and ethyl 4-methylcyclohexanone-2-carboxylate, the compound separated from pyridine in microscopic needles, m. p. 324° (Found: C, 74.2; H, 6.8; N, 6.1. $C_{15}H_{17}O_2N$ requires C, 74.1; H, 7.0; N, 5.8%).

9-Methoxy-3-methyl-1 : 2 : 3 : 4-tetrahydroacridone (XVI).—Obtained in 62% yield from *o*-anisidine and ethyl 4-methylcyclohexanone-2-carboxylate, the compound separated from alcohol in rectangular plates, m. p. 270–273° (Found: C, 73.7; H, 7.1; N, 6.1. $C_{15}H_{17}O_2N$ requires C, 74.1; H, 7.0; N, 5.8%).

7-Methoxy-1-methyl-1 : 2 : 3 : 4-tetrahydroacridone (XVII).—Obtained in 41% yield from *p*-anisidine and ethyl 6-methylcyclohexanone-2-carboxylate, the compound separated from aqueous alcohol in

1038 Tetrahydroacridones and Related Compounds as Antimalarials.

rectangular plates, m. p. 280—281° (Found: C, 73.8; H, 7.0; N, 5.7. $C_{18}H_{19}O_2N$ requires C, 74.1; H, 7.0; N, 5.8%).

8-Methoxy-1-methyl-1:2:3:4-tetrahydroacridone (XVIII).—Obtained in 23% yield from *m*-anisidine and ethyl 6-methylcyclohexanone-2-carboxylate, the compound crystallised from spirit in fine needles, m. p. 277—278° (Found: C, 74.0; H, 7.2; N, 5.6. $C_{18}H_{19}O_2N$ requires C, 74.1; H, 7.0; N, 5.8%).

9-Methoxy-1-methyl-1:2:3:4-tetrahydroacridone (XIX).—Obtained in 24% yield from *o*-anisidine and ethyl 6-methylcyclohexanone-2-carboxylate, the compound separated from ethyl acetate in small cubes, m. p. 245—246° (Found: C, 74.0; H, 7.4; N, 5.9. $C_{18}H_{19}O_2N$ requires C, 74.1; H, 7.0; N, 5.8%).

7-Methoxy-3-ethyl-1:2:3:4-tetrahydroacridone (XX).—Obtained in 72% yield from *p*-anisidine and ethyl 4-ethylcyclohexanone-2-carboxylate, the compound separated from alcohol in rectangular plates, m. p. 334° (Found: C, 74.9; H, 7.1; N, 5.7. $C_{18}H_{19}O_2N$ requires C, 74.7; H, 7.4; N, 5.4%).

8-Methoxy-3-ethyl-1:2:3:4-tetrahydroacridone (XXI).—Obtained in 64% yield from *m*-anisidine and ethyl 4-ethylcyclohexanone-2-carboxylate, the compound was purified with some difficulty from the 6-methoxy-isomer, formed simultaneously, by crystallisation from methyl alcohol and separated in fine flattened needles, m. p. 291° (Found: C, 74.8; H, 7.4; N, 5.6. $C_{18}H_{19}O_2N$ requires C, 74.7; H, 7.4; N, 5.4%). A pure specimen of the 6-methoxy-isomer was not isolated.

9-Methoxy-3-ethyl-1:2:3:4-tetrahydroacridone (XXII).—Obtained in 64% yield from *o*-anisidine and ethyl 4-ethylcyclohexanone-2-carboxylate, the compound separated from spirit in microscopic prisms, m. p. 218—219° (Found: C, 74.6; H, 7.2; N, 5.6. $C_{18}H_{19}O_2N$ requires C, 74.7; H, 7.4; N, 5.4%). The intermediate ethyl 2-*o*-anisidino-5-ethylcyclohex-1-enecarboxylate separated from methyl alcohol in rectangular plates, m. p. 60° (Found: C, 70.8; H, 8.5; N, 4.9. $C_{18}H_{21}O_2N$ requires C, 71.3; H, 8.3; N, 4.6%).

7-Methoxy-1-ethyl-1:2:3:4-tetrahydroacridone (XXIII).—Obtained in 40% yield from *p*-anisidine and ethyl 6-ethylcyclohexanone-2-carboxylate, the compound separated from methyl alcohol in rectangular plates, m. p. 252—253° (Found: C, 74.9; H, 7.7; N, 5.8. $C_{18}H_{19}O_2N$ requires C, 74.7; H, 7.4; N, 5.4%).

4-Hydroxy-6-methoxy-3-ethylquinaldine (XXVII).—Obtained in 46% yield from *p*-anisidine and ethyl α -heptylacetate, the compound separated from pyridine in fine needles, m. p. 290° (Found: C, 72.0; H, 7.0; N, 6.6. $C_{18}H_{21}O_2N$ requires C, 72.0; H, 7.0; N, 6.5%).

4-Hydroxy-6-methoxy-3-*n*-heptylquinaldine (XXVIII).—Obtained in 77% yield from *p*-anisidine and ethyl α -*n*-heptylacetate, the compound separated from methyl alcohol in fine rectangular plates, m. p. 236—237° (Found: C, 75.6; H, 8.9; N, 5.0. $C_{18}H_{25}O_2N$ requires C, 75.3; H, 8.7; N, 4.9%).

4-Hydroxy-7-methoxy-3-*n*-heptylquinaldine (*Endochin*) (I) and 4-Hydroxy-5-methoxy-3-*n*-heptylquinaldine (VIII).—A mixture of isomers was obtained in 61% yield from *m*-anisidine and ethyl α -*n*-heptylacetate, which were allowed to interact in the first stage for 7 days at 37°. Crystallisation from methyl alcohol readily afforded the bulk (*ca.* 2/3) of the product, consisting of (I), which separated in fine flattened needles, m. p. 213—214° (Found: C, 75.7; H, 8.5; N, 5.2. Calc. for $C_{18}H_{25}O_2N$: C, 75.3; H, 8.7; N, 4.9%). Combined Intelligence Objectives Sub-Committee, 1945, Item No. 24, File No. XXV—54 (p. 38) records m. p. 207—212°; Leonard *et al.* (*loc. cit.*) record m. p. 218.5—219.5° (*corr.*).

The mother liquors on concentration to small bulk afforded an obvious mixture (7.9 g.), m. p. 180—185°. This mixture on treatment with *n*-hydrochloric acid (100 c.c.) gave a sticky gum which slowly hardened. The solid was collected and the acid filtrate yielded only traces of material (< 0.1 g.) on treatment with excess of ammonia. The solid dissolved readily in methyl alcohol and the clear solution was evaporated to a syrupy consistency. On addition of water (*ca.* 40 c.c.) a sticky gum reappeared, giving way, on addition of methyl alcohol (*ca.* 20 c.c.), to fine needles. These were collected, the mother liquors being retained (see below), and, on treatment in methyl alcoholic solution with aqueous ammonia, afforded a further amount (4.4 g.) of (I), m. p. and mixed m. p. 213—214°. The aqueous methyl alcohol mother liquors, on treatment with aqueous ammonia, afforded (VIII) (2.95 g.), m. p. 213°, depressed to 173—193° on admixture with (I). The pure compound separated from a small volume of methyl alcohol, or from a larger volume of 50% ethyl alcohol, in clusters of fine needles, m. p. 219—220° (Found: C, 75.4; H, 8.5; N, 4.7; OMe, 10.2. $C_{18}H_{25}O_2N$ requires C, 75.3; H, 8.7; N, 4.9; OMe, 10.8%).

4-Hydroxy-8-methoxy-3-*n*-heptylquinaldine (XXIX).—Obtained in 60% yield from *o*-anisidine and ethyl α -*n*-heptylacetate, the compound crystallised from methyl alcohol in fine prisms, m. p. 155—156° (Found: C, 75.1; H, 8.9; N, 5.1. $C_{18}H_{25}O_2N$ requires C, 75.3; H, 8.7; N, 4.9%).

2-Nitro-4-methoxyphenyl Cyanide.—3-Nitro-4-aminoanisole was submitted to the Sandmeyer reaction using a technique previously described (Fuller, Tonkin, and Walker, *loc. cit.*), affording a 75% yield of recrystallised material separating from methyl alcohol in small plates, m. p. 139° (Found: N, 15.7. Calc. for $C_8H_8O_3N_2$: N, 15.7%). Cook *et al.* (*J.*, 1945, 861), using cuprous cyanide, obtained a somewhat lower yield (crude) and record m. p. 140°.

2-Nitro-4-methoxybenzoic Acid.—The preceding cyanide (50 g.) was refluxed for 5 hours with a mixture of equal volumes of glacial acetic acid, concentrated sulphuric acid, and water (each 100 c.c.), crystals separating after about 1½ hours. The cooled mixture was treated with about 2 volumes of water and the product was collected and re-precipitated (45 g.) from solution in aqueous ammonia; m. p. 195—196° as recorded by Simonsen and Rau (*J.*, 1917, 111, 235) and by Ashley, Perkin, and Robinson (*J.*, 1930, 393).

4-Methoxyanthranilic Acid.—The preceding nitro-acid (45 g.) was dissolved in a slight excess of 2*N*-ammonia and hydrogenated in the presence of palladised strontium carbonate (5 g.) at 45 atm. The calculated fall in pressure was observed in about 20 minutes and absorption of hydrogen then ceased. The filtered solution was acidified to about pH 4 and the product (35.4 g.) was collected; m. p. 180° (*efferv.*). On account of ready decarboxylation, recrystallisation from *ca.* 40% aqueous acetic acid was wasteful but afforded fine prisms, m. p. 180—181° (*efferv.*). Friedländer, Bruckner, and Deutsch (*Annalen*, 1912, 385, 46) record m. p. 166° (*decomp.*); Ullmann and Dootson (*Ber.*, 1918, 51, 20) record m. p. 172° (*decomp.*).

Ethyl α -*n*-Heptylideneacetoacetate.—A mixture of freshly distilled oenanthal (100 g.) and ethyl

acetoacetate (114 g.) was cooled in a freezing mixture and saturated with dry hydrogen chloride. After 18 hours in the ice-chest the mixture was poured into water and extracted with ether. The extract was washed well with water, dried, and fractionated, affording a colourless oil (158 g.), b. p. 150–152°/14 mm. (Found: C, 69.1; H, 10.0. Calc. for $C_{13}H_{22}O_3$: C, 69.0; H, 9.7%). Knoevenagel (*Ber.*, 1898, **31**, 737) used piperidine as catalyst and recorded b. p. 145°/10 mm.

Ethyl α -n-Heptylacetate.—The preceding unsaturated ester (145 g.) was hydrogenated in ethyl alcohol (400 c.c.) with palladised strontium carbonate (7 g.) at 45 atm. The calculated fall in pressure was observed in about 20 minutes and no further absorption of hydrogen took place. The product, a colourless oil (133 g.), distilled at 144–146°/11 mm. (Found: C, 68.3; H, 10.5. Calc. for $C_{13}H_{24}O_3$: C, 68.4; H, 10.5%). Wojcik and Adkins (*J. Amer. Chem. Soc.*, 1934, **56**, 2424) record b. p. 130–132°/7 mm.

The authors are greatly indebted to Mr. L. V. Sharp for much preparative assistance and to Mrs. A. M. Yates, B.Sc., for assistance in carrying out antimalarial tests.

193. β -Phellandrene Tetrabromide.

By P. A. BERRY and A. KILLEN MACBETH.

The optically active tetrabromide isolated from the terpene fraction of *E. cneorifolia* oil is derived from *l*- β -phellandrene and is identical with samples prepared from *l*- β -phellandrene derived from Canada-balsam oil. *d*- β -Phellandrene from water-fennel oil also forms an optically active tetrabromide. The β -phellandrene tetrabromides are characterised by rotations of opposite sign to that of the hydrocarbon from which they are derived.

In a previous paper (Berry, Macbeth, and Swanson, *J.*, 1937, 1443) it was shown that a seasonal variation occurred in the oil of *Eucalyptus cneorifolia* with an increase in the terpene content from a minimum of some 10% to a maximum approaching 50% which is attained during the period of active growth in the early summer months. The presence of *l*- α - and *l*- β -phellandrene was established, and after further examination of the terpene fraction it was reported by Berry and Macbeth (*Nature*, 1945, **156**, 175) that a crystalline tetrabromide can be isolated after bromine vapour has been aspirated through solutions of such terpene fractions in acetic acid, and the reaction mixture stored for some days in the refrigerator. The crystalline tetrabromide is separated in amounts corresponding with upwards of 20% of the total terpene when the hydrocarbon is dissolved in about four times its weight of acetic acid, and excess of bromine introduced whilst the temperature is kept below 0°.

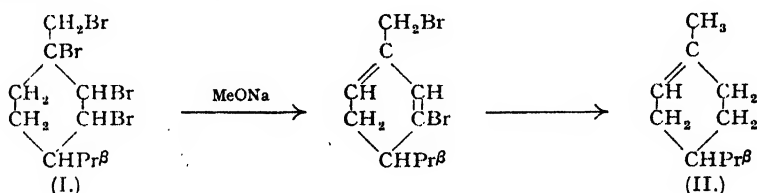

Analysis of the tetrabromide showed the formula to be $C_{10}H_{16}Br_4$, and in view of the fact that the substituent groups in the cyclic compounds occurring in *E. cneorifolia* oil are in the para-positions it may reasonably be concluded that the progenitor of the tetrabromide is a *p*-menthadiene. Of the fourteen possible structures seven inactive compounds are excluded as the tetrabromide is dextrorotatory, and of the remaining seven only two (limonene and *p*-mentha-2 : 8(9)-diene) are optically active and without conjugated double bonds. Henry and Paget (*J.*, 1925, **127**, 1649) isolated from oil of chenopodium an inactive tetrabromide which they considered was derived from *p*-mentha-2 : 8(9)-diene. We have confirmed this observation excepting that our tetrabromide had slight optical activity. The tetrabromides from limonene and dipentene have also been re-examined, and as their properties differ markedly from those of the tetrabromide from *E. cneorifolia* these substances must also be excluded. One is therefore forced to consider the para-menthadienes containing a conjugated system of double bonds despite the fact that crystalline tetrabromides derived from such substances are not described in the literature.

The tetrabromide now described is debrominated by magnesium in ether and yields a hydrocarbon, $C_{10}H_{16}$, which is readily converted into the tetrabromide again. This hydrocarbon showed the characteristics of *l*- β -phellandrene; in particular it formed a nitrosite the mutarotation of which was similar to that of the nitrosite derived from a sample of *l*- β -phellandrene from Canada-balsam oil. Authentic samples of *l*- β -phellandrene gave tetrabromides identical with that derived from the terpene fractions of *E. cneorifolia* oil, in particular having m. p. 118–119° after recrystallisation from ethyl acetate and a specific rotation of approximately +49° in the same solvent, the value being unchanged even after two months. The specific rotation in chloroform was higher (+53.6°) and these solutions too showed little change in rotation on storage.

The chief feature of the tetrabromide derived from β -phellandrene is the change of sign of

rotation, the levorotatory hydrocarbon giving a dextrorotatory tetrabromide. This characteristic property provides a convenient and useful criterion for β -phellandrene, the identification of which has hitherto mainly rested on the optical properties of derivatives such as the nitrosite. A sample of *d*- β -phellandrene from water-fennel oil was available (Berry, Macbeth, and Swanson, *J.*, 1937, 1448), and this yielded a tetrabromide having m. p. 118–119° which had a specific rotation of the same magnitude as that derived from *l*- β -phellandrene but of opposite sign.

Wallach (*Annalen*, 1894, 281, 129) examined the debromination of limonene tetrabromide by sodium methoxide and obtained as a product a monobromo-compound which nascent hydrogen converted into carveol methyl ether. The reaction with β -phellandrene tetrabromide (I) follows quite a different course, as only two bromine atoms are removed by the methoxide, and nascent hydrogen converts the product into a levorotatory hydrocarbon of low density having the composition $C_{10}H_{18}$. The reactions appear to result in the formation of *l*-*p*-menth-1-ene (II), as the molecular refraction (45.85) agrees with the calculated value (45.7) and the compound forms a nitrosochloride having m. p. 93–94° and $[\alpha]_D -342^\circ$ (ether). The nitrosochloride derived from *d*-*p*-menth-1-ene (Wallach, *Annalen*, 1911, 381, 58; Vavon, *Compt. rend.*, 1911, 152, 1675) has m. p. 95–96° and $[\alpha]_D +344^\circ$, the sign of rotation of the derivative being the same as that of the parent hydrocarbon.

EXPERIMENTAL

Tetrabromide from Terpene Fraction of E. cneorifolia Oil.—Preliminary experiments showed that the amount of tetrabromide formed varied greatly with conditions, and the factors favourable to high yield were mainly (1) the use of freshly distilled terpene fraction dissolved in about four times its volume of acetic acid, (2) a bath temperature below 0° but not so low as to cause much crystallisation of acetic acid on the walls of the reaction vessel, (3) steady aspiration of bromine vapour at such a rate that bromination was completed within an hour and the additional excess of bromine introduced for a further fifteen minutes, (4) efficient stirring to ensure that the temperature of the reaction mixture did not rise above about 5°, and (5) subsequent storage in the refrigerator for several days.

In a typical experiment freshly distilled terpene (100 c.c.) having $\alpha_D -42.4^\circ$ (homogeneous) was dissolved in acetic acid (350 c.c.) and brominated for 70 minutes, the flask being immersed in an ice-salt mixture. Bromine (140 g.) was rapidly absorbed during 45 minutes and aspiration was stopped after an excess (180 g. in all) had been introduced (70 minutes). The mixture was placed in the refrigerator, and crystallisation of the tetrabromide was beginning within an hour. After five days the crystals were removed at the pump and washed with cold acetic acid. Yield, 56 g. of crude tetrabromide having m. p. 109–110°, $[\alpha]_D 57.1^\circ$ in chloroform (*c*, 4.468). This is equivalent to upwards of 20% of the terpene taken.

In another experiment terpene (100 c.c.; $\alpha_D -43.2^\circ$) in acetic acid (400 c.c.) was brominated by aspiration of bromine (195 g.) for an hour, the temperature of the bath being -8° . Some acetic acid crystallised on the walls during reaction and the yield of crude washed tetrabromide collected after seven days was 47 g. having m. p. 109–111, $[\alpha]_D 59.5^\circ$. In a further experiment terpene (75 c.c., $\alpha_D -38^\circ$) in acetic acid (300 c.c.) after treatment in a similar way with bromine (147 g.) gave crude washed tetrabromide (37.3 g.) having m. p. 108–110°, $[\alpha]_D 52.7^\circ$ in chloroform. This corresponds with about 18% of terpene taken.

The combined yields of tetrabromide (140 g.) from the above preparations after four crystallisations from ethyl acetate gave pure tetrabromide as flat glistening plates having m. p. 116–117°, $[\alpha]_D 53.6^\circ$ in chloroform (*c*, 5.41). Further recrystallisation raised the m. p. to 118–119°. The solubility in ethyl acetate at 17° is 10.4% w/w and tetrabromide of good quality can be recovered as a first crop after concentration of the mother liquors. The specific rotation of the tetrabromide in ethyl acetate is somewhat lower than in chloroform, a solution (*c*, 4.004) having a value of 48.8° which was unchanged after the solution had been kept for two months (Found: C, 26.4; H, 3.65; Br, 70.2. $C_{10}H_{18}Br_4$ requires C, 26.3; H, 3.5; Br, 70.1%).

Debromination of the Tetrabromide.—The method of debromination used was essentially that described by Brown and Lemke (*Ber.*, 1923, 56, 1562) in the preparation of limonene from its tetrabromide by the action of magnesium in ether. Purified tetrabromide (39 g.) in anhydrous ether (196 c.c.) was gently warmed with magnesium (6.2 g.) and a trace of iodine. After 90 minutes the ethereal layer was separated and washed with water (twice), and the washings were used to wash the original lower (magnesium bromide) layer. The separated ether from this was washed with water and the total ether distilled to remove solvent and then steam distilled. From two such experiments unchanged tetrabromide (5.3 g.) was recovered from the steam-distillation flask, and an oil (15.8 g.) of low density ($d_{4^\circ} 0.843$) was recovered from the distillate. The hydrocarbon obtained on distilling the oil over sodium had $d_{4^\circ} 0.8411$ and $[\alpha]_D^{20} -16.2^\circ$. It had the formula $C_{10}H_{18}$ and gave a nitrosite (Found: C, 88.3; H, 11.95. Calc.:

C, 88.15; H, 11.8%). When brominated as described above the hydrocarbon gave a tetrabromide identical with the original.

Tetrabromide of *l*- β -Phellandrene.—The formation of a nitrosite suggested that the hydrocarbon was possibly a phellandrene, and this was supported by the fact that a terpene fraction from which the phellandrene was removed gave, on bromination, only a small quantity of crystals which were inactive and had m. p. 220°. This was evidently benzene hexabromide derived from traces of benzene in the solvents used during removal of the phellandrene as nitrosite. The bromination of *l*- β -phellandrene was therefore examined, the material being available as an old sample derived from Canada-balsam oil. On steam distillation this gave terpene having $\alpha_D -42^\circ$, and after bromination as described above crude tetrabromide (7.2 g.) was obtained in amount equivalent to about 10% of the terpene. It had m. p. 110–112°, $[\alpha]_D^{20} 57.3^\circ$ in ethyl acetate (c. 4.265), and after several recrystallisations from the same solvent the m. p. had risen to 116–117°. The sample showed no depression of m. p. on admixture with the pure tetrabromide derived from *E. cneorifolia* oil.

A small sample of the residue from water fennel oil from which *d*-cryptone and *d*-phellandral had been removed some years before was steam distilled, and the terpene collected (which contained *d*- β -phellandrene and was dextrorotatory) was brominated in the usual way. The crude tetrabromide of *d*- β -phellandrene had m. p. 111–113° and a high *l*ævo-rotation ($[\alpha]_D -56.6^\circ$) in ethyl acetate (c. 5.492). After four recrystallisations from ethyl acetate the pure tetrabromide had m. p. 116–116.5°, and $[\alpha]_D^{20} -55.1^\circ$ in ethyl acetate (c. 4.046). The m. p. of the substance is the same as that of the tetrabromide of *l*- β -phellandrene and its optical activity of the same order, but of opposite sign.

The tetrabromide of *dl*- β -phellandrene was separated as long needles when a solution of equimolecular amounts of the *d*- and the *l*-compound in ethyl acetate was allowed to evaporate slowly. The substance was inactive and had m. p. 112–113°, not changed by further crystallisation.

Debromination by Sodium Methoxide.—The tetrabromide of *l*- β -phellandrene (50 g.) was refluxed for more than 8 hours with sodium methoxide (8 g. sodium in 100 c.c. of methyl alcohol). After the addition of some water the reaction mixture was steam distilled, and the oil (30 g.) recovered from the distillate was dried (KOH) and fractionated under reduced pressure. It distilled as a main fraction (28 g.) which was again refluxed for 7 hours with sodium methoxide, and the oil was worked up again giving a main fraction (26 g.) which distilled at 144–148°/11 mm. and had *d* 1.448; $[\alpha]_D 19.2^\circ$; $n_D^{20} 1.5643$. Bromine combined as sodium bromide in the still residue after the steam distillations amounted in the first case to 18.5 g. which is equivalent to the removal of 2.1 atoms of bromine from the tetrabromide. After the second treatment with methoxide bromine removed was assayed as equivalent to a further 0.2 atom only.

The partly debrominated oil (24 g.) was dissolved in absolute alcohol (250 c.c.) and gradually treated with sodium (20 g.), the mixture being heated on the water-bath as reaction slowed down. The oil collected on steam distillation still contained bromine and was again subjected to the action of nascent hydrogen. The oil then collected on steam distillation, after being dried (KOH), distilled at 75–76°/34 mm. and had $d_{15.5}^{20} 0.8228$; $[\alpha]_D -81.2^\circ$ (homogeneous); $n_D^{20} 1.4581$ (Found: C, 87.2; H, 13.0. Calc. for $C_{10}H_{18}$: C, 86.85; H, 13.1%). The oil readily decolorised bromine in acetic acid and gave a nitrosochloride, m. p. 93–94°, which was very stable and did not decompose on heating to 140°. In ether (c. 0.714) the nitrosochloride had $[\alpha]_D -342^\circ$ which had fallen after 13 hours to -322° and after 85 hours to -280° . It appears that the compound is *l*-*p*-menth-1-ene as the constants are in good agreement with those recorded for *d*-*p*-menth-1-ene, the optical values being of opposite sign.

Other Tetrabromides.—In the course of the work several tetrabromides were prepared for comparison with the product obtained from *E. cneorifolia* oil. *d*-Limonene tetrabromide was prepared from sweet orange oil of pharmaceutical quality, and had m. p. 104–105°, $[\alpha]_D 79.2^\circ$ in chloroform. Dipentene tetrabromide was prepared from a sample of dipentene kindly supplied by Professor T. G. Jones, and a further preparation was carried out from cineol. The tetrabromide was inactive and had m. p. 126–127°. A tetrabromide was also prepared from an imported sample of pharmaceutical oil of chenopodium; it had m. p. 115–116°, $[\alpha]_D 2.2^\circ$ in chloroform (c. 16.13) (compare Henry and Paget, *loc. cit.*).

JOHNSON CHEMICAL LABORATORIES, UNIVERSITY OF ADELAIDE.

[Received, October 23rd, 1946.]

194. *Molecular Rearrangement and Displacement of Arylamine Residues in α -Arylamino-ketones. Part I.*

By R. M. COWPER and T. S. STEVENS.

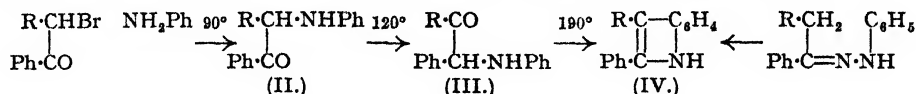

When an arylaminodeoxybenzoin (e.g., II) is heated with a mixture of an arylamine and its hydrobromide, rearrangement may take place (to III); if the arylamine does not correspond to the arylamine residue in the ketone, this residue may be displaced by that of the reagent, with or without simultaneous rearrangement. The observations are only partly explicable by the mechanism proposed by Bischler for the rearrangements and displacements involved in the conversion of phenacylarylamines into arylindoles, and other mechanisms are discussed.

McGEOCH and STEVENS (J., 1935, 1032) observed that the action of aniline on phenyl 1-bromo-2-phenylethyl ketone afforded an anomalous by-product (I):

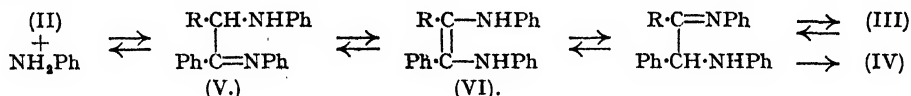

Related reactions of more tractable materials have been studied in detail, and the observations and tentative conclusions are reported now in view of publications by other workers in the same field (Crowther, Mann, and Purdie, *J.*, 1943, 58; Verkade and Janetzky, *Rec. Trav. chim.*, 1943, 62, 763, 775; Julian, Meyer, Magnani, and Cole, *J. Amer. Chem. Soc.*, 1945, 67, 1203). The results of the principal series of experiments are summarised in the table.

The α -bromo-derivatives of 4- and 4'-methoxydeoxybenzoin react in the first instance normally, by direct displacement, with aniline, *p*-toluidine, or methylaniline (Cowper and Stevens, *J.*, 1940, 347; which see for proofs of constitution of substances described in this paper); but at higher temperatures, in presence of arylamine and arylamine hydrobromide, such transformations as the following may occur (R = *p*-anisyl, throughout) :

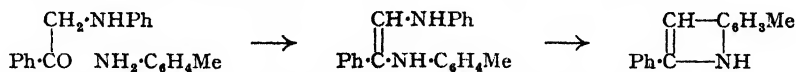

The conversion of the base (II) into (III) is sensibly complete, like the thermal transformation (Julian and Passler, *J. Amer. Chem. Soc.*, 1932, 54, 4756; cf. Luis, *J.*, 1932, 2547) of the corresponding benzoin into its isomeride, $\text{R}\cdot\text{CH}(\text{OH})\cdot\text{COPh} \rightarrow \text{R}\cdot\text{CO}\cdot\text{CH}(\text{OH})\text{Ph}$. It is plausibly explained on the basis of Bischler's mechanism for the formation of 2-phenylindole from anilinoacetophenone (*Ber.*, 1892, 25, 2860; 1893, 26, 1336; cf. Strain, *J. Amer. Chem. Soc.*, 1929, 51, 270) :

This explanation does not exclude rearrangement of the *N*-methyl derivative of (II) in presence of methylaniline and its hydrobromide, through direct formation and hydrolysis of the intermediate (as VI); but the process might be expected to be more difficult, in view of the failure of the carbonyl group of benzoin to react with a secondary base (Cowper and Stevens, *loc. cit.*). In fact, no reaction was observed below 170°, higher temperatures leading, not to the methyl derivative of (III), but by indolisation to that of (IV). Indolisation is structurally excluded in *phenyl α -(N-methylmesidino)-p-methoxybenzyl ketone*, $\text{Ph}\cdot\text{CO}\cdot\text{CHR}\cdot\text{NMe}\cdot\text{C}_6\text{H}_4\text{Me}_3$, but when this was heated with methylmesidine and its hydrobromide at 170° it was recovered unchanged, and at 190° the only isolable product was nitrogen-free.

Julian *et al.* (*loc. cit.*) record similar (reversible) rearrangements, *i.e.*, (II; R = Me or CH_2Ph) \rightarrow (III; R = Me or CH_2Ph), and also demonstrate the formation, under similar experimental conditions, of anilinodeoxybenzoin anil (as V) from anilinodeoxybenzoin and aniline.

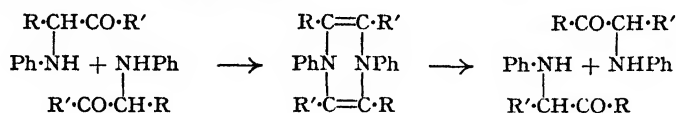

The Bischler mechanism accounts well for the conversion of anilinoacetophenone, by heating with excess of *p*-toluidine and its hydrochloride, into 2-phenyl-5-methylindole, aniline being in effect displaced by toluidine (Bischler, *loc. cit.* For other examples, see Julian *et al.*, *J. Amer. Chem. Soc.*, 1933, 55, 2105; 1945, 67, 1203; Verkade and Janetzky, *loc. cit.*) :

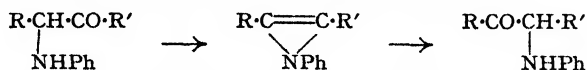

Such a displacement is not necessarily associated with indolisation; thus when (II) or (III) is heated at 120° with excess of *p*-toluidine and *p*-toluidine hydrobromide the product is the toluidino-analogue of (III), displacement being accompanied in the former case by rearrangement. Further similar results are recorded in the table.

The reactions of rearrangement and/or displacement so far discussed can be accommodated by the Bischler-Strain scheme; alternatively, a somewhat similar mechanism could be envisaged, involving as an intermediate stage a product of the type $(\text{NHAr}\cdot\text{CR}\cdot\text{CPh})_2\text{NAr}$, discovered by Crowther, Mann, and Purdie (*loc. cit.*); but it is not clear why the *N*-methyl derivatives of (II) and (III) are unaffected by aniline-aniline hydrobromide up to 170°; and most surprising that (II), with methylaniline and its hydrobromide, readily affords (III) by rearrangement without displacement. The rearrangement of (II) is, moreover, smoothly effected by boiling with pyridine hydrobromide in pyridine or in butyl alcohol, a result explicable on Bischler's hypothesis only if part of the initial material furnishes free aniline by decomposition. This remote possibility was examined, and the strictly intramolecular character of the rearrangement

indicated, by heating a mixture of two arylamino-ketones with pyridine hydrobromide in pyridine and seeking evidence for an exchange of arylamine residues. For experimental convenience, one selected initial substance was desylanthranilic acid, $\text{Ph}\cdot\text{CO}\cdot\text{CHPh}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{H}$, rearrangement of which is concealed by symmetry but from which aniline readily displaces anthranilic acid. The second initial material was (II), and the only products, isolated in good yield, were (III) and desylanthranilic acid. The result also discredits such a mechanism as the following (cf. Gabriel, *Ber.*, 1908, **41**, 1146) :

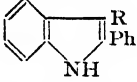

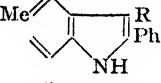

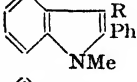

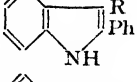

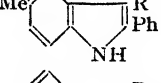

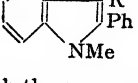

A strictly intramolecular rearrangement can be formulated in conventional structural terms only by postulating an intermediate having a three-membered ring :

For unsaturated C_2N rings compare Neber and Burgard (*Annalen*, 1932, **493**, 281).

Attempts were also made to effect the displacement of one arylamine by another, where the Bischler mechanism could be excluded. When α -anilinophenylacet-*p*-chloroanilide, $\text{NHPh}\cdot\text{CHPh}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\text{Cl}$, is heated at 200° with *p*-toluidine hydrobromide in *p*-toluidine, the aniline residue only is displaced; here the Bischler intermediate would be a tautomeric amidine, $\text{NHPh}\cdot\text{CHPh}\cdot\text{C}(\text{NPh})\cdot\text{NH}\cdot\text{C}_6\text{H}_4\text{Cl} \rightleftharpoons \text{NHPh}\cdot\text{CHPh}\cdot\text{C}(\text{NHPh})\cdot\text{N}\cdot\text{C}_6\text{H}_4\text{Cl}$, and its formation and decomposition would lead to extensive displacement of chloroaniline also. The high temperature necessary for the reaction, however, forbids the inference that a direct displacement is likely with arylamino-ketones at 120° . Under the same energetic conditions *p*-toluidine displaces aniline from benzylaniline; but benzhydryl-*p*-toluidine, which might have been expected to be very reactive, was unaffected by aniline-aniline hydrobromide at 150° .

It would appear, in sum, that in presence of a base and its salt an arylamino-ketone can react in two independent ways : (a) according to the Bischler-Strain scheme made very probable by Julian and his co-workers, leading in appropriate cases to arylamine displacement, to indolisation, and possibly to rearrangement; and (b) a strictly intramolecular rearrangement, perhaps by the mechanism suggested above.

Initial material.	Action of base + salt at 120° :			Product of indolisation.
	NH_2Ph .	$\text{NH}_2\cdot\text{C}_6\text{H}_7$.	NHPhMe .	
$\text{R}\cdot\text{CH}\cdot\text{COPh}$ NHPh	Rearr.	Rearr. + Displ.	Rearr.	
$\text{R}\cdot\text{CH}\cdot\text{COPh}$ $\text{NH}\cdot\text{C}_6\text{H}_7$	Rearr. + Displ.	Rearr.	Rearr.	
$\text{R}\cdot\text{CH}\cdot\text{COPh}$ NMePh	Unch.	Unch.	Unch.	
$\text{R}\cdot\text{CO}\cdot\text{CHPh}$ NHPh	Unch.	Displ.		
$\text{R}\cdot\text{CO}\cdot\text{CHPh}$ $\text{NH}\cdot\text{C}_6\text{H}_7$	Displ.	Unch.		
$\text{R}\cdot\text{CO}\cdot\text{CHPh}$ NMePh	Unch.	Unch.	Unch.	

Indolisation.—The base (II) and its analogues, each heated at 190 – 200° with the corresponding arylamine and its hydrobromide, yielded indoles; in all cases the product was that which would have resulted from the direct dehydration of an arylaminobenzyl *p*-anisyl ketone (as

(III), the stable type when simple rearrangement can be effected. Attempted indolisation of (II) and of its *p*-toluidino-analogue in pyridine-pyridine hydrobromide gave as sole definable product a trace of nitrogen-free material, different in the two cases. This failure is not general (see Crowther, Mann, and Purdie, *loc. cit.*), and so not clearly significant as to the mechanism of Bischler synthesis. This investigation as a whole, however, shows that many of the anomalies recorded in this synthesis may be due to demonstrable transformations of the arylamino-ketones before cyclisation, and not to an *ortho*-migration as postulated by Crowther, Mann, and Purdie :

EXPERIMENTAL.

Rearrangement.—The following experiment is typical. Phenyl α -anilino-*p*-methoxybenzyl ketone (II) was heated with aniline (3 mols.) and aniline hydrobromide (0.5 mol.) at 115–120° for 3 hours. The mixture was treated with dilute hydrochloric acid and ether; the combined acid layers deposited long needles of the hydrochloride of (III), which with alcoholic ammonia gave the free base (85%), identified by mixed m. p. and by reduction to *p*-methoxyphenyl benzyl ketone. No unchanged (II) could be recovered.

The same result followed when (II) was boiled for 3 hours with pyridine hydrobromide in pyridine, or with pyridine hydrobromide or sulphate in *n*-butyl alcohol. It was recovered unchanged after 2.5 hours' heating with *p*-toluidine alone at 130°.

Phenyl *N*-methylmesidino-*p*-methoxybenzyl ketone, prepared from the related bromo-ketone and methylmesidine (Ullmann, *Annalen*, 1903, **327**, 110) in the usual way (Cowper and Stevens, *loc. cit.*), crystallised from alcohol in colourless needles, m. p. 89–90° (Found: N, 4.0. $C_{25}H_{27}O_2N$ requires N, 3.8%). It was unchanged after 5–6 hours' heating with methylmesidine and its hydrobromide at 170°; after 6 hours at 190° the only isolable product was a little nitrogen-free material, white, glittering laminae from alcohol, m. p. 96–98°.

Displacement.—Phenyl α -anilino-*p*-methoxybenzyl ketone (II) or *p*-methoxyphenyl α -anilino benzyl ketone (III) was heated at 115–120° for 3 hours with *p*-toluidine (3 mols.) and *p*-toluidine hydrobromide (0.5 mol.). Fractional crystallisation of the product from alcohol yielded in each case 75% of *p*-methoxyphenyl α -*p*-toluidinobenzyl ketone, m. p. and mixed m. p. 141–142°, and 25% of material, m. p. 115–117°, indistinguishable from a mixture of the toluidino-ketone with an equal quantity of (III).

Simultaneous Rearrangement of (II) and Desylanthranilic Acid.—The acid, from benzoic acid and anthranilic acid (Weckowicz, *Ber.*, 1908, **41**, 4144), crystallised from alcohol in cream-coloured plates, m. p. 225–227° (Found: N, 4.4. Calc. for $C_{11}H_{11}O_3N$: N, 4.2%). Heated with aniline and aniline hydrobromide, it rapidly yielded desylaniline with some unchanged material. Equal weights of desylanthranilic acid and the ketone (II) were boiled for 3 hours in pyridine with pyridine hydrobromide. After addition of ether the filtered solution was extracted successively with sodium hydroxide solution and hydrochloric acid. The extracts yielded respectively desylanthranilic acid and the ketone (III), each in 90% yield, with no evidence of any other product. Three parts of (II) to one of desylanthranilic acid were used in another experiment with similar results. For comparison, phenyl α -(*o*-carboxyanilino)-*p*-methoxybenzyl ketone, $MeO \cdot C_6H_4 \cdot CHBz \cdot NH \cdot C_6H_4 \cdot CO_2H$, was prepared from benzanisoin and anthranilic acid: white needles, m. p. 198–199° (Found: N, 4.0. $C_{22}H_{19}O_4N$ requires N, 3.9%). With aniline and aniline hydrobromide it yielded (III).

“Direct” Displacement of Arylamine Residues.—Ethyl α -anilinophenylacetate (Stöckenius, *Jahresber.*, 1878, 780) was unaffected by boiling *p*-chloroaniline, but when *p*-chloroaniline and the ester were added successively to ethylmagnesium bromide in ether at room temperature (compare Hardy, *J.*, 1930, 398), α -anilinophenylacet-*p*-chloroanilide was obtained: long prisms from alcohol, m. p. 157–158° (Found: N, 8.6; Cl, 10.4. $C_{20}H_{17}ON_2Cl$ requires N, 8.3; Cl, 10.5%). The anilide was boiled for 3 hours with *p*-toluidine hydrobromide (0.5 mol.) in *p*-toluidine (3 mols.), and the mixture treated with ether and dilute hydrochloric acid. The tarry mass deposited by the acid layer afforded, after several crystallisations from ammoniacal alcohol, white needles, m. p. 183–185°. These were identical with α -*p*-toluidinophenylacet-*p*-chloroanilide, prepared in the same way as the anilino-compound (Found: N, 7.9. $C_{21}H_{19}ON_2Cl$ requires N, 8.0%). When methylaniline was used in place of *p*-toluidine, much non-basic material was formed and no individual product could be isolated.

Benzylaniline hydrobromide was boiled under reflux with *p*-toluidine (5 mols.) for 4 hours, and the basified mixture distilled in steam. The non-volatile material, with benzenesulphonyl chloride in pyridine, gave benzenesulphonbenzyl-*p*-toluidide (mixed m. p.) which depressed the m. p. of benzenesulphonbenzylanilide. Benzhydryl-*p*-toluidine (Busch and Rinck, *Ber.*, 1905, **38**, 1768) was unchanged by 3 hours' heating with aniline and aniline hydrobromide at 150°; treatment at 180–190° afforded an oil, b. p. 239–245°/15 mm., which gave no crystalline derivative.

Indolisation.—The ketone (II) was heated at 200° for 2.5 hours with aniline (3 mols.) and aniline hydrobromide (0.5 mol.), and the crude non-basic material distilled in a vacuum and crystallised from alcohol. 2-Phenyl-3-*p*-methoxyphenylindole (IV) formed colourless prisms, m. p. 188–190° (Found: N, 4.5. $C_{21}H_{19}ON$ requires N, 4.7%). The same product was obtained in small yield by heating (II) with pyridine hydrobromide (0.1 mol.) at 180° for 30 mins.; and was also synthesised by boiling with alcoholic hydrochloric acid phenyl *p*-methoxybenzyl ketone phenylhydrazone, prepared in alcohol-acetic acid as cream-coloured plates, m. p. 124–125° (Found: N, 8.7. $C_{21}H_{20}ON_2$ requires N, 8.8%).

The method first described was applied to the preparation of 2-phenyl-3-*p*-methoxyphenyl-5-methylindole, long prisms, m. p. 150–151° (Found: N, 4.8. $C_{22}H_{19}ON$ requires N, 4.5%), and of 2-phenyl-

3-*p*-methoxyphenyl-1-methylindole, needles, m. p. 131—133° (Found: N, 4.6%). The former was also synthesised by boiling phenyl *p*-methoxybenzyl ketone with *p*-tolylhydrazine in alcoholic hydrochloric acid for 3 hours; and for comparison 3-phenyl-2-*p*-methoxyphenylindole was prepared in like manner from *p*-methoxyphenyl benzyl ketone: needles, m. p. 140—142°, depressed by admixture with its isomeride (Found: N, 4.3%). The latter was synthesised by methylating (IV) as follows: To the indole (0.4 g.) in lukewarm acetone (6 c.c.) were added excess of powdered potassium hydroxide and, portion-wise, methyl sulphate (1 c.c.). After 45 mins., the mixture was treated with water, and the product extracted with benzene and crystallised from alcohol.

When (II) was heated with pyridine hydrobromide in pyridine in a sealed tube at 200°, the only isolable product crystallised from alcohol in nitrogen-free plates, m. p. 94—96°; the related *p*-toluidinoketone similarly gave a nitrogen-free substance, m. p. 92—94°, mixed m. p. with its analogue, 79—85°.

The authors are indebted to the Carnegie Trust for the Universities of Scotland for a Scholarship (to R. M. C.), and to Mr. J. M. L. Cameron for micro-analyses.

195. *Experiments with Diazomethane and its Derivatives. Part XIII.** *Action of Diazomethane on Hydroxyanils.*

By ALEXANDER SCHÖNBERG, AHMED MUSTAFA, and (in part) MUSTAFA KAMAL HILMY.

The *o*-hydroxyanils listed in Table I are *stable* or very resistant towards *ethereal* diazomethane solution, but, reacting in the ketonic form, they yield coumaran derivatives (listed in Table II) when treated with diazomethane *in the presence of methyl alcohol*; scheme (C) illustrates the proposed reaction mechanism. The stability towards *ethereal* diazomethane is believed to be due to the fact that in *ethereal* solution the anils do not contain a free hydroxyl group, but a chelate ring system (I or II), and that they react with methyl alcohol with formation of an intermolecular hydrogen bridge and the opening of the chelate ring system (III).

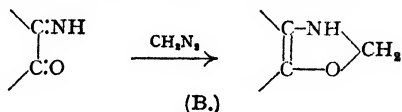

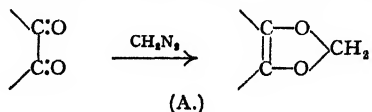

The importance of the above findings for the theory of chelation is stressed.

THIS paper deals with the remarkable behaviour of a number of anils (see Table I) derived from *o*-hydroxyaldehydes which were found to be stable towards diazomethane in *ethereal* solution, but reacted with it in the presence of methyl alcohol. By analogy with our previous findings (Schönberg and Mustafa, *J.*, 1946, 746), this is ascribed to the fact that these *o*-hydroxyanils are not true *o*-hydroxy-compounds but resonance hybrids having the hydrogen bridge (see I and II); when, however, methyl alcohol is present, the six-membered ring is opened and the ketonic

form (III) is established. The differential behaviour of substances listed in Table I towards diazomethane in *ethereal* and in *methyl-alcoholic* solution thus constitutes an additional criterion for the existence of chelation.

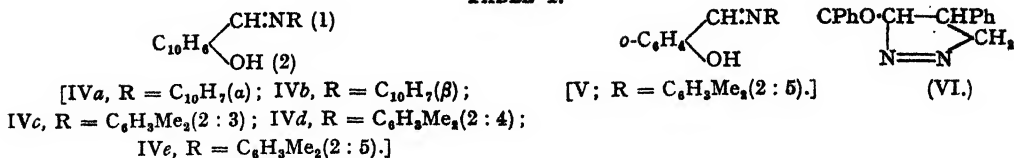

The anils mentioned above, in the presence of methyl alcohol, have the nature of compounds related to *o*-quinones and *o*-quinoneimines, which react with diazomethane to form five-membered heterocyclic compounds [see Arndt, Amende, and Ender, *Monatsh.*, 1932, 59, 202; Fieser and Hartwell, *J. Amer. Chem. Soc.*, 1935, 57, 1479; Schönberg and Mustafa, *loc. cit.*, in the case of (A), and Schönberg and Awad, *loc. cit.*, in the case of (B)]. By analogy, it would

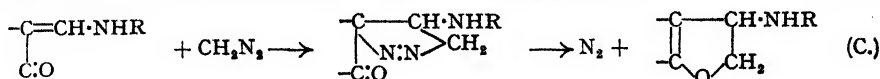

be expected that benzocoumaran derivatives should be obtained when (III) and its analogues are treated with diazomethane in the presence of methyl alcohol, and this is indeed the case (*e.g.*, formation of VIIa).

* For earlier papers (not numbered) by Schönberg and his co-workers on the action of diazomethane and its derivatives on organic substances, see *Ber.*, 1929, 62, 440, 1663; 1930, 63, 3102; 1931, 64, 1390, 2324, 2577; 1932, 65, 289; 1933, 66, 246; *Annalen*, 1930, 483, 176; *J.*, 1941, 348; *J.*, 1946, 746; this vol., in the press.

TABLE I.

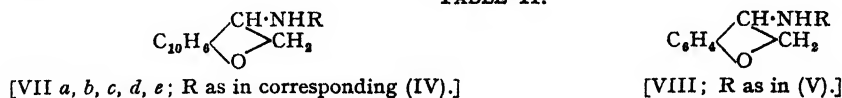

Mechanism of the Formation of the Coumaran Derivatives.—We believe that reaction occurs according to (C): similar schemes are proposed for the above-mentioned actions of diazomethane

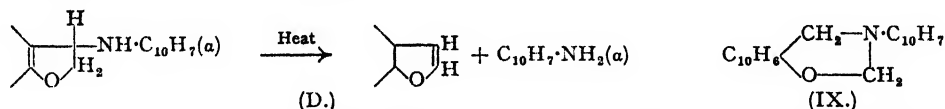

on *o*-quinones (1:2-diketones; *e.g.*, benzil) or *o*-quinoneimines; compare also the formation of (VI) from benzylideneacetophenone and diazomethane (Smith and Prings, *J. Org. Chem.*, 1937, 2, 23).

TABLE II.

Constitution of the Products listed in Table II.—These products are of an analogous structure; 3-(α -naphthylamino)-4:5-benzocoumaran (VIIa) is taken as an example. Its constitution is based on three facts: (a) the analogy of its formation (see A and B); (b) its properties; (c) the fact that no other formula can be proposed which fits the physical and chemical properties of the substance.

In contrast to (IVa), (VIIa) is colourless, in agreement with the proposed formula [reaction has taken place involving the chromophoric system in (III)]; (VIIa) has no methoxyl group and has one active hydrogen atom (the same holds true for all substances listed in Table II). When it is heated at 250°, it affords α -naphthylamine in addition to a resin, believed to be the polymerisation product of benzocoumarone (see D); the reaction product from (IVa) and diazomethane cannot therefore contain a tertiary nitrogen atom, for such a compound (*e.g.*, IX) cannot give α -naphthylamine on pyrolysis.

The compound (VIIa) was recovered unchanged when treated with phenylmagnesium bromide followed by hydrolysis; it does not react with diazomethane. The substances listed in Table II have basic properties; *e.g.*, 3-(*p*-2-xylyldino)coumaran (VIII) reacts with gaseous hydrogen chloride to form the corresponding hydrochloride. (VIIa) is completely different from the yellow 2-methoxynaphthylmethylene- α -naphthylamine (*O*-methyl ether of IVa); the nature of the latter is established by the fact that it is obtained by the action of methyl sulphate on the sodium salt of 2-hydroxynaphthylmethylene- α -naphthylamine (IVa) and by condensation of 2-methoxy-1-naphthaldehyde with α -naphthylamine. The same is true in the case of the β -naphthyl derivative (IVb). The substances listed in Table II are all solids, except (VIII), which was analysed as its hydrochloride.

Action of Diazomethane on the Anils of p-Hydroxyaldehydes.—It was found that 4-hydroxy-naphthylmethylene- α -naphthylamine and the corresponding β -naphthyl derivative react with diazomethane to form the known 4-methoxyl derivatives. This action took place even in ethereal diazomethane solution, which was to be expected since in these *p*-hydroxy-compounds the hydroxyl groups are free, no chelation being possible.

EXPERIMENTAL.

The ethereal diazomethane solution was prepared by the action of aqueous potassium hydroxide on nitrosomethylurethane followed by distillation (*Org. Synth.*, Vol. 15, p. 3).

Action of Ethereal Diazomethane Solution on p-Hydroxybenzylidene- α - and - β -naphthylamine.—These compounds (Senier and Forster, *J.*, 1914, 105, 2470) were converted into the corresponding *O*-methyl ethers by the action of an ethereal diazomethane solution in the cold (Found, respectively: C, 82.3;

H, 5.9; N, 5.7; and C, 82.5; H, 5.8; N, 5.8. Calc. for $C_{18}H_{18}ON$: C, 82.8; H, 5.7; N, 5.4%. Further identification was carried out by mixed m. p. determination with authentic specimens of *p*-methoxybenzylidene- α - (Pope and Fleming, *J.*, 1908, **93**, 1916) and β -naphthylamine (Steinhart, *Annalen*, 1887, 241, 341), respectively.

2-Hydroxy-1-naphthylmethylene-*o*-3-xylydine (IVc) was obtained by the condensation of equimolecular amounts of 2-hydroxy-1-naphthaldehyde and *o*-3-xylydine in yellow needles; m. p. 153° (Found: C, 83.1; H, 6.2; N, 5.3. $C_{18}H_{17}ON$ requires C, 82.9; H, 6.2; N, 5.1%). The condensation was carried out as described by Senier and Clarke (*J.*, 1911, **99**, 2084) for the synthesis of (IVd).

o-Hydroxyanils which resist the Action of an Ethereal Solution of Diazomethane.—Ethereal solutions of 1 g. each of (IVa) (Bartsch, *Ber.*, 1903, **36**, 1975), (IVb) (*idem*, *ibid.*), (IVc), (IVd) (Senier and Clarke, *loc. cit.*), (IVe) (*idem*, *loc. cit.*), and (V) were treated with excess of cold diazomethane (prepared from nitrosomethylurethane, 8 g.), and the mixture left for 48 hours at 0°. The ether was then evaporated off, and in every case the crude products showed the properties of the starting materials and after recrystallisation showed the same m. p. and mixed m. p.

Action of Diazomethane on *o*-Hydroxyanils in the Presence of Methyl Alcohol.—(a) 2-Hydroxy-1-naphthylmethylene- α -naphthylamine (IVa) (Bartsch, *loc. cit.*) (1 g.) in cold methyl alcohol (10 c.c.) was treated as in the preceding paragraph, fresh amounts of ethereal diazomethane being added during the 48 hours. The methyl alcohol and ether were evaporated off, and the solid residue was crystallised from benzene-light petroleum (b. p. 30–50°), forming colourless crystals, m. p. 169°. 3-(α -Naphthylamino)-4-5-benzocoumaran (VIIa) is insoluble in hot water, soluble in hot benzene, hot ethyl alcohol, and cold ether, and gives a yellow colour with concentrated sulphuric acid (Found: C, 85.4; H, 5.5; N, 4.2; active hydrogen, 0.34. $C_{22}H_{17}ON$ requires C, 84.9; H, 5.5; N, 4.5; active hydrogen, 0.32%). When crystallised from hot glacial acetic acid, it gave colourless crystals of the acetyl derivative, m. p. 225° (Found: C, 77.4; H, 5.9. $C_{24}H_{19}O_2N$ requires C, 77.6; H, 5.6%); when the solution of this derivative in hot water was treated with aqueous ammonia, (VIIa) was recovered (m. p. and mixed m. p.).

(b) Similarly, 3-(β -naphthylamino)-4-5-benzocoumaran (VIIb) was obtained from 2-hydroxy-1-naphthylmethylene- β -naphthylamine (IVb) in almost colourless crystals, m. p. 190°. It is soluble in hot benzene and ethyl alcohol and gives a yellowish-green colour when treated with concentrated sulphuric acid (Found: C, 84.8; H, 5.7; N, 4.5%). It was crystallised from benzene-light petroleum (b. p. 30–50°).

(c) The action of ethereal diazomethane in the presence of methyl alcohol on 2-hydroxy-1-naphthylmethylene-*o*-3-xylydine (IVc) gave colourless crystals of 3-(*o*-3-xylydino)-4-5-benzocoumaran (VIIc), readily crystallised from benzene, m. p. 173°; soluble in ether and hot ethyl alcohol, difficultly soluble in light petroleum (b. p. 50–60°) (Found: C, 83.1; H, 6.6; active hydrogen, 0.36. $C_{20}H_{15}ON$ requires C, 83.0; H, 6.6; active hydrogen, 0.35%).

(d) Similarly, 2-hydroxy-1-naphthylmethylene-*m*-4-xylydine (IVd) was treated with ethereal diazomethane in the presence of methyl alcohol, and 3-(*m*-4-xylydino)-4-5-benzocoumaran (VIId) obtained in colourless crystals; it is readily crystallised from benzene or methyl alcohol, m. p. 200°, difficultly soluble in ether, soluble in hot benzene (Found: C, 82.7; H, 6.2; N, 4.9. $C_{20}H_{15}ON$ requires C, 83.0; H, 6.6; N, 4.8%).

(e) In the usual manner (IVe) was converted into 3-(*p*-xylydino)-4-5-benzocoumaran (VIIe), which formed colourless crystals from benzene-light petroleum (b. p. 50–70°), m. p. 162–163° (yellow-brown melt), readily soluble in ether and benzene and difficultly soluble in light petroleum (b. p. 50–70°) (Found: C, 82.8; H, 6.1; N, 5.3; active hydrogen, 0.36%).

(f) Salicylidene-*p*-xylydine (V) (Senier and Shephard, *J.*, 1909, **95**, 443) was treated similarly; evaporation of the ether and methyl alcohol gave an oily product. Its ethereal solution on treatment with a stream of dry hydrogen chloride gave the hydrochloride of 3-(*p*-xylydino)-4-5-coumaran (VIII) in colourless crystals, m. p. 183° (not sharp); difficultly soluble in benzene and cold ethyl alcohol, soluble in hot water (Found: C, 69.9; H, 6.7; N, 5.1; Cl, 12.8. $C_{18}H_{15}ONCl$ requires C, 69.8; H, 6.5; N, 5.1; Cl, 12.8%).

Preparation of *o*-Methoxyanils.—The following *O*-methyl ethers of *o*-hydroxyanils were prepared by condensation of equimolecular amounts of 2-methoxy-1-naphthaldehyde (Barger and Stirling, *J.*, 1911, **99**, 2032) and the corresponding aromatic amine (cf. Steinhart, *loc. cit.*). The reaction mixture in alcohol was heated under reflux for 2 hours; on cooling, and if necessary on concentration, the methyl ethers of the hydroxyanils separated out. Colours obtained with concentrated sulphuric acid are given in parenthesis after the m. p.

2-Methoxy-1-naphthylmethylene- α -naphthylamine was obtained in brownish-yellow crystals from ethyl alcohol, m. p. 143–144° (red); it is readily crystallised from hot benzene (Found: C, 84.3; H, 5.6; N, 4.9; OMe, 9.4. $C_{22}H_{17}ON$ requires C, 84.9; H, 5.5; N, 4.5; OMe, 9.9%). The β -naphthyl analogue formed yellow crystals, readily crystallised from ethyl alcohol, m. p. 123° (reddish-orange) (Found: C, 84.3; H, 5.0; N, 4.8%). The *o*-3-xylydine compound formed yellow crystals from ethyl alcohol, m. p. 120° (orange-yellow), soluble in hot ethyl alcohol and benzene (Found: C, 83.2; H, 6.8; N, 4.7. $C_{20}H_{15}ON$ requires C, 83.0; H, 6.6; N, 4.8%). The *m*-4-xylydine analogue crystallised from methyl alcohol in yellow crystals, m. p. 71° (orange), easily soluble in benzene (Found: C, 83.1; H, 6.4; N, 4.8%). The *p*-xylydine compound formed yellow crystals from methyl alcohol, m. p. 117° (orange) (Found: C, 82.4; H, 6.8; N, 4.9%).

Action of Methyl Sulphate on 2-Hydroxy-1-naphthylmethylene- β -naphthylamine (IVb).—A suspension of (IVb) (1 g.) in hot methyl alcohol (15 c.c.) was treated gradually with methyl sulphate (about 2 c.c.), followed by addition of a methyl-alcoholic solution of potassium hydroxide till alkaline. The mixture was set aside at room temperature for 2 hours, poured into water, extracted with ether, and crystallised from ethyl alcohol; it formed yellow crystals, m. p. 123° (red-brown melt), not depressed when admixed with a specimen of 2-methoxy-1-naphthylmethylene- β -naphthylamine prepared as above. The α -analogue was similarly obtained in yellow crystals, m. p. 143°, not depressed when admixed with a specimen of 2-methoxy-1-naphthylmethylene- α -naphthylamine prepared as above.

Phenylmagnesium Bromide and 3-(α -Naphthylamino)-4-5-benzocoumaran.—The benzocoumaran

(VIIa) was treated with excess of phenylmagnesium bromide in ether-benzene, heated under reflux for 2 hours, and left overnight at room temperature. On hydrolysis, the starting substance was obtained unchanged or almost unchanged.

Action of Heat on 3-(α -Naphthylamino)-4:5-benzocoumaran.—The coumaran (VIIa) (1 g.) was heated in a stream of dry carbon dioxide for $\frac{1}{2}$ hour (bath temp., 250°). An almost colourless oil distilled over, which, on cooling, followed by extraction with hot light petroleum (b. p. 30–50°) and evaporation of the latter, gave colourless crystals of α -naphthylamine (m. p. and mixed m. p.). The part insoluble in the light petroleum was a resin which could not be identified.

196. *The Quantitative Determination of Galactose, Mannose, Arabinose, and Rhamnose.*

By E. L. HIRST, J. K. N. JONES, and E. A. WOODS.

Methods are described for the quantitative analysis of mixtures of galactose, mannose, arabinose, and rhamnose, which may occur amongst the hydrolysis products of plant gums. Galactose is estimated as its phenylmethylhydrazone, mannose as its phenylhydrazone, and arabinose as its benzoylhydrazone. The methods are accurate to within 9 mg. on weights above 0.1 g. Rhamnose can be determined as the benzoylhydrazone with an accuracy of ± 30 mg. on weights above 0.25 g.

THE plant gums are complex polysaccharides which contain a variety of sugar residues and amongst the products of hydrolysis galactose, mannose, arabinose, and rhamnose frequently occur. The quantitative determination of these sugars is a matter of some difficulty, the more so when they are admixed with other sugars and acids formed during the hydrolysis of the gums. We have carried out by the standard mucic acid method a large number of determinations of galactose in mixtures of sugars obtained from the hydrolysis of plant products, and have found the method inadequate, especially when only small quantities of material are available and when *d*-galacturonic acid and *l*-galactose are present. Other methods which have been described are (1) the fermentation method using special strains of yeast (Wise and Appling, *Ind. Eng. Chem. Anal.*, 1944, 16, 28), and (2) a method in which the insoluble phenylmethylhydrazone of galactose is weighed. This latter method has been used by Neuberg (*Biochem. Z.*, 1907, 3, 519), Lüdtké (*Biochem. Z.*, 1919, 212, 419), Neuberg and Schweitzer (*Monatsh.*, 1937, 71, 46), and Freeman, Challinor, and Willis (*Biochem. J.*, 1940, 34, 316). These authors converted pure galactose into its phenylmethylhydrazone under standard conditions and used a factor for the conversion of the weight of derivative isolated into the weight of galactose in solution. This method, however, gives accurate results only if the amounts of galactose in the control and in the unknown solution are identical. To avoid the necessity of carrying out a control estimation on each occasion we have determined the yields, under standard conditions, of the phenylmethylhydrazone of galactose obtained from various amounts of galactose (Table I). From the results a graph was constructed which showed that the relationship between galactose and the yields of galactose phenylmethylhydrazone was linear even when glucose, xylose, rhamnose, and glucuronic acid were present. Mannose and arabinose interfere with the estimation, but the difficulties thus arising can be readily circumvented. Mannose can be estimated by the phenylhydrazine method (Bourquelot and Herissey, *Compt. rend.*, 1899, 129, 339; see below) and can be removed by fermentation. Arabinose cannot be removed by fermentation but can be estimated by means of diphenylhydrazine (Neuberg, *Ber.*, 1900, 33, 2243; Wise and Paterson, *Ind. Eng. Chem.*, 1930, 22, 365) or by boiling with 12% hydrochloric acid and estimation of the furfural evolved. Since the precipitation of arabinose with phenylmethylhydrazine appears to be nearly quantitative in the presence of galactose, an estimate of the galactose present can be made after deducting the weight of phenylmethylhydrazone formed from the arabinose, the amount of which has been estimated by another method.

The quantitative estimation of arabinose in the presence of galactose is a matter of some difficulty since most reagents which give insoluble derivatives with arabinose also give insoluble derivatives with galactose, e.g., phenylmethylhydrazine and phenylbenzylhydrazine. A reagent which does not possess this disadvantage is benzoylhydrazone. This reagent also has the advantage of ease of preparation and of stability (Fischer and Paulus, *Arch. Pharm.*, 1935, 83; Militzer, *J. Chem. Educ.*, 1941, 25). In this estimation the mixture of sugars containing

arabinose (50 mg. in 500 mg.) is dissolved in water (2 c.c.) and a solution of benzoylhydrazine in alcohol (10 c.c.) is added; after two days the insoluble derivative is filtered off, dried, and weighed. Of many sugars examined the only one which interfered with this estimation was rhamnose, when present in quantities of over 300 mg. The standardisation was carried out as described above (see Table II *a* and *b*), and gave a method of estimating arabinose accurate to within 9 mg. on 100 mg. when using weights of arabinose above 0.1 g. In the absence of arabinose this reagent can be used for the characterisation and quantitative estimation of rhamnose (see Table III).

The estimation of mannose with phenylhydrazine has already been described (Bourquelot and Herissey, *Compt. rend.*, 1899, 129, 339). By adoption of the modified procedure described in the experimental section this method can be used for the estimation of mannose with an accuracy of approximately ± 3 mg. on quantities of 100 mg. and over of mannose. The method was standardised in a manner similar to that described for galactose and arabinose (Table IV), and it was found that no interference was caused by glucose, galactose, rhamnose, or arabinose.

EXPERIMENTAL.

Galactose. Reagent and Method of Analysis.—1-Phenyl-1-methylhydrazine (25 g.) was mixed with absolute alcohol (100 c.c.) containing glacial acetic acid (3 c.c.). The reagent was kept in a tightly stoppered brown glass bottle at 0°.

To the sugar sample (containing not more than 1.4 g. of sugars) dissolved in water (10 c.c.) the above reagent (10 c.c.) was added and the mixture was kept in a tightly stoppered flask at 33° for 12 hours with occasional shaking. It was then cooled to 0° for 9 hours and the crystals (m. p. 186°) were collected in a tared Gooch crucible, washed with ice-cold ethyl alcohol (10 c.c.), dried at 100° for 30 minutes, and weighed. The yields of phenylmethylhydrazone obtained from various weights of galactose with and without the presence of other sugars are given in Table I. From these results it can be seen that the method is accurate to within ± 3 mg. on amounts above 0.1 g.

TABLE I.

¹ 0.245 G. of mannose phenylmethylhydrazone.

² 0.283 G. of *l*-arabinose phenylmethylhydrazone.

From these figures the equation $y = 0.673x + 0.013$ can be deduced where y corresponds to the weight of galactose giving a weight x of phenylmethylhydrazone.

Arabinose. Reagent and Method of Analysis.—Benzoylhydrazine, recrystallised from water and having m. p. 112–113° (25 g.), was dissolved in 95% alcohol (500 c.c.) and the solution was kept in a stoppered bottle until required. The sugar sample containing between 50 and 500 mg. of arabinose was dissolved in water (2 c.c.) in a 50 c.c. stoppered flask, and the reagent (10 c.c.) then added. The mixture was kept with occasional shaking at 20° for 24 hours and then at -3° for 22 hours. The crystalline residue, m. p. 186–190° (decomp.), was collected in a tared Gooch crucible, washed with ice-cold alcohol (10 c.c.), dried at 100° for $\frac{1}{2}$ hour and weighed. It will be seen (Table IIa) that of the sugars glucose, mannose, xylose, galactose, glucurone, and rhamnose, only the last named interfered with the estimation and then only when present in amounts above 300 mg. The relationship between the weight of arabinose and the yield of derivative was linear and fitted the equation $y = 0.555x + 0.022$ where y is the weight of arabinose corresponding to a weight x of derivative isolated.

d-Arabinose benzoylhydrazone was prepared, as described above, from *d*-arabinose and benzoylhydrazine, m. p. 186° (decomp.). *d*-Glucose gave with benzoylhydrazine a derivative {m. p. 176–179° (decomp.), $[\alpha]_D^{20} + 15^\circ \xrightarrow{17 \text{ hrs.}} -23^\circ$ in water} which was much more soluble than the derivative of

arabinose and rhamnose; it did not interfere with the estimation of these two sugars (Found: C, 52.4; H, 6.0; N, 9.6. $C_{15}H_{18}O_6N_2$ requires C, 52.4; H, 6.0; N, 9.4%).

In the second method of estimation of arabinose, an aqueous solution of benzoylhydrazine saturated at 20° (ca. 4.3 g./100 c.c. of water) was used as a reagent. The derivative is more soluble in this reagent

but separates in a more easily filtered form. Since the reagent contains no alcohol, alcohol-insoluble materials such as oligosaccharides and the barium salts of uronic acids remain in solution during the reaction and do not contaminate the precipitate of arabinose benzoylhydrazone. The dry, water-soluble product to be analysed, containing between 50 and 150 mg. of arabinose, is dissolved in the reagent (5 c.c.) and kept at 30° for 48 hours and then cooled to 0° for 2 hours. The crystalline precipitate is filtered off, washed with 10 c.c. of 95% alcohol, and dried at 100° to constant weight. If the residue contains between 150 and 400 mg. of arabinose, more of the reagent (10 c.c.) is used. The derivative is isolated and weighed as above. From the results obtained the equation $y = 0.67x + 0.010$ can be deduced where y is the weight of arabinose required to give a weight x of derivative (see Table IIb).

Rhamnose.—Rhamnose cannot be so successfully estimated as arabinose by the use of benzoylhydrazine, owing to the greater solubility of the rhamnose derivative and the interfering effect of small

quantities of arabinose. The sugar sample (250 to 600 mg. in 2 c.c. water) was mixed with saturated alcoholic benzoylhydrazone solution (10 c.c.) and the solution kept at 30° for 41 hours. After 17 hours the solution was seeded with a trace of the rhamnose derivative. After 41 hours the solution was cooled to -3° and the product filtered off and washed with 95% alcohol (30 c.c. in all). To avoid charring it was necessary to dry the product first in a desiccator and then at 90° for 1 hour. From the yields of derivative (see Table III) the equation $y = 0.482x + 0.217$ was deduced, where y is the weight of rhamnose hydrate which will give a yield, x , of rhamnose benzoylhydrazone. The rhamnose benzoylhydrazone separated as very fine white crystals which could be recrystallised from methyl alcohol. The derivative separated from methyl alcohol as long white needles, m. p. 180° (decomp.) (Found: C, 55.5; H, 6.4; N, 10.0. $C_{13}H_{18}O_5N_2$ requires C, 55.3; H, 6.4; N, 9.9%).

Mannose. Reagent and Method of Analysis.—Phenylhydrazine (redistilled) (25 c.c.) was mixed with absolute alcohol (100 c.c.) containing glacial acetic acid (3 c.c.). The mixture was kept at 0° in a well-stoppered, dark bottle.

The sugar sample was dissolved in water (10 c.c.), the above reagent (10 c.c.) added, and the mixture kept in a well-stoppered flask at 32° for 15 hours, with occasional shaking. It was then cooled to 0° for 12 hours, and the phenylhydrazone was filtered off, washed with ice-cold alcohol (10 c.c.), dried at 100° for 30 minutes, and weighed. The yields of phenylhydrazone from various weights of mannose, together with the effect of various other sugars on the estimation, are given in Table IV.

TABLE IV.

Mannose (g.).	Sugar impurity (g.).	Yield of hydrazone (g.).	Mannose (from graph) (g.).	Error (g.).
0.026	—	nil	nil	-0.026
0.051	—	0.011	0.033	-0.018
0.100	—	0.114	0.100	nil
0.203	—	0.277	0.205	+0.002
0.401	—	0.573	0.400	-0.001
0.601	—	0.890	0.610	+0.009
1.001	—	1.488	1.003	+0.002
0.221	Glucose, 0.500	0.310	0.228	+0.007
0.260	Arabinose, 0.500	0.355	0.258	-0.002
0.214	Galactose, 0.500	0.300	0.220	+0.006
0.225	Rhamnose, 0.500	0.298	0.219	-0.006
0.205	Glucuronic acid, 0.500	0.280	0.207	+0.002

These figures fit the equation $y = 0.652x + 0.031$ where y is the weight of mannose giving a weight x of mannose phenylhydrazone.

From these results it can be seen that glucose, arabinose, galactose, rhamnose, and glucuronic acid do not interfere with the estimation of mannose, and that it is possible to carry out the estimation to within ± 3 mg. on amounts above 100 mg.

One of us (E. A. W.) wishes to thank The Khaki University of Canada for making arrangements which made it possible for him to take part in the work. We wish also to thank Imperial Chemical Industries Ltd. and Simon-Carves Ltd. for grants.

197. A Synthesis of Cytidine.

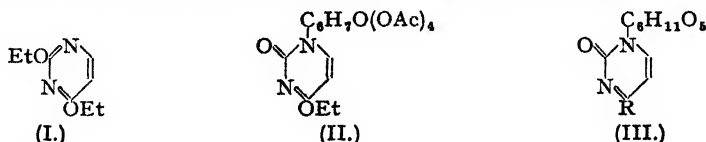

By G. A. HOWARD, B. LYTGOE, and A. R. TODD.

Hydrogenolysis of 1:2:3-triacetyl 5-trityl *d*-ribofuranose gives a syrupy 1:2:3-triacetyl *d*-ribofuranose converted on acetylation into the crystalline 1:2:3:5-tetra-acetyl *d*-ribofuranose. Treatment of the latter with liquid hydrogen bromide gave crude acetobromoribofuranose which was used directly to prepare *theophylline-7-β-d-ribofuranoside*. By reaction of the acetobromoribofuranose with 2:6-diethoxypyrimidine, followed by treatment of the product with methanolic ammonia, 3-β-*d*-ribofuranosidocytosine has been synthesised identical with the natural nucleoside, cytidine.

METHODS for the synthesis of nucleosides have been under investigation in this laboratory for some time with a variety of objects in view. On the one hand it was hoped that a successful outcome of the work would render available for biological examination a range of structural analogues of the natural nucleosides as a possible means of elucidating the mode of action of the latter in organised systems; on the other, study of the simpler compounds seemed a necessary preliminary to broader synthetic investigations relating to the co-enzymes and polynucleotides in the molecules of which nucleoside structures are preformed.

In a series of papers in this *Journal* ("Experiments on the Synthesis of Purine Nucleosides," Parts I—XVI, reviewed in *J.*, 1946, 647) we have reported progress made in the development of methods for the synthesis of analogues of adenosine, perhaps the most important of the natural nucleosides. General methods have been made available for the synthesis of 9-glycopyranosido- and 9-glycofuranosido-adenine derivatives, and answers have been provided to certain structural questions on which at the outset there was either no evidence or on which available evidence was not completely rigid. With the major problems of this part of the field approaching, as we hope, a satisfactory solution, it seemed desirable to broaden the scope of the investigations to include compounds of the type of guanosine, the pyrimidine ribosides, and the pyrimidine and purine deoxyribosides. The present communication records experiments which have led to the synthesis of the natural pyrimidine riboside, cytidine.

The problems of synthesis of pyrimidine glycosides have been examined by a number of previous workers. The route which has received most attention depends on the direct introduction of an acetylated glycosyl residue into the nucleus of an appropriate pyrimidine derivative by use of an acetohalogeno-sugar, a method essentially similar to Fischer and Helferich's synthesis of purine glycosides (*Ber.*, 1914, 47, 210). The early investigators (Fischer and Helferich, *loc. cit.*; Fischer, *Ber.*, 1914, 47, 1377; Levene and Sobotka, *J. Biol. Chem.*, 1925, 65, 469) employed, for glycosidisation, pyrimidine derivatives containing substituents such as hydroxyl, to which, as a result of their capacity for prototropic change, the glycosyl residue became attached, so that they were not successful in obtaining heterocyclic *N*-glycosides. This difficulty was overcome by Hilbert and his collaborators, employing 2:6-dialkoxy-pyrimidines, in which tautomerisation possibilities are excluded. Thus interaction of 2:6-diethoxypyrimidine (I) and acetobromoglucose gave the tetra-acetyl glucoside (II) which could be converted by methanolic hydrogen chloride into a 3-*d*-glucosidouracil (III; R = OH), or by methanolic ammonia into a 3-*d*-glucosidocytosine (III; R = NH₂) (Hilbert and Johnson, *J. Amer. Chem. Soc.*, 1930, 52, 4489; Hilbert and Jansen, *ibid.*, 1936, 58, 60).

Structural analogues of (III) carrying various glycosyl residues have been obtained by this method (Hilbert, *ibid.*, 1937, 117, 331) including a 3-*d*-ribosidouracil (Hilbert and Rist, *J. Biol. Chem.*, 1937, 117, 331); all these compounds must, from their mode of preparation, be pyranosides.

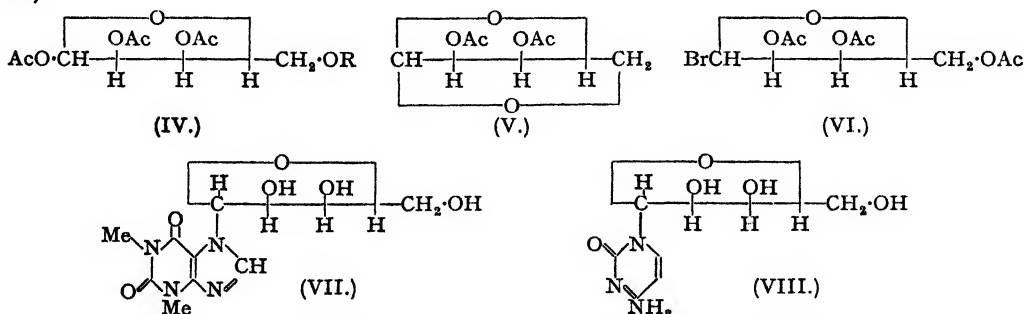

An alternative synthesis of pyrimidine nucleosides may be envisaged involving cyclisation of an appropriate glycosidamino-compound; such a method would be analogous in principle to our method for synthesis of purine-9-glycosides from 5-amino-4-glycosidaminopyrimidine derivatives. If developed, such a method might offer, in comparison with the synthesis from acetohalogeno-sugars, advantages such as the demonstration of the position of the sugar residue in the final product. It was in part this consideration that influenced us in our choice of a route for the synthesis of purine-9-glycosides, but it seemed of less importance in the case of the

pyrimidine nucleosides, since the N₃ location of the sugar residue in uridine has been fully established by Levene and Tipson (*J. Biol. Chem.*, 1934, **104**, 385), and we have shown (Davoll, Lythgoe, and Todd, *J.*, 1946, 833) that in the uracil-*d*-glucoside obtained by Hilbert's method the glucose residue does in fact, as formerly assumed from analogy (Hilbert and Johnson, *loc. cit.*), occupy the same position. We therefore decided in the first instance to attempt the synthesis of cytidine by extending Hilbert's method.

The acetohalogeno-ribofuranose required for this purpose belongs to a class of compounds which in spite of their potential synthetic value have been little explored, mainly because of the inaccessibility of suitable furanose intermediates. In the pentose series no true representative of this class has been obtained, and amongst the hexoses only those derived from galactose (Schlubach and Wagenitz, *Z. physiol. Chem.*, 1932, **213**, 87). Aniline-*d*-ribofuranoside (Berger and Lee, *J. Org. Chem.*, 1946, **11**, 75) seemed at first sight to be a suitable starting material for the preparation of acetobromoribofuranose. It has been stated (*idem, ibid.*; Berger, Solmsen, Leonard, Wenis, and Lee, *ibid.*, p. 91) that this compound can be acetylated to a 2 : 3 : 5-triacetyl *d*-ribosidoaniline which yields on careful acidic hydrolysis 2 : 3 : 5-triacetyl *d*-ribofuranose. However, as already recorded by us (Howard, Kenner, Lythgoe, and Todd, *J.*, 1946, 855) the acetylation is accompanied by a change to the isomeric pyranoside, so that in fact the product of the above reaction series is 2 : 3 : 4-triacetyl *d*-ribopyranose.

It was therefore decided to study in more detail the method used by Bredereck, Köthnig, and Berger (*Ber.*, 1940, **73**, 956) in their attempt to obtain acetobromoribofuranose. These investigators prepared 1 : 2 : 3-triacetyl 5-trityl *d*-ribose (IV; R = CPh₃), but attempts at selective removal of the trityl group from this compound were unsuccessful, giving instead of the desired 1 : 2 : 3-triacetyl *d*-ribofuranose (V; R = H) a diacetyl anhydribose <1 : 5> <1 : 4> (V) owing to simultaneous loss of the acetyl group at C₁. In these experiments hydrogen bromide in acetic acid or aqueous acetic acid was used for fission of the trityl ether linkage, but it is known (*e.g.*, Micheel, *Ber.*, 1932, **65**, 262) that the fission may be effected by hydrogenolysis. By using the latter method we were successful in preparing from (IV; R = CPh₃) a syrupy 1 : 2 : 3-triacetyl *d*-ribofuranose (IV; R = H), in which the terminal location of the free hydroxyl group was shown by its conversion into a syrupy tosyl derivative which readily exchanged its tosyl group for iodine in the Oldham-Rutherford reaction. Further acetylation of (IV; R = H) gave in good yield a crystalline 1 : 2 : 3 : 5-tetra-acetyl *d*-ribofuranose (IV; R = Ac). In order to convert this into acetobromoribofuranose we adopted the method used by Schlubach and Wagenitz (*loc. cit.*) for the preparation of acetobromogalactofuranose. Brief treatment of (IV; R = Ac) with liquid hydrogen bromide gave a syrup consisting essentially of the desired acetobromo-compound (VI); on account of its evident lability, isolation of the pure compound was not attempted, the crude product being used directly in glycosidation experiments.

When allowed to react with a suspension of theophylline silver in dry xylene, triacetyl theophylline-*d*-ribofuranoside was obtained as a gum, which on treatment with methanolic ammonia gave in good yield a crystalline theophylline-7-β-*d*-ribofuranoside (VII). The structure of this compound follows from the fact that it reacts with sodium metaperiodate, giving a crystalline α-theophylline-7-α'-hydroxymethylidiglycollic aldehyde identical with that obtained from similar oxidation of theophylline-7-β-*d*-glucopyranoside (Lythgoe and Todd, *J.*, 1944, 592).

These reactions provided satisfactory evidence of the nature of the crude acetobromoribofuranose and we could now proceed to the synthesis of cytidine (VIII). Interaction of 2 : 6-diethoxypyrimidine with (VI) at 65° gave a gummy product which on treatment with methanolic ammonia yielded a mixture of bases, from which cytidine was isolated by recrystallisation of the

picrates and finally of the sulphate. The cytidine sulphate so obtained agreed in composition and physical constants with that isolated from yeast nucleic acid. The Molisch test was negative, but after prolonged heating with the perchloric acid-tryptophan reagent (Cohen, *J. Biol. Chem.*, 1944, **156**, 691) the green colour characteristic of pentoses was slowly developed; natural cytidine sulphate behaved in the same manner. Final confirmation of the identity of the natural and synthetic products was obtained by comparison of their X-ray crystal photographs, for which we are indebted to Dr. Clews and Mr. Nicol of the Department of Crystallography.

The work described above represents the first synthesis of a naturally occurring nucleoside. Since it is known that cytidine can be deaminated to give uridine, the work also constitutes a synthesis of uridine, and provides confirmation of the degradative evidence relating to the structures of these two nucleosides.

EXPERIMENTAL.

1 : 2 : 3 : 5-Tetra-acetyl d-Ribofuranose.—1 : 2 : 3-Triacetyl 5-trityl d-ribofuranose (21 g.; Brederick, Köthnig, and Berger, *loc. cit.*) dissolved in glacial acetic acid (250 c.c.) was hydrogenated at 35° and atmospheric pressure in presence of Adams's palladium oxide (1 g.). After 3 hours 900 c.c. of hydrogen had been absorbed and the filtered solution was evaporated to dryness under reduced pressure. Crystallisation of the residue from alcohol gave triphenylmethane (8 g.), and the mother liquors after evaporation were dissolved in a little chloroform, light petroleum (b. p. 100–120°) was added, and the chloroform was removed by evaporation. The petroleum layer was removed, and the insoluble 1 : 2 : 3-triacetyl d-ribose acetylated in the usual way by acetic anhydride in pyridine. The acetylated material, isolated in the usual way, was dissolved in chloroform, washed with aqueous sodium bicarbonate and then with water, and the chloroform was removed from the dried solution under reduced pressure. Distillation of the residue at 100–110° (bath temp.)/10⁻⁴ mm. gave 1 : 2 : 3 : 5-tetra-acetyl d-ribofuranose as a syrup which crystallised on standing; m. p. 58°, $[\alpha]_D^{25} + 20^\circ (\pm 1^\circ)$ (c. 0.645 in chloroform). Yield, 9 g. (70%) (Found: C, 49.1; H, 5.7. $C_{13}H_{18}O_8$ requires C, 49.2; H, 5.2%).

Theophylline-7-β-d-ribofuranoside.—Pure anhydrous liquid hydrogen bromide (5 c.c.) was distilled into a Carius tube containing 1 : 2 : 3 : 5-tetra-acetyl d-ribose (1.5 g.) and, after being sealed, the tube was kept at room temperature for 10 minutes; dissolution was then complete. The tube was then opened and hydrogen bromide allowed to evaporate at room temperature, and the brown residue was evaporated twice with benzene under reduced pressure at 30° and finally heated to 35° in a high vacuum to remove hydrogen bromide as completely as possible. The crude acetobromoribofuranose so obtained was dissolved in a little xylene and the solution refluxed with a suspension of dry theophylline silver (1.5 g.) in dry xylene (50 c.c.) for 1 hour with exclusion of moisture. Silver bromide was removed from the hot solution, which was allowed to cool and filtered from a little theophylline which had separated. The filtrate was evaporated to dryness under reduced pressure and set aside for 2 days at 0° with methanolic ammonia. Removal of solvents and crystallisation of the residue from water gave theophylline-7-β-d-ribofuranoside as colourless needles, m. p. 189°, $[\alpha]_D^{25} + 27^\circ (\pm 5^\circ)$ (c. 0.257 in water) (Found in material dried at 100° and 0.1 mm.: C, 45.1; H, 5.5; N, 19.7. $C_{15}H_{18}O_8N_4$ requires C, 45.0; H, 5.0; N, 20.0%). Yield, 0.88 g. (60%).

Periodate Oxidation.—The above glycoside (209.2 mg.) was treated with a solution of sodium metaperiodate (208 mg. per 6 c.c. water) and set aside for 24 hours. The crystalline deposit of α-theophylline-7-α'-hydroxymethylidiglycolic aldehyde was collected (140 mg.), and had m. p. 205–206° (decomp.), $[\alpha]_D^{25} - 38^\circ$ (c. 0.21 in water) (Found: C, 43.7; H, 4.9. Calc. for $C_{12}H_{14}O_8N_4.H_2O$: C, 43.9; H, 4.9%). Lythgoe and Todd (*loc. cit.*) record for the same compound obtained from theophylline-7-β-d-glucopyranoside, m. p. 207–208° (decomp.), $[\alpha]_D^{25} - 42^\circ$.

In one experiment on the preparation of theophylline-α-d-ribofuranoside by the method described, there was isolated as sole product a substance separating from aqueous alcohol as colourless needles, m. p. 193°, $[\alpha]_D^{25} + 110^\circ$ (c. 0.254 in water) (Found: C, 45.8; H, 5.0; N, 17.9. $C_{15}H_{18}O_8N_4$ requires C, 46.2; H, 5.1; N, 17.9%). This substance required 1.06 mols. of periodate per mol. for complete oxidation, the oxidised product having $[M]_D^{25} 1.03^\circ (\pm 0.5^\circ) \times 10^4$. It seems possible that it may be theophylline-7-α-d-ribofuranoside.

Cytidine Sulphate.—Crude syrupy acetobromoribofuranose prepared in the manner described above from 1 : 2 : 3 : 5-tetra-acetyl d-ribose (5 g.) was dissolved in 2 : 6-diethoxypyrimidine (15 g.; Hilbert and Jansen, *J. Amer. Chem. Soc.*, 1935, **57**, 553) and the solution maintained at 65° for 24 hours with exclusion of moisture. After filtration from a little resin the solution was freed from excess of diethoxypyrimidine by evaporation at 100°/10⁻² mm. The residual 9 g. were dissolved in methanolic ammonia (40 c.c., saturated at 0°) and the solution was maintained at 80° for 4 days and then evaporated under reduced pressure. To a solution of the residue in hot alcohol (10 c.c.) hot alcoholic picric acid (5 g. in 50 c.c.) was added. The picrate separating on cooling was recrystallised from water, and then had m. p. ca. 150°. It was decomposed with dilute sulphuric acid, picric and sulphuric acids were removed in the usual manner, and the solution was concentrated to 5 c.c. After addition of concentrated sulphuric acid (0.7 c.c.) and alcohol (25 c.c.), inoculation with a trace of cytidine sulphate caused crystallisation. The product after recrystallisation from alcohol containing dilute sulphuric acid had m. p. 224° (decomp.) alone and in admixture with authentic material. $[\alpha]_D^{25} + 35^\circ$ (c. 0.366 in 1% aqueous sulphuric acid). Yield, 350 mg. [Found in material dried at 140°/0.1 mm.: C, 37.2; H, 5.2; N, 14.0. Calc. for $(C_8H_{12}O_5N_3)_2.H_2SO_4$: C, 37.0; H, 4.8; N, 14.2%].

We acknowledge gratefully a Maintenance Grant made to one of us (G. A. H.) by the Department of Scientific and Industrial Research.

198. The Constitution of Cherry Gum. Part II. The Products of Hydrolysis of Methylated Cherry Gum.

By J. K. N. JONES.

Methylated cherry gum has been hydrolysed and the following products of hydrolysis have been identified: 2:3:5-trimethyl *l*-arabinose, 2:5-dimethyl *l*-arabinose, 2:4:6-trimethyl *d*-galactose, 2:4-dimethyl *d*-galactose, 2:3:4-trimethyl *d*-glucuronic acid, and 2:3-dimethyl *d*-glucuronic acid. Derivatives of *d*-mannose and of *d*-xylose are also present but remain to be identified; other methylated derivatives of *d*-galactose may also be present.

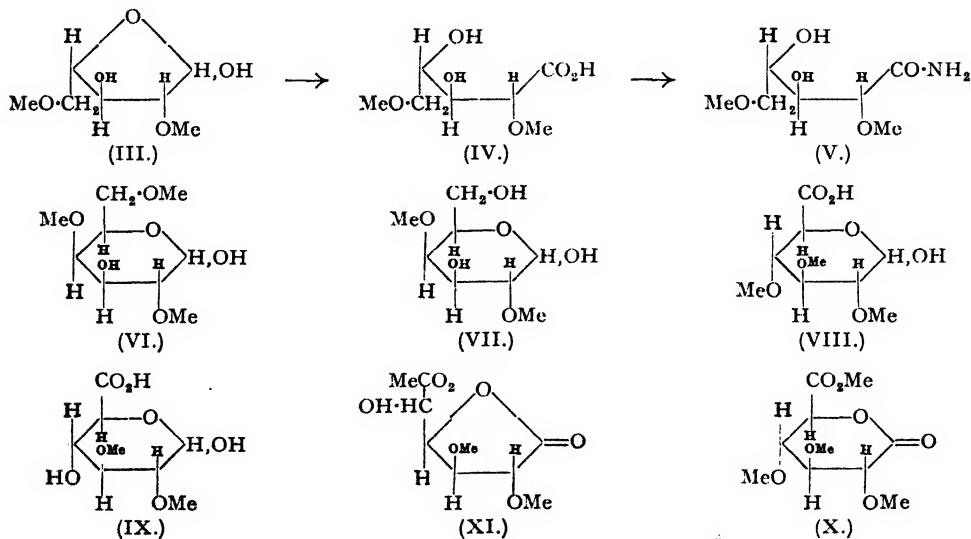

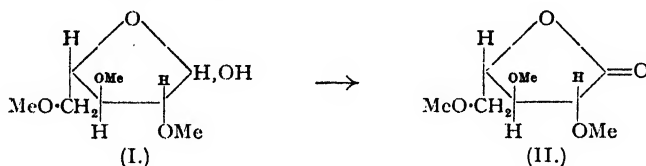

The results indicate the main structural features of the polysaccharide, but owing to the difficulty encountered in effecting the quantitative separation of these sugars it is not possible at this stage to suggest a unique structural formula.

It has been shown (Jones, *J.*, 1939, 558) that cherry gum contains the following sugars in the approximate proportions indicated: *d*-glucuronic acid (1 part), *d*-mannose (1 part), *d*-galactose (2 parts), *l*-arabinose (6 parts), and *d*-xylose (*ca.* 1.5%). The polysaccharide has now been converted into the fully methylated derivative by the thallium hydroxide method of methylation (Menzies, *J.*, 1926, 937; Hirst and Jones, *J.*, 1938, 502). This product is substantially homogeneous since no portions differing materially one from another were obtained on fractionation.

Methylated cherry gum, like methylated damson gum, readily underwent partial methanolysis with methyl alcoholic hydrogen chloride (2%) but there remained a resistant residue which required further prolonged boiling with this reagent before the reaction was complete. Six different sugars were recognised after fractional distillation of the methanolysis products, namely: 2:3:5-trimethyl *l*-arabinose, 2:5-dimethyl *l*-arabinose, 2:4:6-trimethyl *d*-galactose, 2:4-dimethyl *d*-galactose, 2:3:4-trimethyl *d*-glucuronic acid, and 2:3-dimethyl *d*-glucuronic acid. Derivatives of *d*-mannose and of *d*-xylose must be present, but their isolation has not yet been accomplished. It is possible that other methylated galactoses may also be present amongst the products of hydrolysis.

Proof of the identity of these sugar derivatives was obtained as follows:

(a) 2:3:5-Trimethyl *l*-arabinose (I) was identified after oxidation as crystalline 2:3:5-trimethyl *l*-arabonolactone (II).

(b) 2 : 5-Dimethyl *l*-arabinose (III) was recognised after oxidation as the crystalline lactone and amide (V) of 2 : 5-dimethyl *l*-arabonic acid (IV) (Smith, *J.*, 1940, 1035).

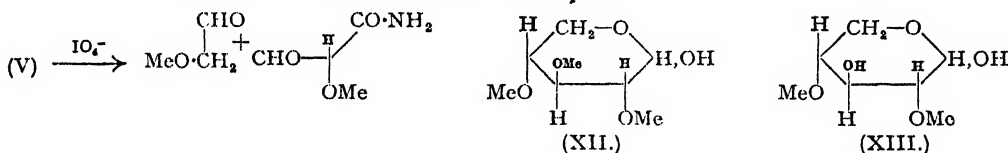

(c) 2 : 4 : 6-Trimethyl *d*-galactose (VI) was converted into its characteristic crystalline anilide (Bell and Wilson, *J.*, 1938, 1196; Percival and Somerville, *J.*, 1937, 1615).

(d) 2 : 4-Dimethyl *d*-galactose was isolated as crystalline 2 : 4-dimethyl *d*-galactose (VII) and its crystalline anilide (Smith, *J.*, 1940, 1050).

(e) 2 : 3 : 4-Trimethyl (VIII) and 2 : 3-dimethyl *d*-glucuronic (IX) acids were recognised as the corresponding crystalline derivatives of saccharic acid, *viz.* methyl 2 : 3 : 4-trimethyl *d*-saccharolactone ester (X) and methyl 2 : 3-dimethyl *d*-saccharolactone ester (XI).

Owing to the difficulty in identifying and separating quantitatively the various glycosides it is not possible to give a precise quantitative estimate of the various sugar derivatives formed on hydrolysis of the methylated polysaccharide. Hence no attempt is made to give a unique formula for cherry gum at this stage. However, a semi-quantitative examination of various sugar residues identified indicates that the ratio of trimethyl *l*-arabofuranose to 2 : 5-dimethyl *l*-arabinose is about 1 : 1 and that the ratio of 2 : 4 : 6-trimethyl *d*-galactose to 2 : 4-dimethyl *d*-galactose is also about 1 : 1.

An inspection of the constants for the pentose fractions shows that derivatives other than 2 : 3 : 5-trimethyl *l*-arabinose and 2 : 5-dimethyl *l*-arabinose must be present in them since both the free sugars and the lactones derived from the pentose fractions had optical rotations too high in the positive sense. 2 : 5-Dimethyl *l*-arabonic acid (IV) and its amide (V) possess hydroxyl groups on adjacent carbon atoms (C_3 and C_4) and should be oxidised by salts of periodic acid. Accordingly, fractions 23, 24, and 25 (see experimental section) were oxidised with periodic acid. From the product a lactone was obtained which must have possessed no α -glycol grouping, and since this lactone behaved as a pyranolactone it must be a derivative of 2 : 4-dimethyl (XIII) or 2 : 3 : 4-trimethyl *d*-xylose (XII) or 2 : 4 : 6-trimethyl *d*-galactose (VI). A pyranose derivative of *l*-arabinose is ruled out as it is known that all the arabinose units are in the furanose form (Jones, *loc. cit.*).

It has already been shown that 2-(*d*-glucuronosido)-*d*-mannose is part of both the damson gum and cherry gum molecules (Hirst and Jones, *J.*, 1938, 1174), and it is now obvious that both polysaccharides possess other points of similarity. For example, *d*-galactose units which are linked through positions C_3 and C_1 and C_6 , C_3 , and C_1 occur in both; in addition both molecules contain terminal *l*-arabinose and *d*-glucuronic acid units, and a *d*-glucuronic acid residue linked through C_1 and C_4 is common to both gums. A point of difference, however, is that in cherry gum *l*-arabinose residues occur which are linked through C_1 and C_3 (cf. gum arabic, Smith, *J.*, 1940, 1035) whilst in damson gum the linkage is through C_1 and C_5 .

It seems that cherry gum is built up on the same lines as damson gum (Hirst and Jones, *loc. cit.*) and gum arabic (Smith, *loc. cit.*) with probably a main chain of *d*-galactose units to which are attached side chains of aldobionic acids and pentose residues.

A complication arises from the fact that cherry trees may be grown as grafts on different stocks and it remains to be decided whether or not the chemical nature of the exuded gum is dependent upon the type of stock (private communication from F. W. Sansome). Although all the samples of cherry gum which have been examined possess very similar properties, until these points are investigated it cannot be claimed that the results now brought forward necessarily apply to all varieties of cherry gum.

EXPERIMENTAL.

Methylation.—The cherry gum (of English origin) had equiv. 1503, furfuraldehyde 31.8%, and $[\alpha]_D - 28^\circ$. It appeared to be identical with cherry gum obtained from the South of France which had equiv. 1487, furfuraldehyde 31.9%, and $[\alpha]_D - 28^\circ$ (mean values of determinations on seven separate nodules of gum). These figures are closely similar to those given in the literature for other samples of cherry gum isolated from widely different sources. Purified cherry gum (50 g.) (Jones, *J.*, 1939, 558) was dissolved in water (300 c.c.) containing a little *n*-thallous hydroxide, and a hot concentrated solution of thallous hydroxide (300 c.c. of 4*N*) was added with stirring. The precipitated thallium complex was rapidly filtered off, washed with methyl alcohol, and dried in a vacuum at 40° . The powdered thallium

derivative (120 mesh) was stirred with methyl iodide, with the exclusion of light and moisture, until the initial reaction had subsided, and the mixture was then boiled (under reflux) until the solid no longer gave an alkaline reaction (50 hours). Excess of methyl iodide was boiled off, the residue was exhaustively extracted with methyl alcohol, and the extracts were concentrated to a cream coloured solid (52 g.). This partly methylated derivative was dissolved in alcohol, and *n*-thallous ethoxide in benzene (300 c.c.) was added and the mixture evaporated to dryness with the exclusion of carbon dioxide. The solid was powdered (120 mesh), and boiled with methyl iodide until it no longer gave an alkaline reaction to litmus paper. The methylated product was extracted (as above) and the process of methylation with thallous ethoxide twice repeated. A final methylation with Purdie's reagents gave methylated cherry gum (48.0 g.); $[\alpha]_D^{20} = -28^\circ$ (*c.* 2.1 in methyl alcohol) (Found: equiv., 1650; OMe, 40.7%). This material (42 g.) was submitted to fractionation by precipitation from chloroform solution by addition of light petroleum. Three fractions were obtained as cream coloured solids, soluble in methyl alcohol, benzene, chloroform, acetone, dioxan, and cold water, insoluble in hot water and light petroleum. *Fraction R* (3.0 g.), $[\alpha]_D^{20} = -30^\circ$ (*c.* 1.4 in methyl alcohol) (Found: uronic anhydride (by boiling with 12% hydrochloric acid under the standard conditions), 10.1%; equiv. (by titration with 0.1*N*-sodium hydroxide), 1645; OMe, 39.0%). *Fraction S* (37.1 g.), $[\alpha]_D^{20} = -27^\circ$ (*c.* 2.4 in methyl alcohol) (Found: uronic anhydride, 10.4%; equiv., 1650; OMe, 42.4%). *Fraction T* (1.5 g.), $[\alpha]_D^{20} = -28^\circ$ (*c.* 0.9 in methyl alcohol) (Found: uronic anhydride, 10.3%; equiv., 1660; OMe, 40.1%). Calc. for fully methylated cherry gum: uronic anhydride, 10.1%; equiv. 1742; OMe, 42.7%.

Hydrolysis.—The methylated gum (*Fraction S*, 30 g.) was dissolved in 2% methyl alcoholic hydrogen chloride (300 c.c.) and boiled under reflux for 70 hours by which time $[\alpha]_D$ had changed from -27° to $+14^\circ$. The cooled solution was neutralised with silver carbonate, filtered, and evaporated to a syrup (34.4 g.), part of which was soluble in ether (A, 27.3 g., n_D^{20} 1.4545) and part insoluble (B, 7.1 g., n_D^{20} 1.4810).

The ether-soluble syrup (A, 27.3 g.) was heated to 90° with 0.3*N*-barium hydroxide (70 c.c.) for 15 hours, cooled, neutralised with carbon dioxide, and filtered, and the filtrate exhaustively extracted with chloroform in an all-glass apparatus. The chloroform extracts were evaporated to a syrup, n_D^{20} 1.4492, which on extraction with boiling ether gave a fraction soluble in ether (C, 17.45 g., n_D^{21} 1.4453) and an insoluble residue (D, 3.80 g., n_D^{21} 1.4624). The aqueous solution of the chloroform extraction was evaporated at $40^\circ/12$ mm. to a brown solid (E, 6.4 g.).

Fraction C (17.45 g.) was fractionally distilled in a vacuum, giving: *Fraction (1)*, 2:3:5-trimethyl methyl-*l*-arabofuranoside (7.80 g.), b. p. $110-120^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4380 (Found: OMe, 60.5%). *Fraction (2)*, a mixture of 2:3:5-trimethyl methyl-*l*-arabofuranoside and 2:5-dimethyl methyl-*l*-arabofuranoside (2.11 g.), b. p. $120^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4438 (Found: OMe, 58.3%). *Fraction (3)*, mainly 2:5-dimethyl methyl-*l*-arabofuranoside (5.14 g.), b. p. $125-140^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4532 (Found: OMe, 51.0%).

To the still residue was added *Fraction D* (3.80 g.) and the distillation continued. *Fraction (4)*, mainly 2:4:6-trimethyl methyl-*d*-galactoside (2.66 g.), b. p. $140-150^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4560 (Found: OMe, 50.4%). *Fraction (5)*, 2:4:6-trimethyl methyl-*d*-galactoside (0.85 g.), b. p. $150-160^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4618 (Found: OMe, 50.4%). This fraction partially crystallised. Still residue (F).

The ether-insoluble syrup B (7.1 g.) and the solid residue E (6.4 g.) were united and boiled with 2% methyl-alcoholic hydrogen chloride (300 c.c.) for 72 hours. The solution was neutralised with silver carbonate, filtered, and concentrated to a syrup which was heated with 0.3*N*-barium hydroxide (90 c.c.) for 12 hours. The cooled solution was neutralised with carbon dioxide, filtered, and exhaustively extracted with chloroform, and the extracts were concentrated to a syrup (G, 4.78 g., n_D^{19} 1.4730), which was added to the still residue (F) and the fractionation continued, giving: *Fraction (6)*, mainly 2:3:5-trimethyl methyl-*l*-arabofuranoside (1.278 g.), b. p. $110^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4372 (Found: OMe, 58.0%). *Fraction (7)*, a mixture of 2:5-dimethyl methyl-*l*-arabofuranoside and 2:4:6-trimethyl methyl-*d*-galactoside (0.70 g.), b. p. $120-150^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4572 (Found: OMe, 52.3%). *Fraction (8)*, mainly 2:4-dimethyl methyl-*d*-galactoside (4.25 g.), b. p. $160^\circ/0.001$ mm. (bath temp.), n_D^{20} 1.4750 (Found: OMe, 38.4%). *Fraction (9)*, dimethyl and monomethyl methyl-hexosides (1.15 g.), b. p. $160-200^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4845 (Found: OMe, 31.7%). Still residue, (0.38 g.).

The aqueous solution from G was evaporated to dryness and the residual barium salts were boiled with 6% methyl alcoholic hydrogen chloride (200 c.c.) for 24 hours. The solution was neutralised with barium carbonate, filtered, and evaporated to a syrupy mass which was exhaustively extracted with acetone. Removal of the solvent at $40^\circ/12$ mm. gave a syrup (n_D^{21} 1.4722), part of which (3.80 g.) was separated into two fractions by extraction with ether. The ether-soluble material (2.90 g., n_D^{19} 1.4625) was fractionally distilled in a vacuum, giving: *Fraction (10)*, mainly the methyl ester of 2:3:4-trimethyl methyl-*d*-glucuronoside (1.63 g.), b. p. $120^\circ/0.001$ mm. (bath temp.), $n_D^{19.5}$ 1.4530 (Found: OMe, 55%). This fraction was partially crystalline. *Fraction (11)*, mainly the methyl ester of dimethyl methylglucuronoside (0.83 g.), b. p. $150^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4681 (Found: OMe, 48.7%). To the still residue was added the ether-insoluble portion (0.90 g.) of the glucuronic acid fractions and the distillation was continued, giving: *Fraction (12)*, a mixture of the methyl esters of 2:3:4-trimethyl methyl-*d*-glucuronoside and dimethyl methyl-*d*-glucuronoside (0.60 g.), b. p. $160-200^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4698 (Found: OMe, 48.8%).

Examination of the Various Fractions.—Fractions (1), (2), and (6) were combined (11.1 g.) and hydrolysed with 0.1*N*-sulphuric acid (90 c.c.) for $7\frac{1}{2}$ hours at 90° . $[\alpha]_D^{20} = -20^\circ$ (*c.* 11.1 in 0.1*N*-sulphuric acid, initial value); -20° ($1\frac{1}{2}$ hours); -10° ($3\frac{1}{2}$ hours); $\pm 0^\circ$ ($7\frac{1}{2}$ hours, constant value). The solution was neutralised with barium carbonate, filtered, and evaporated to a syrup at $40^\circ/12$ mm., and the sugars were exhaustively extracted with chloroform. Concentration of the extracts gave a syrup (9.28 g., n_D^{19} 1.4522), a portion (8.68 g.) of which was fractionally distilled in a vacuum giving: *Fraction (13)* (7.40 g.), 2:3:5-trimethyl *l*-arabofuranose, b. p. $108-120^\circ/0.001$ mm. (bath temp.), n_D^{19} 1.4540; $[\alpha]_D^{20} \pm 0^\circ$ (*c.* 0.9 in water) (Found: OMe, 48.0. Calc. for $C_6H_{12}O_5$: OMe, 48.4%).

Fraction (14) (0.83 g.), b. p. 120–140°/0.001 mm. (bath temp.), $[n_D^{20}]$ 1.4668, $[\alpha_D^{20}] + 47^\circ$ (c, 0.55 in water) (Found: OMe, 42.8%). *Residue* (0.25 g.).

Fraction (13) (6.80 g.) was dissolved in water (20 c.c.) and oxidised with bromine (5 c.c.). The lactones (6.40 g.; n_D^{20} 1.4538) isolated in the usual manner were fractionally distilled giving *Fraction (15)*, mainly 2:3:5-trimethyl *l*-arabonolactone (2.5 g.), b. p. 104°/0.001 mm. (bath temp.), n_D^{20} 1.4452 (supercooled liquid), m. p. and mixed m. p. with an authentic specimen 27°, $[\alpha_D^{20}] - 28^\circ$ (initial value in water; c, 1.58); -29° (2 hours); -32° (4½ hours); -35° (6½ hours); -33° (22 hours); -32° (29½ hours); -31° (49 hours) (Found: equiv., 198; OMe, 48.3%). With liquid ammonia the lactone gave in good yield 2:3:5-trimethyl *l*-arabonamide, m. p. and mixed m. p., 138°. *Fraction (16)* (1.93 g.), mainly 2:3:5-trimethyl *l*-arabonolactone, b. p. 104–124°/0.001 mm. (bath temp.), n_D^{20} 1.4500, $[\alpha_D^{20}] + 8^\circ$ (c, 1.8 in water, initial value); -2° (1 hour); -17° (4 hours); -19° (6 hours); -26° (22 hours); -25° (33 hours); -24° (49 hours) (Found: equiv., 198; OMe, 51.0%). With liquid ammonia this lactone gave 2:3:5-trimethyl *l*-arabonamide, m. p. 138° in 70% yield. Fractions (15) and (16) were both contaminated with a lactone which, from its rate of mutarotation, was a δ -lactone and which may have been a derivative of *d*-xylonic or *d*-galactonic acid. The residue (2.0 g.) is considered below.

Fractions (3), (4), and (7) were combined (8.40 g.) and hydrolysed with *N*-sulphuric acid (100 c.c.) during 7 hours at 90°. $[\alpha_D^{20}] + 21^\circ$ (initial value); $+55^\circ$ (½ hour); $+56^\circ$ (1½ hours); $+54^\circ$ (2½ hours); $+52^\circ$ (4 hours); $+48^\circ$ (7 hours, constant value). The solution was neutralised with barium carbonate, filtered, and evaporated, and the residual syrupy sugars (7.64 g., n_D^{20} 1.4740) were isolated in the usual manner and distilled, giving: *Fraction (17)* (2.29 g.), mainly 2:5-dimethyl *l*-arabinose, b. p. 128–133°/0.001 mm. (bath temp.), n_D^{20} 1.4668, $[\alpha_D^{20}] + 60^\circ$ (c, 0.96 in water) (Found: OMe, 41.4%). *Fraction (18)* (3.36 g.), b. p. 135°/0.001 mm. (bath temp.), n_D^{20} 1.4735, $[\alpha_D^{20}] + 36^\circ$ (c, 1.6 in water) (Found: OMe, 42.0%). *Fraction (19)* (1.07 g.), b. p. 140–170°/0.001 mm. (bath temp.), $[\alpha_D^{20}] + 39^\circ$ (c, 0.88 in water) (Found: OMe, 36.9%). *Residue* (0.73 g.).

Fractions (14), (17), (18), and (19) were combined (7.4 g.) and oxidised with bromine water. The lactones (6.60 g.) were isolated, combined with the residue (2.0 g.) from fractions (15) and (16), and fractionally distilled in a vacuum giving *Fraction (20)* (1.15 g.), 2:5-dimethyl *l*-arabonolactone admixed with some other lactone of higher positive rotation (2:4:6-trimethyl *d*-galactonolactone?), b. p. 130–140°/0.001 mm. (bath temp.), n_D^{20} 1.4562, $[\alpha_D^{20}] + 14^\circ$ (c, 1.25 in water, initial value); $+4^\circ$ (1½ hours); -12° (5½ hours); -16° (9 hours); -15° (22 hours) (Found: equiv., 187; OMe, 38.8%). Calc. for $C_7H_{12}O_6$: equiv., 176; OMe, 35.2%). With liquid ammonia the lactone gave 2:5-dimethyl *l*-arabonamide in good yield, m. p. and mixed m. p. with an authentic specimen, 131° (Smith, J., 1939, 751) depressed to 122° on admixture with 2:3-dimethyl *l*-arabonamide. 2:5-Dimethyl *l*-arabonamide gave a negative Weerman test.

Conversion of 2:5-Dimethyl l-Arabonamide into 2:5-Dimethyl l-Arabonolactone.—The amide (0.4 g.) was heated at 90° with excess of *N*-sodium hydroxide until ammonia was no longer evolved (2 hours). The solution was acidified with *N*-sulphuric acid and then extracted exhaustively with chloroform. Concentration of the chloroform solution gave a syrup (0.35 g.) which was distilled in a vacuum; b. p. 160°/0.3 mm. The product crystallised, had m. p. 60°, and was pure 2:5-dimethyl *l*-arabonolactone (Found: OMe, 35.0. Calc. for $C_7H_{12}O_6$: OMe, 35%). *Fraction (21)* (5.09 g.) was mainly 2:5-dimethyl *l*-arabonolactone, b. p. 150°/0.001 mm. (bath temp.), n_D^{20} 1.4642, $[\alpha_D^{20}] + 21^\circ$ (c, 1.97 in water, initial value); $+8^\circ$ (1½ hours); -8° (5½ hours); -11° (9 hours); -11° (22 hours); -10° (38 hours) (Found: equiv., 189; OMe, 35.3%). With liquid ammonia the lactone gave 2:5-dimethyl *l*-arabonamide, m. p. 131°, in 60% yield. *Fraction (22)* (1.50 g.), had b. p. 160–180°/0.001 mm. (bath temp.), n_D^{20} 1.4720 (Found: OMe, 32.8%), and gave no crystalline amide with liquid ammonia.

The non-crystalline amides from Fractions (15) and (16) were combined and heated with barium hydroxide in a stream of nitrogen until the solution was free from ammonia. Excess of barium hydroxide was removed by carbon dioxide and the filtered solution decomposed with the calculated quantity of *N*-sulphuric acid, filtered, and evaporated to a syrup. In a similar manner lactones were regenerated from fractions (20), (21), and (22). The lactones recovered from (15) and (16) were distilled in a vacuum, giving *Fraction (23)*, b. p. 120°/0.001 mm. (bath temp.), n_D^{20} 1.4550, $[\alpha_D^{20}] + 33^\circ$ (c, 0.84 in water); $+27^\circ$ (1 hour); $+14^\circ$ (2 hours); $+7^\circ$ (3½ hours); -5° (7 hours); -11° (11 hours); -11° (23 hours). (Found: equiv., 200; OMe, 46.4%). With liquid ammonia the lactone gave an amide from which a small amount (50 mg.) of 2:3:5-trimethyl *l*-arabonamide was isolated; m. p. 138°. The syrupy amide gave a negative Weerman reaction showing the absence of amides with hydroxyl groups on C_2 . The lactones from Fractions (20), (21), and (22) were fractionally distilled in a vacuum, giving: *Fraction (24)*, b. p. 160°/0.001 mm. (bath temp.), n_D^{20} 1.4648, $[\alpha_D^{20}] + 43^\circ$ (c, 2.35 in water; initial value); $+32^\circ$ (1 hour); $+18^\circ$ (2 hours); $+8^\circ$ (3½ hours); -4° (7 hours); -10° (22 hours) (Found: equiv., 184; OMe, 39.5%). With liquid ammonia this lactone gave a syrupy amide which gave a negative Weerman test. *Fraction (25)*, b. p. 160–170°/0.001 mm., n_D^{20} 1.4740, $[\alpha_D^{20}] + 14^\circ$ (c, 0.85 in water, initial value); $+8^\circ$ (1½ hours); $+0^\circ$ (2½ hours); -6° (12½ hours); -11° (25 hours); -7° (31½ hours) (Found: equiv., 186; OMe, 36.4%). This lactone reacted with liquid ammonia giving a syrupy amide which gave a positive Weerman reaction.

The non-crystalline amides (3.50 g.) from the above lactones [Fractions (23), (24), and (25)] were dissolved in water and excess of periodic acid added. The solution became hot, and an odour resembling that of acetaldehyde was detected; this reaction destroyed all the 2:5-dimethyl *l*-arabonamide present in the syrupy amides. The solution was neutralised with barium carbonate and filtered, and the filtrate concentrated at 40°/12 mm. The distillate had an aldehydic odour and reduced hot Fehling's solution. The residual syrup was dissolved in water and oxidised with bromine in the presence of barium carbonate until non-reducing to Fehling's solution. Bromine was removed by aeration, the filtered solution evaporated to dryness, and the residue boiled with 2% methyl alcoholic hydrogen chloride for 10 hours. Hydrochloric acid was removed with silver carbonate, and the filtered solution evaporated at 90°/760 mm., to a syrup which was distilled in a vacuum, giving: *Fraction (26)* (1.8 g.), b. p. 135–145°/0.001 mm. (bath temp.), n_D^{20} 1.4538, $[\alpha_D^{20}] + 50^\circ$ (c, 1.2 in water, initial

value); + 40° (1½ hours); + 23° (4 hours); + 15° (7 hours); + 11° (23 hours); + 11° (28 hours, constant value) (Found: equiv., 175; OMe, 47.9%). With liquid ammonia the distilled lactone gave no crystalline amide. As no dimethyl dimethoxysuccinate was isolated, it is inferred that 2 : 3-dimethyl arabinose and 2 : 3-dimethyl xylose are not present in Fractions (23), (24), and (25). Fraction (27) (0.8 g.), b. p. 145–165°/0.001 mm. (bath temp.), n_D^{25} 1.4628. $[\alpha]_D^{20} + 77^\circ$ (c, 1.0 in water, initial value); + 59° (2 hours); + 33° (5½ hours); + 23° (24 hours, constant value) (Found: equiv., 190; OMe, 45.7%). This fraction gave no crystalline derivative on conversion into the corresponding amide by solution in liquid ammonia. This amide and the amide from Fraction (26) gave no sodium cyanate with sodium hypochlorite, proving the absence of a hydroxyl group on C₂. 3 : 4-Dimethyl arabinose, 3 : 4-dimethyl xylose, and 3 : 4 : 6-trimethyl *d*-mannose are thus absent from this fraction.

Fraction (5) (0.82 g.) was dissolved in *N*-hydrochloric acid (20 c.c.) and heated at 90–95° for 3 hours. $[\alpha]_D^{20} + 90^\circ$ (initial value); + 77° (1 hour); + 69° (2½ hours, constant value). The solution was neutralised with silver carbonate, filtered and evaporated to a syrup (0.80 g.), n_D^{20} 1.4738. $[\alpha]_D^{20} + 75^\circ$ (c, 4.0 in water) (Found: OMe, 39.0%). The syrup (0.79 g.) on being refluxed with alcoholic aniline gave 2 : 4 : 6-trimethyl *d*-galactose anilide (0.47 g.), m. p. and mixed m. p. 179°. The non-crystalline anilide was heated with *N*-hydrochloric acid (10 c.c.) at 70° for 3 hours. The cooled solution was neutralised with silver carbonate, filtered, and exhaustively extracted with light petroleum, and the extracted solution evaporated to a syrup which did not crystallise. The recovered sugar was oxidised with bromine water and the lactone isolated as a syrup which gave with liquid ammonia a non-crystalline amide. The amide gave no sodium cyanate with sodium hypochlorite (Weerman reaction), proving the absence of a hydroxyl group on C₂ and therefore of a mannose derivative in this fraction (see Jones, *loc. cit.*). The yield of 2 : 4 : 6-trimethyl *d*-galactose anilide corresponds to the presence of 0.50 g. of 2 : 4 : 6-trimethyl *d*-galactose in this fraction.

Fraction (8) (4.19 g.) was dissolved in *N*-hydrochloric acid (50 c.c.) and heated at 90–95° for 4 hours. $[\alpha]_D^{20} + 74^\circ$ (initial value), rising to + 78° (constant value). The solution was neutralised with silver carbonate, filtered, and evaporated to a syrup (3.98 g.) which did not crystallise and had $[\alpha]_D^{20} + 85^\circ$ (in water) (Found: OMe, 25.2%). The sugar (3.50 g.) on being heated with alcoholic aniline gave 2 : 4-dimethyl *d*-galactose anilide (0.62 g.), m. p. and mixed m. p. with an authentic specimen 212°, and a syrupy anilide (Y). This corresponds to the presence of 1.08 g. of 2 : 4-dimethyl *d*-galactose in this fraction. The crystalline anilide was hydrolysed with *N*-hydrochloric acid at 90° for 2 hours, the cooled solution neutralised with silver carbonate, and filtered, aniline extracted with ether, and the aqueous solution evaporated to a syrup which crystallised on nucleation with the monohydrate of 2 : 4-dimethyl *d*-galactose; m. p. and mixed m. p. with an authentic specimen 105°. The sugar (0.30 g.) was oxidised with bromine water and the lactone of 2 : 4-dimethyl *d*-galactonic acid (0.20 g.) isolated as a syrup, $[\alpha]_D^{20} + 100^\circ \rightarrow + 40^\circ$ (60 hours, constant value), which on solution in liquid ammonia gave 2 : 4-dimethyl *d*-galactonamide (0.11 g.). $[\alpha]_D^{20} + 58^\circ$ (c, 1.1 in water); m. p. and mixed m. p. 164° (Found: OMe, 27.6. Calc. for C₈H₁₇O₆N: OMe, 27.8%).

The filtrate from the anilide (Y) was evaporated to a syrup and hydrolysed with *N*-hydrochloric acid, and the free sugar (2.35 g., n_D^{20} 1.4842) isolated in the usual manner. The sugar was boiled in 2% methyl alcoholic hydrogen chloride and the resulting glycosides isolated and distilled; b. p. 160–180°/0.002 mm. (bath temp.), n_D^{25} 1.4700 (Found: OMe, 41.7%). This substance which analysed as a dimethyl methylhexoside failed to give any crystalline products on hydrolysis.

Fraction (9) (0.91 g.) was hydrolysed with *N*-hydrochloric acid (30 c.c.) for six hours at 95°. $[\alpha]_D^{20} + 60^\circ \rightarrow + 85^\circ$ (constant value). The sugars (0.7 g.) isolated in the usual manner did not crystallise and no crystalline derivative could be isolated from them.

Fraction (10) (1.3 g.) was hydrolysed with boiling *N*-hydrochloric acid and the resultant 2 : 3 : 4-trimethyl *d*-glucuronic acid isolated. It was converted by oxidation with bromine water into 2 : 3 : 4-trimethyl *d*-saccharic acid which was isolated as follows. Bromine was removed mainly by aeration, the last traces being removed by the passage of sulphur dioxide. The solution containing the methylated derivative was then extracted exhaustively with chloroform and the extracts were concentrated to a syrup (1.1 g.) which was esterified by boiling with methyl alcoholic hydrogen chloride. The resultant dimethyl ester of 2 : 3 : 4-trimethyl *d*-saccharic acid was isolated and converted into the methyl ester of 2 : 3 : 4-trimethyl saccharolactone by distillation in a vacuum. The product (0.9 g.), n_D^{20} 1.4605, crystallised and was purified by recrystallisation from ether; m. p. and mixed m. p. with an authentic specimen 110°.

Fractions (11) and (12) were combined and a portion of the mixture (0.9 g.) was hydrolysed. The resultant mixture of 2 : 3 : 4-trimethyl *d*-glucuronic acid and 2 : 3-dimethyl *d*-glucuronic acid was oxidised and the product converted into the corresponding dimethyl esters of 2 : 3 : 4-trimethyl and 2 : 3-dimethyl *d*-saccharic acid as described above. Distillation of this mixture (0.6 g.) gave a fraction (0.2 g.), b. p. 140°/0.0 mm., n_D^{20} 1.4650, which crystallised in part and from which methyl 2 : 3 : 4-trimethyl *d*-saccharolactone, m. p. 110°, was obtained by tiling the crystals followed by recrystallisation of the product from ether. A higher boiling fraction (0.3 g.), up to 200°/0.01 mm., n_D^{20} 1.4730, crystallised on nucleation with methyl 2 : 3-dimethyl *d*-saccharolactone. The crystals were separated by tiling and were purified by recrystallisation from alcohol-ether; m. p. 101°—not depressed on admixture with an authentic specimen.

The author wishes to thank Professor E. L. Hirst, F.R.S., for his interest and advice.

199. Some Reactions and Derivatives of 6- and 7-Nitro-2-naphthylamines. Part II. Nitration and Diazo-coupling.

By HERBERT H. HODGSON and EDWARD R. WARD.

The acetyl and toluene-*p*-sulphonyl derivatives of 6- and 7-nitro-2-naphthylamines nitrate in the 1-position, and the dinitro-compounds are highly resistant to further nitration. 6- and 7-Nitro-2-naphthylamines couple in the 1-position, and the resulting *o*-aminoazo-compounds are oxidised to triazoles. Replacement of the amino by the acetoxy-group in 6- and 7-nitro-*p*-nitrobenzeneazo-2-naphthylamines readily occurs by heating in glacial acetic acid with sodium nitrite.

FURTHER nitration of both the acetyl and the toluene-*p*-sulphonyl derivatives of 6- and 7-nitro-2-naphthylamines occurs in the 1-position only, and absence of nitration in the 3-position, as pointed out by Bell (*J.*, 1929, 2784) for the corresponding derivatives of β -naphthylamine, is now further emphasised.

It may be noted that the further nitration of six of the eight possible heteronuclear mononitrotoluene-*p*-sulphon-naphthalides has now been investigated, and whereas the four heteronuclear mononitro-2-naphthalides are only mononitrated in acetic acid medium with fuming nitric acid, both 5- and 6-nitro-1-naphthalides are simultaneously dinitrated. This is in contrast to the simultaneous dinitration of the unsubstituted 1- and 2-toluene-*p*-sulphon-naphthalides. Incidentally, however, the *m*-nitrobenzenesulphonyl derivatives of 8-nitro- and 1:6-dinitro-2-naphthylamines both afforded the 1:6:8-trinitro-derivative on further nitration (Bell, *loc. cit.*).

The constitutions of the 1:7-dinitroaceto- and 1:7-dinitrotoluene-*p*-sulphon-2-naphthalides were established by hydrolysis to the amine followed by its diazotisation and deamination to the known 1:7-dinitronaphthalene (cf. Hodgson and Birtwell, *J.*, 1943, 433).

6- and 7-Nitro-2-naphthylamines, used as second components, both couple in alcoholic acetic acid with diazotised amines in the 1-position as shown by oxidation of the resulting *o*-aminoazo-compounds to triazoles, by their resistance to acetylation, and by their diazotisation and conversion into a mixture of *o*-azonaphthol and *o*-azonaphthyl acetate by the sodium nitrite-glacial acetic procedure of Hodgson and Foster (*J.*, 1942, 435) [cf. also Morgan and Chazan (*J. Soc. Chem. Ind.*, 1922, 41, 1r) and Morgan and Gilmour (*ibid.*, p. 61r) who showed similarly that 5- and 8-nitro-2-naphthylamines coupled in the 1-position]. 6- and 7-Nitro-*p*-nitrobenzeneazo-2-naphthylamines behaved somewhat differently towards the Hodgson and Foster procedure (*loc. cit.*), the former being hydrolysed more readily to give predominant naphthol in the mixture of naphthol and naphthyl acetate obtained, whereas the latter afforded a good yield of the 7-nitro-1-*p*-nitrobenzeneazonaphthyl acetate. It is noteworthy that tar was absent in these decompositions, indicating ease of replacement of the amine by the acetoxy-group. Previously, Hodgson and Foster (*loc. cit.*) had found, for azo-dyes with unsubstituted β -naphthylamine as second component, that meta-directing groups in the first component promoted this replacement, so that evidence is now to hand of the same effect by the meta-directing 6- and 7-nitro-groups in the β -naphthylamine component.

In connection with the transmissions of effects from the 6- to the 2-position (cf. Robinson and Thompson, *J.*, 1932, 2015), it is of interest that 6-nitro-2-naphthol would not couple with diazotised *p*-nitroaniline in either ethanol or aqueous sodium carbonate solution, showing the deactivating effect of the 6-nitro- on the phenolic group, in the potential ionic quinonoid structure, in which the 1-position, instead of acquiring the anionoid activity requisite for coupling, becomes kationoid.

The claim of Friedländer and Littner (*Ber.*, 1915, 48, 330) to have prepared some 5-nitro-aceto-2-naphthalide from β -acetonaphthalide, and since disproved by Veselý and Jakeš (*Bull. Soc. chim.*, 1923, 33, 942), has erroneously been repeated in *Org. Synth.*, 1933, 13, 73.

EXPERIMENTAL.

Nitration of 7-Nitro-2-acetonaphthalide.—7-Nitro-2-naphthylamine (3 g.) was refluxed with glacial acetic acid (12 c.c.) and acetic anhydride (3 c.c.) for 10 minutes; on cooling, an almost quantitative separation of 7-nitro-2-acetonaphthalide was obtained, which, after recrystallisation from 50% ethanol, had m. p. 221°. This acetyl compound (3 g.) was added gradually to nitric acid (12 c.c., *d* 1.5) during 15 minutes (the temperature being kept below 20°), and, after being stirred for a further 15 minutes, the mixture was poured on ice and the precipitate of 1:7-dinitro-2-acetonaphthalide (3.5 g.) removed, washed with water, and dried; it crystallised from glacial acetic acid in pale yellow needles, m. p. 222°

(Found: N, 15.1. $C_{11}H_9O_2N_3$ requires N, 15.3%). Should the temperature be allowed to rise during nitration even as high as 60° for 5–10 minutes, some oxidation occurs although the final product is mainly 1:7-dinitro-2-acetonaphthalide.

1:7-Dinitro-2-naphthylamine was obtained when the acetyl derivative above (2.5 g.) was hydrolysed by refluxing with a solution of ethanol (25 c.c.) and 50% aqueous sulphuric acid (25 c.c.) for 45 minutes; after cooling, the separated 1:7-dinitro-2-naphthylamine (2 g.) was filtered off, washed with ethanol, and dried; it crystallised from 50% aqueous pyridine in golden yellow needles, m. p. 248–249° (Found: N, 18.1. $C_{10}H_7O_4N_3$ requires N, 18.0%). Deamination of the amine (1.5 g.) occurred when its solution below 20° in sulphuric acid (8 c.c., *d* 1.84) containing sodium nitrite (0.6 g.) was stirred gradually into glacial acetic acid (20 c.c.), the stirring continued for 30 minutes, red copper oxide (2–3 g.) added portionwise during 15 minutes, and the temperature allowed to rise to 40°. After being stirred for a further 1 hour, the mixture was poured on ice, the precipitate of 1:7-dinitronaphthalene filtered off, washed with water, dried, extracted with boiling ethylene dichloride, the solvent removed from the extract, and the 1:7-dinitronaphthalene purified by sublimation at 190–200°/15 mm.; m. p. and mixed m. p. with an authentic specimen, 156° (Vesely and Dvorák, *Bull. Soc. chim.*, 1923, **33**, 319, give m. p. 156°).

Nitration of 7-Nitrotoluene-*p*-sulphon-2-naphthalide.—A solution of the naphthalide (2.5 g.) in glacial acetic acid (20 c.c.) at 60° was treated first with a crystal of sodium nitrite and then with 7.5 c.c. of a solution made up of nitric acid (1 c.c., *d* 1.5) in glacial acetic acid (9 c.c.); nitration began when the temperature was raised to 65°, and for completion the mixture was kept at 90° for 5 minutes; on cooling, 1:7-dinitro-*p*-toluenesulphon-2-naphthalide (1.7 g.) crystallised out; after removal, it was washed with glacial acetic acid and ether, and dried. It crystallised from glacial acetic acid in bright yellow rectangular plates, m. p. 165–166° (Found: N, 11.0. $C_{17}H_{13}O_6N_3S$ requires N, 10.8%). On hydrolysis by dissolution (1 g.) in sulphuric acid (10 c.c., *d* 1.84) and heating for 5 minutes at 40°, 1:7-dinitro-2-naphthylamine was obtained and precipitated by pouring the mixture on ice, with subsequent treatment as above. Alternatively, the 1:7-dinitro-*p*-toluenesulphon-2-naphthalide was converted directly into 1:7-dinitronaphthalene by the Hodgson and Birtwell procedure (*loc. cit.*), but diazotisation had to be carried out carefully since hydrolysis and diazotisation followed rapidly.

Coupling with Diazo-compounds.—To a solution of the naphthylamine (0.01 g.-mol.) in ethanol (400 c.c.) containing sufficient sodium acetate for the replacement by acetic acid of all mineral acid involved, was added an aqueous solution of the diazonium salt (chloride or sulphate, 0.01 g.-mol.), prepared from *p*-nitroaniline, *p*-chloroaniline, or *p*-toluidine, from which free nitrous acid had been removed by urea. The mixture was stirred for 1 hour, and the azo-dye filtered off, washed with cold ethanol (50 c.c.) and hot water, dried, and crystallised from nitrobenzene (charcoal). All the azo-dyes now described were moderately soluble in boiling acetic anhydride or boiling glacial acetic acid, and resisted acetylation thereby even at 100°; they were only slightly soluble in boiling toluene or ethanol. The sequence of colours produced by concentrated sulphuric acid and subsequent dilution with water are recorded immediately after the m. p. The large amount of ethanol used for the couplings is necessary to prevent uncoupled amine from separating with the azo-dye.

6-Nitro-*p*-nitrobenzeneazo-2-naphthylamine formed micro-needles, m. p. 304° (sintered at 290°; blood-red, salmon-pink, brownish-red precipitate) (Found: N, 21.1. $C_{18}H_{11}O_4N_5$ requires N, 20.8%). 6-Nitro-1-*p*-chlorobenzeneazo-2-naphthylamine formed orange-red micro-needles, m. p. 261° (sintered at 245°; magenta, red to yellow-brown) (Found: N, 17.4. $C_{18}H_{11}O_2N_4Cl$ requires N, 17.15%). 6-Nitro-1-*p*-tolylazo-2-naphthylamine formed orange red micro-plates, m. p. 234° (mauve, magenta, reddish-brown, orange) (Found: N, 18.5. $C_{17}H_{14}O_2N_4$ requires N, 18.3%). 7-Nitro-1-*p*-chlorobenzeneazo-2-naphthylamine formed felted scarlet needles, m. p. 199° (magenta, purple, brown precipitate) (Found: N, 17.4. $C_{18}H_{11}O_2N_4Cl$ requires N, 17.15%). 7-Nitro-1-*p*-nitrobenzeneazo-2-naphthylamine formed very dark red almost black needles, m. p. 265–266° (crimson, reddish-blue) (Found: N, 21.1. $C_{18}H_{11}O_4N_5$ requires N, 20.8%).

Oxidation of Azo-dyes to Triazoles.—The dye (0.5 g.) was dissolved in boiling glacial acetic acid (30 c.c.), and a solution of chromium trioxide (0.5 g.) in water (1 c.c.) was added with caution to the stirred boiling mixture; the red colour disappeared, to be replaced by a white precipitate. On cooling and dilution with water, the triazole separated; it was filtered off, washed with hot water until the filtrate was colourless, dried at 100°, and recrystallised from hot nitrobenzene.

6-Nitro-1:2-naphtho-*p*-nitrophenyltriazole crystallised in flesh-coloured micro-plates, m. p. 288° (Found: N, 21.3. $C_{16}H_9O_4N_5$ requires N, 20.9%). 7-Nitro-1:2-naphtho-*p*-nitrophenyltriazole crystallised in flesh-coloured plates, m. p. 311–312° (sintered at 300°) (Found: N, 21.3. $C_{16}H_9O_4N_5$ requires N, 20.9%).

Reactions of 6- and 7-Nitro-1-*p*-nitrobenzeneazo-2-naphthylamines with Sodium Nitrite in Glacial Acetic Acid.—(a) The 6-nitro-compound (1.0 g.) was dissolved in hot glacial acetic acid (350 c.c.) at 70°, and treated portionwise with finely powdered sodium nitrite (1 g.); nitrogen was briskly evolved, and, when the evolution had ceased, the solution was raised to the boil for 15 minutes. On cooling, no separation occurred, so water was added to precipitate the reaction product which was a mixture of difficultly separable 6-nitro-1-*p*-nitrobenzeneazo-2-naphthol and its acetate. When the precipitate (0.25 g.) was refluxed with ethanol (50 c.c.) containing hydrochloric acid (2 c.c., *d* 1.18) for 30 minutes, complete hydrolysis occurred, and the 6-nitro-1-*p*-nitrobenzeneazo-2-naphthol separated on cooling and was removed, washed, and dried; it crystallised from boiling glacial acetic acid in pillar-box red microcrystals, m. p. 314° (sintered at 305°; reddish salmon pink, orange-red) (Found: N, 16.7. $C_{16}H_{10}O_5N_4$ requires N, 16.5%), which were only slightly soluble in hot glacial acetic acid, almost insoluble in boiling ethanol, and readily soluble in boiling nitrobenzene. Alternatively, the dye (0.5 g.) was added gradually to a solution of sodium nitrite (0.15 g.) in sulphuric acid (4 c.c., *d* 1.84) at 0°, followed by the gradual addition of glacial acetic acid (5 c.c.) over 15 minutes below 20°. After a further 15 minutes ice chips were added and stirring maintained until evolution of nitrogen had ceased; on dilution with water 6-nitro-1-*p*-nitrobenzeneazo-2-naphthol separated.

(b) The 7-nitro-compound (1 g.) was dissolved in glacial acetic acid (200 c.c.), in which it is more soluble than the 6-nitro-isomeride, and treated as above so far as the boiling operation, when on cooling

there separated 7-nitro-1-p-nitrobenzenesazo-2-naphthyl acetate, which crystallised from boiling acetic acid in orange red needles, m. p. 233° (red violet, orange) (Found N, 15.0. $C_{18}H_{13}O_5N_4$ requires N, 14.7%). 7-Nitro-1-p-nitrobenzenesazo-2-naphthol was obtained by hydrolysis as above, and crystallised from boiling nitrobenzene in red micro-crystals, m. p. 310° (decomp.) (Found: N, 16.7. $C_{18}H_{13}O_5N_4$ requires N, 16.5%).

The authors are indebted to the Charles Brotherton Trust for a Research Scholarship (to E. R. W.), to Imperial Chemical Industries Ltd., Dyestuffs Division, for gifts of chemicals, and to Mr. Frank Hobson for micro-analyses.

200. The Synthesis of 3-Methyl and 3:5-Dimethyl 1-Arabinose.

By E. L. HIRST, J. K. N. JONES, and (Miss) E. WILLIAMS.

3-Methyl 1-arabinose has been prepared from 5-p-toluenesulphonyl 1:2-monoacetone l-arabinose. It forms a crystalline anilide and on oxidation gives 3-methyl 1-arabonolactone, further characterised as its crystalline amide. Methylation of 3-methyl 1:2-monoacetone l-arabinose gives 3:5-dimethyl 1:2-monoacetone l-arabinose which on hydrolysis yields the known 3:5-dimethyl l-arabinose (White, *J. Amer. Chem. Soc.*, 1946, 68, 272) which on oxidation gives 3:5-dimethyl l-arabonolactone, characterised as the crystalline amide and phenylhydrazide.

THE araban associated with pectin is known to be of the branched chain type (Hirst and Jones, *J.*, 1939, 454) since the methylated derivative gave on hydrolysis three products, namely, 2:3:5-trimethyl l-arabofuranose, 2:3-dimethyl l-arabinose, and a monomethyl derivative

the identity of which was not conclusively established though on the balance of evidence the methyl group was assigned tentatively to the 3-position. This monomethyl arabinose gave on

oxidation a furano-lactone, and since the free sugar had the properties of a derivative of arabopyranose it must be either 2- or 3-methyl 1-arabinose. The latter possibility was thought to be the correct one since the non-crystalline amide prepared from the crude lactone gave a positive Weerman reaction indicating the presence of an α -hydroxy-amide. The synthesis of 3-methyl 1-arabinose was accordingly undertaken in order to provide material of known constitution for comparison with that obtained from araban. The starting material in this synthesis was methyl 1-arabofuranoside (I) (Baker and Haworth, *J.*, 1925, 365) which was converted into the syrupy 5-*p*-toluenesulphonyl derivative (II) by reaction with the calculated quantity of *p*-toluenesulphonyl chloride in dry pyridine. The known 5-*p*-toluenesulphonyl 1 : 2-monoacetone 1-arabinose (III) [prepared previously from 1-arabinose diethylmercaptal (Compton and Levene, *J. Biol. Chem.*, 1936, 116, 189)] was then prepared from (II) by reaction with acetone containing hydrogen chloride. Methylation of (III) with silver oxide and methyl iodide gave 5-*p*-toluenesulphonyl 3-methyl 1 : 2-monoacetone 1-arabinose (IV) which on reductive alkaline hydrolysis (Compton and Levene, *loc. cit.*) gave 3-methyl 1 : 2-monoacetone 1-arabinose (V). On acidic hydrolysis this product was converted into syrupy 3-methyl 1-arabinose (VI). This compound formed a crystalline *anilide* on heating with alcoholic aniline and a crystalline *furanolactone* (VII) on oxidation with bromine water. A crystalline *amide* (VIII) was produced on reaction of the lactone with liquid ammonia (cf. Jellinek and Upson, *J. Amer. Chem. Soc.*, 1938, 60, 356). This amide depressed the melting point of 2-methyl 1-arabonamide and gave a positive Weerman test indicating the presence of a hydroxyl group on C2.

The monomethyl sugar isolated from the hydrolysis of peanut araban differs from 3-methyl 1-arabinose and must therefore be 2-methyl 1-arabinose. This has been subsequently confirmed by the synthesis of 2-methyl 1-arabinose which was found to be identical with the monomethyl sugar isolated from methylated peanut araban (forthcoming publications).

3-Methyl 1 : 2-monoacetone 1-arabinose (V) on further methylation gave 3 : 5-dimethyl 1 : 2-monoacetone 1-arabinose (IX) which on hydrolysis gave 3 : 5-dimethyl 1-arabinose (X); this on oxidation gave the corresponding furano-lactone (XI) which was smoothly converted into the α -hydroxy-amide (positive Weerman test) (XII) with liquid ammonia (cf. White, *loc. cit.*) and into the *phenylhydrazide* on heating with alcoholic phenylhydrazine.

EXPERIMENTAL.

5-*p*-Toluenesulphonyl Methyl-1-arabofuranoside and 5-*p*-Toluenesulphonyl 1 : 2-Monoacetone 1-Arabinose.—Methyl-1-arabofuranoside (31 g.) was dissolved in dry pyridine (250 c.c.) and *p*-toluenesulphonyl chloride (37 g.), dissolved in pyridine (50 c.c.), was added at 20°. Heat was evolved, and the solution was then left overnight (20 hours). Next morning pyridine was removed under reduced pressure at 60°, and the syrupy residue dissolved in chloroform and the solution washed successively with *n*-sulphuric acid, saturated sodium hydrogen carbonate solution, and water. The chloroform extract [dried (Na_2SO_4) and filtered] was then concentrated under reduced pressure to the syrupy 5-*p*-toluenesulphonyl methyl-1-arabofuranoside (36 g.). The syrup (30 g.), without further purification, was dissolved in acetone (300 c.c.) containing dry hydrogen chloride (3 g.). After 70 hours the acetone solution was poured into excess of sodium hydrogen carbonate solution and the arabinose derivative extracted with chloroform. Concentration of the chloroform extracts [dried (Na_2SO_4)] gave 5-*p*-toluenesulphonyl 1 : 2-monoacetone 1-arabofuranose, m. p. 130°, after recrystallisation from acetone-ether (yield, 21 g.) (cf. Compton and Levene, *loc. cit.*).

5-*p*-Toluenesulphonyl 3-Methyl 1 : 2-Monoacetone 1-Arabofuranose.—5-*p*-Toluenesulphonyl 1 : 2-monoacetone 1-arabofuranose (5 g.) was methylated by dissolution in methyl iodide (10 c.c.) and portionwise addition of silver oxide. The *product*, isolated in the usual manner, was recrystallised from acetone-light petroleum (b. p. 40–60°). The yield was quantitative, m. p. 101° (Found : C, 53.6; H, 6.1; OMe, 8.4; $\text{C}_8\text{H}_{12}\text{O}_7\text{S}$ requires C, 53.6; H, 6.2; OMe, 8.7%).

3-Methyl 1 : 2-Monoacetone 1-Arabofuranose.—5-*p*-Toluenesulphonyl 1 : 2-monoacetone 3-methyl-1-arabofuranose (4 g.) was dissolved in methyl alcohol (50 c.c.) and water (20 c.c.), and sodium amalgam (40 g., 4%) added with stirring at 30° (cf. Compton and Levene, *loc. cit.*). The resultant monoacetone derivative was extracted with chloroform and the extracts were dried (MgSO_4) and filtered. Removal of the solvent left crude 3-methyl 1 : 2-monoacetone 1-arabinose (1.8 g.), n_D^{20} 1.4565, which was purified by vacuum distillation; b. p. 120° (bath temp.)/2 mm., n_D^{20} 1.4572 (Found : C, 52.8; H, 7.5; OMe, 15.5. $\text{C}_8\text{H}_{12}\text{O}_6$ requires C, 52.9; H, 7.8; OMe, 15.2%).

3-Methyl 1-Arabinose.—3-Methyl 1 : 2-monoacetone 1-arabofuranose (0.73 g.) was dissolved in 20% acetic acid (20 c.c.) and boiled for 3 hours; $[\alpha]_D^{20}$ – 29° (initial value); + 95° (final value). The 3-methyl arabinose was isolated as a syrup on concentration of the solution in a vacuum; $[\alpha]_D^{20}$ + 110° (c, 3.6 in water) (Found : OMe, 19.2. $\text{C}_8\text{H}_{12}\text{O}_5$ requires OMe, 18.9%). On being heated with alcoholic aniline (180 mg.) the sugar (111 mg.) gave a crystalline *anilide* (100 mg.), m. p. 117° after recrystallisation from alcohol (Found : C, 60.1; H, 7.3; N, 5.9; OMe, 12.6. $\text{C}_{11}\text{H}_{17}\text{O}_4\text{N}$ requires C, 60.2; H, 7.1; N, 5.9; OMe, 13.0%).

No crystalline phenylhydrazone could be isolated. On oxidation of the sugar with bromine water under the usual conditions 3-methyl 1-arabofuranolactone was isolated as a crystalline solid (m. p. 71°) which was purified by sublimation in a vacuum, and then had m. p. 78° (constant value); $[\alpha]_D^{20}$ – 74° (c, 0.34 in water), no observable change in 24 hours (Found : C, 44.3; H, 6.7; OMe, 19.2; equiv., 162.

$C_6H_{10}O_5$ requires C, 44.4; H, 6.2; OMe, 19.1%; equiv., 162). With liquid ammonia the lactone gave 3-methyl *l*-arabonamide, m. p. 132°, after recrystallisation from alcohol-acetone (Found: C, 40.3; H, 7.3; N, 7.5; OMe, 17.1. $C_6H_{13}O_5N$ requires C, 40.2; H, 7.27; N, 7.8; OMe, 17.3%). This amide gave a positive Weerman test and depressed the m. p. of 2-methyl *l*-arabonamide.

3:5-Dimethyl Monoacetone *l*-Arabofuranose.—3-Methyl monoacetone *l*-arabinose (0.8 g.) was methylated with Purdie's reagents and the product (0.8 g.), isolated in the usual manner, was distilled under reduced pressure; b. p. 120° (bath temp.)/0.5 mm., n_D^{25} 1.4420 (Found: OMe, 28.1. $C_{10}H_{18}O_5$ requires OMe, 28.4%).

The above derivative (242 mg.) was boiled with 25% acetic acid (20 c.c.) for 3 hours; $[\alpha]_D^{20}$ — 39°, unchanged on heating. The solution was concentrated under reduced pressure and the resultant 3:5-dimethyl *l*-arabofuranose purified by solution in acetone followed by filtration. The sugar had n_D^{25} 1.4600 (Found: OMe, 34.6. Calc. for $C_7H_{14}O_5$: OMe, 34.8%).

The sugar (200 mg.) was oxidised with bromine (1 c.c.) in water (5 c.c.) at 20° for 24 hours. Excess of bromine was removed by aeration and the last traces of bromine by passage of sulphur dioxide. The lactone was then removed from the aqueous solution by continuous extraction with chloroform. Concentration of the extracts gave crystalline 3:5-dimethyl *l*-arabonolactone, m. p. 73° (after sublimation in a vacuum), depressed to 50° on admixture with 2:5-dimethyl *l*-arabonolactone; $[\alpha]_D^{20}$ — 83° (c, 0.12 in water), no observable change in 24 hours (Found: OMe, 33.9; equiv., 169. Calc. for $C_7H_{12}O_5$: OMe, 35.2%; equiv., 176). With liquid ammonia the lactone gave the corresponding amide, m. p. 144° (depressed to 120° on admixture with 2:5-dimethyl *l*-arabonamide), which gave a positive Weerman reaction (Found: C, 43.8; H, 7.6; N, 7.0; OMe, 31.2. Calc. for $C_7H_{15}O_5N$: C, 43.5; H, 7.8; N, 7.25; OMe, 32.1%).

The phenylhydrazide, m. p. 144° [depressed to 132° on admixture with the phenylhydrazide (m. p. 163°) of 2:5-dimethyl *l*-arabonic acid], was prepared by heating the lactone with an alcoholic solution of phenylhydrazine. It was recrystallised from acetone-ether (Found: C, 54.5; H, 6.8; N, 9.8; OMe, 21.6. $C_{13}H_{20}O_5N_2$ requires C, 54.8; H, 7.0; N, 9.9; OMe, 21.8%).

201. The Constitution of Egg-plum Gum. Part I.

By E. L. HIRST and J. K. N. JONES.

The gum exuded on the bark of the egg-plum has been examined and shown to consist of *l*-arabinose (3 parts), *d*-xylose (1 part), *d*-galactose (3 parts), and *d*-glucuronic acid (1 part). The aldobionic acid which is present in the portion of the gum molecule more resistant to acidic hydrolysis is *d*-glucuronosido-6-*d*-galactose identical with the aldobionic acid component present in gum arabic. The oxidation of the gum with potassium periodate has been studied.

IN common with many other fruit trees of the family *Rosaceæ* the egg or yellow Pershore plum tree forms a gum during the months of August and September. The gums from several other trees have already been examined (see Hirst and Jones, *J.*, 1946, 506) and it was of interest to determine whether Pershore plum gum has a similar constitution. The gums obtained from exudation usually contain small amounts only of nitrogenous materials, which may be part of the enzyme system originally responsible for their synthesis (M. Stacey, private communication). They are salts of acidic polysaccharides, the acidity being due to the presence of *d*-glucuronic or *d*-galacturonic acids or of their methyl ethers. *d*-Galactose and *l*-arabinose appear to be invariable constituents, whilst *d*-mannose, *d*-xylose, and *l*-rhamnose have also been detected in some plant gums.

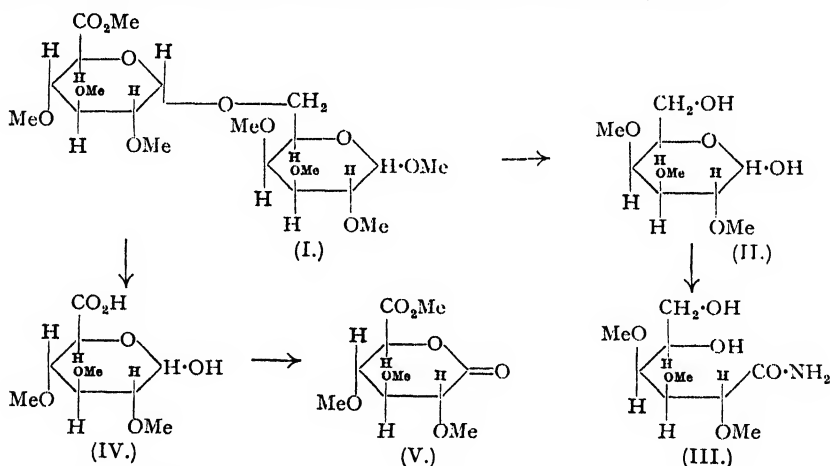

Purified ash-free Pershore plum gum is a white powder soluble in water giving an acidic solution which does not reduce Fehling's solution. So far as present evidence is available the gum so prepared appears to be a homogeneous substance, and attempts to extract from it by solvents fractions differing in elementary and physical properties have been unsuccessful. Gums obtained from several trees in the same area (Worcestershire) all have the same physical properties. The possibility remains, however, that the type of gum exuded by the tree may be dependent upon the type of stock on which the tree is grafted rather than upon the type of plum produced. Further work will be necessary before this can be settled.

The analytical figures for uronic acid residues (14.7%) and furfuraldehyde (25.5%) were obtained by boiling the polysaccharide with 12% hydrochloric acid and determining the amounts of carbon dioxide and furfuraldehyde formed. From these results estimates can be made of the pentose and the uronic acid content of the gum. An aqueous acidic solution of the ash-free polysaccharide undergoes graded hydrolysis on heating at 100°, the sugars obtained after hydrolysis consisting of a mixture of *l*-arabinose and *d*-xylose in the approximate proportion of 3 to 1. The remainder of the polysaccharide consists of *d*-galactose and *d*-glucuronic acid, since on

hydrolysis with *N*-sulphuric acid crystalline *D*-galactose is obtained together with an aldobionic acid having the structure *D*-glucuronosido-*D*-galactose (1 : 6 linkage) identical with the aldobionic acid in gum arabic. This structure, therefore, is an important feature in the mode of construction of the sugar residues in the repeating unit of the gum. It follows that Pershore plum gum resembles gum arabic, rather than damson or cherry gum (cf. Smith, *J.*, 1940, 1035), and in common with many other gums so far examined it contains a repeating unit consisting of two molecules of galactose united to an aldobionic acid. It is to be remembered, however, that owing to the difficulty encountered in isolating the aldobionic acid component of the gum in quantitative yield the possibility remains that some aldobionic acid other than 1 : 6-*D*-glucuronosido-*D*-galactose may be a component of the gum molecule. Conclusive proof is furnished below, however, of the presence of 1 : 6-*D*-glucuronosido-*D*-galactose as a part of the gum molecule.

The proof of the structure of the aldobionic acid follows from the observation that on methylation followed by hydrolysis of the methylated product (I), two products are obtained, namely, 2:3:4-trimethyl *D*-galactose (II), identified as its crystalline anilide and as the crystalline amide of 2:3:4-trimethyl *D*-galactonic acid (III), and 2:3:4-trimethyl *D*-glucuronic acid (IV), identified as the methyl ester of 2:3:4-trimethyl *D*-saccharolactone (V).

A quantitative estimation of the various sugars produced on hydrolysis of the original Pershore plum gum indicates that they were combined in the following proportions: *d*-glucuronic acid (1 part); *d*-galactose (3 parts); *l*-arabinose (3 parts); *d*-xylose (1 part).

When the gum is oxidised with potassium periodate under mild conditions, designed to prevent over-oxidation (see Brown, Dunstan, Halsall, Hirst, and Jones, *Nature*, 1945, **156**, 785) approximately one mol. of formic acid is produced and five mols. of periodate are consumed per equivalent of approximately 1220. The resulting oxidised polysaccharide, on being boiled under standard conditions with 12% hydrochloric acid, gives furfuraldehyde (10.8%) in a much diminished yield. This proves that some of those sugar residues in the original unoxidised polysaccharide which yield furfuraldehyde on distillation with hydrochloric acid have been destroyed during the oxidation. Since under the conditions of oxidation there is no continual rise in formic acid titre followed by a subsequent liberation of iodine, the glucuronic acid residue is not an end group (see Brown, Dunstan, Halsall, Hirst, and Jones, *loc. cit.*).

The oxidised polysaccharide on hydrolysis gives some *l*-arabinose (estimated as its benzoyl-hydrazone), but xylose could not be detected (see Breddy and Jones, *J.*, 1945, 738). The yields of *d*-galactose and *l*-arabinose indicated that at least 1.5 mols. of *d*-galactose and 0.5 mol. of *l*-arabinose per equivalent of 1220 are not oxidised by the periodate and therefore cannot possess adjacent hydroxyl groups in their combination in the gum molecule.

An examination of the product isolated from the reaction between the gum and triphenylmethyl chloride in pyridine shows that there are approximately four primary alcohol groups (Method of Linstead, *Arkiv Kemi, Min. Geol.*, 1945, 20 A, No. 13) per equivalent of 1220.

EXPERIMENTAL.

Purification of Egg-plum Gum.—The gum, which resembled damson and cherry gums in properties, was purified by precipitation with alcohol from aqueous solutions to which hydrochloric acid had been

added (for further details see Hirst and Jones, *J.*, 1938, 1177). The gum gave no precipitate with calcium or copper salts but gave a white precipitate on addition of a large excess of thallium hydroxide. It was unaffected by takadiastase and pectinase at pH 7 at 35°. Two samples were prepared: (A) from gum collected from several different trees in two orchards, (B) from gum collected off one tree (see Table).

	Gum A.	Gum B.
$[\alpha]_D^{20}$ (c, 2.4 as the sodium salt in water)	-27°	-25°
Equiv. (by titration with 0.1N-sodium hydroxide)	1228	1215
Furfuraldehyde	26%	25%
Uronic anhydride	—	14.7%
Galactan (from mucic acid determinations)	43%	44%

The samples from different trees are therefore substantially the same. The purified gum had a small iodine number (1.0 g. required 2.5 c.c. of 0.1N-iodine). [Found (crude gum): OMe, trace; N, nil.] The purified gum had a small methoxyl content (2.0%), probably owing to esterification during the purification process. Furfuraldehyde and uronic anhydride were determined after treatment of the purified polysaccharide with boiling 12% hydrochloric acid (Found: furfuraldehyde, 25.5; uronic anhydride or 2-ketohexonic acid, 14.7%). Methylpentose appears to be absent. [A substance yielding 14.7% of uronic anhydride or 2-ketohexonic acid and containing no other acidic residues should have an equivalent of 1197. Found by titration of the gum with alkali: equiv., 1222 (mean of two values).] This proportion of uronic anhydride accounts for 3.7% of the total furfuraldehyde, leaving 21.8% of furfuraldehyde contributed by the pentosan part of the polysaccharide, and since the greater part of the pentose present is *l*-arabinose (see below), the calculated anhydroarabinose content of the gum is approximately 44% (Calc. for a polysaccharide containing four pentosan units per repeating unit of equivalent 1190, 44.8%). Anhydrogalactose (estimated after oxidation to mucic acid), 43%.

Graded Hydrolysis of Egg-plum Gum.—(a) Egg-plum gum (50 g.) was heated with water (1½ l.) at 90–95°, the acidity of the solution being sufficient to bring about slow graded hydrolysis; the reaction was followed by polarimetric and iodometric observations: $[\alpha]_D^{20}$ -27° (initial value); -24° (40 mins.); -9° (3.1 hrs.); +32° (15.5 hrs.); +41° (22 hrs.); +47° (34 hrs.); +50° (50 hrs.). A much slower hydrolysis continued beyond this stage. The increase in iodine titre was followed by titration of portions of the solution with 0.1N-iodine by Baker and Hulton's method (*Biochem. J.*, 1920, 14, 754). Initial value (in c.c. 0.1N-iodine, calculated for 1 g. of gum) 2.5 c.c.; 6 c.c. (40 mins.); 15.5 c.c. (3.1 hrs.); 54 c.c. (15.5 hrs.); 58 c.c. (22 hrs.); 66 c.c. (34 hrs.); 72.6 c.c. (50 hrs.). The solution was evaporated at 40°/12 mm. to 500 c.c. and poured into alcohol (1½ l.); it then gave an alcohol-insoluble polysaccharide (A) (22.5 g.) which was washed with alcohol.

(b) *Reducing sugars obtained by graded hydrolysis.* The filtrate from (A) on concentration at 40°/12 mm. gave an acidic syrup which was dissolved in water, neutralised with barium carbonate, and filtered, and the filtrate poured into alcohol with stirring. The precipitated barium salt (B), which appeared to be the barium salt of the polysaccharide (A) which had escaped precipitation, was filtered off and the filtrate evaporated at 40°/12 mm. to a syrup which crystallised on standing. The crystalline solid (10.4 g.) was triturated with methyl alcohol and filtered off; it was identified as slightly impure *l*-arabinose, m. p. 154°; $[\alpha]_D^{20}$ +96° (c, 3.8 in water; equilibrium value); diphenylhydrazone, m. p. 194°. The filtrate from the crystalline solid on evaporation gave a syrup (C) (15.2 g.) which had $[\alpha]_D^{20}$ +38° and contained some oligosaccharide, since the iodine titre indicated the presence of only 9.3 g. of pentose. A furfuraldehyde determination indicated the presence of some 10.0 g. of pentose, whilst an arabinose estimation by means of diphenylhydrazine indicated the presence of approximately 5.0 g. of *l*-arabinose. Mucic acid was isolated after oxidation of a portion of the syrup with nitric acid, proving the presence of some 2.4 g. of galactose (free or combined). The syrup underwent further hydrolysis on heating with 0.5N-sulphuric acid for 1 hour. The optical rotation became constant at +60° and the iodine titre on a portion of the solution (A) showed that approximately 15 g. of reducing sugars were now present in solution. An estimation by means of diphenylhydrazine now showed the presence of 5.8 g. of *l*-arabinose, an increase of only 0.8 g. It can be inferred, therefore, that the oligosaccharide originally present contained *d*-galactose and *d*-xylose since the increase in reducing power of the solution is not due to increase of *l*-arabinose content but to an increase of *d*-galactose and *d*-xylose. A portion of the solution (A) after hydrolysis was neutralised with barium carbonate and filtered, and the filtrate evaporated to a syrup. *l*-Arabinose was removed from this syrup as its diphenylhydrazone, and the non-crystalline diphenylhydrazones remaining were then decomposed by warming with form aldehyde solution in the presence of acetic acid. The mixture was exhaustively extracted with ether and the aqueous solution evaporated to a syrup. [A portion of this gave the characteristic crystalline derivative of xylose, m. p. 210°, with a methyl alcoholic solution of benzaldehyde (see Breddy and Jones, *J.*, 1945, 738).] The syrup was boiled for 4 hours with 4% methyl alcoholic hydrogen chloride, and the solution was then neutralised with silver carbonate, filtered, and evaporated to a syrup which was methylated first by the thallium method (Menzies, *J.*, 1926, 937), and then with Purdie's reagents. The methylated sugars (4.0 g.) were distilled in a vacuum and gave a fraction (3.6 g.), b. p. 100° (bath temp.)/0.1 mm.; n_D^{18} 1.4438; $[\alpha]_D^{20}$ +53° in water. This fraction was hydrolysed with *N*-hydrochloric acid (50 c.c.) on the boiling water-bath. $[\alpha]_D^{20}$ fell from +53° to +44°. The free sugars were worked up in the usual manner and distilled in a vacuum; the distillate then crystallised. 2:3:4-Trimethyl *d*-xylose was recognised by its m. p. and mixed m. p. 91°, after recrystallisation from ether. The non-crystalline sugars gave some tetramethyl galactose anilide on heating with alcoholic aniline. This result, taken in conjunction with reducing values, furfuraldehyde yields, rotational values, and yield of *l*-arabinose diphenylhydrazone, indicates that the sugars produced on autohydrolysis consist of *l*-arabinose and *d*-xylose in the approximate proportion of three to one and that a small amount of galactose is also produced during the hydrolysis. A polysaccharide of equivalent weight 1222 and containing this amount of arabinose would yield 36.8% of arabinose on hydrolysis (Found: arabinose content, 32.4%).

(c) *Examination of the barium salt (B).* The barium salt (B) (10.4 g.) was obtained as a white powder

easily soluble in water, giving a yellow neutral solution, $[\alpha]_D^{20} +4^\circ$ (c. 3.3 in water). OMe, 3.0% (probably derived from adsorbed alcohol). It contained 11% of barium, gave 8.3% of furfuraldehyde on boiling with 12% hydrochloric acid, and on oxidation gave mucic acid equivalent to the presence of 50% of galactan. It was slightly reducing to Fehling's solution and reduced alkaline iodine (1 g. required 40.5 c.c. of 0.1N-iodine). On being heated with N-sulphuric acid for $3\frac{1}{2}$ hours the barium salt underwent hydrolysis with an increase in iodine titre; initial value (in c.c. of 0.1N-iodine per 1 g. of barium salt) 41 c.c.; 58 c.c. (1 $\frac{1}{2}$ hrs.); 65.4 c.c. (2 hrs.); 70.7 c.c. (3 hrs.); 74.4 c.c. (3 $\frac{1}{2}$ hrs., constant value). The change in rotation was not observable owing to the colour of the solution. The solution was neutralised with barium carbonate, filtered, and evaporated to a syrup, which was extracted with methyl alcohol. Concentration of the extracts gave a syrup which soon crystallised. Trituration with alcohol gave crystalline *d*-galactose, $[\alpha]_D^{20} +78^\circ$ in water, m. p. and mixed m. p. 164° , in 42% yield calculated on the weight of the syrup isolated. (6.65 G. of barium salt gave 2.7 g. of syrup.) The non-crystalline barium-free residue showed $[\alpha]_D^{20} +45^\circ$ (c. 1.22 in water) and was 50% galactose (calc. on the yield of mucic acid obtained after oxidation with nitric acid under standard conditions). Mannose appeared to be absent since no mannose phenylhydrazone could be isolated after treatment of a portion of the non-crystalline syrup with phenylhydrazine solution. The remaining sugar was not identified but may have been *d*-xylose. The above figures show that hydrolysis of the barium salt with N-acid produced 29% of *d*-galactose calculated on the weight of the original barium salt.

The barium salt (3.40 g.) remaining after methyl alcoholic extraction was obtained as a white powder, very soluble in water, giving a yellow solution which reduced Fehling's solution vigorously on boiling. 1 G. of barium salt reduced 39 c.c. of 0.1N-iodine; this is equivalent to a molecular weight of 512. The solution showed $[\alpha]_D^{20} +4^\circ$ (c. 1.0 in water) (Found: OMe, 3.0%, but this value is probably not significant). The barium content of the salt was 15.7%, and on oxidation with nitric acid, mucic acid was produced, in amount showing the presence of some 40% of galactose residues (Calc. for the barium salt of an aldobionic acid; Ba, 16.2; galactose residues, 42%).

(d) *Polysaccharide (A)*. This material (22.5 g.) was obtained as a white powder, easily soluble in water giving a brown solution with an acidic reaction to Congo-red. On boiling it with 12% hydrochloric acid, furfuraldehyde (8.1%) and carbon dioxide (equivalent to the presence of 26.0% of uronic anhydride) were evolved. $[\alpha]_D^{20} +24^\circ$ (in water, c. 0.7). The polysaccharide on being heated with nitric acid (*d* 1.2) gave mucic acid equivalent to the presence of some 50% of anhydrogalactose; this figure is low owing to the difficulty experienced in hydrolysing polysaccharide (*A*) completely. The equivalent (by titration with 0.1N-sodium hydroxide) was 640 (Calc. for a repeating unit containing three hexose residues and a uronic acid residue, 662). On titration with alkaline iodine by the method of Bergmann and Machemer, 1 g. of polysaccharide (*A*) required 23 c.c. of 0.1N-iodine.

Polysaccharide (*A*) (1.49 g.) underwent hydrolysis on heating at 90° with N-sulphuric acid (50 c.c.). $[\alpha]_D^{20}$ changed from $+28^\circ$ (initial value) to $+30^\circ$ (3 hrs., constant value). The iodine titre (in c.c. of 0.1N-iodine per g. of polysaccharide) was 23 c.c. (initial value); 47 ($\frac{1}{2}$ hr.); 57 (1 hr.); 73 (2 hrs.); 75 (3 hrs.). The cooled solution was neutralised with barium carbonate, filtered, and evaporated to dryness, and the residue exhaustively extracted with alcohol. Concentration of the extracts gave crystalline *d*-galactose (0.4 g.), m. p. 164° , $[\alpha]_D^{20} +80^\circ$ (c. 1.3 in water). The residual barium salt showed $[\alpha]_D^{20} \pm 0^\circ$ (c. 2.0 in water). On oxidation with nitric acid (*d* 1.2) it gave mucic acid equivalent to the presence of some 50% of anhydrogalactose, and contained 16.3% of barium (Calc. for a barium aldobionate: Ba, 16.2%).

The barium salt of the aldobionic acid from polysaccharide (*A*) underwent further hydrolysis with much decomposition on being heated at 95° with 4N-sulphuric acid for 24 hours. From the solution, after neutralisation with barium carbonate and filtration, *d*-galactose was obtained in crystals, m. p. 163° , $[\alpha]_D^{20} +77^\circ$ (c. 1.1, in water), and as its phenylmethylhydrazone, m. p. 190° . The barium salt of the uronic acid was identified as barium glucuronate (see below). The total percentage yields of *d*-galactose and barium glucuronate isolated were small, but the proof of the presence of these two compounds combined as an aldobionic acid is furnished by a study of the hydrolysis products of the methylated aldobionic acid.

Methyl heptamethyl aldobionate. The barium salt of the aldobionic acid (3.3 g.) was dissolved in water and the barium precipitated as sulphate by the addition of the calculated quantity of 0.1N-sulphuric acid. The solution was filtered, and the filtrate evaporated to a syrup which was simultaneously esterified and converted into the glycoside by boiling with 2% methyl alcoholic hydrogen chloride for 20 hours. This time of esterification was too long, since much hydrolysis to monosaccharides had taken place. The solution was neutralised with silver carbonate, filtered, and evaporated to a syrup which was methylated by means of thallium hydroxide and methyl iodide in the usual manner (for details, see Hirst and Jones, *loc. cit.*). The methylated material was extracted with acetone, the solvent boiled off, and the residual syrup (2.85 g., n_D^{20} 1.4545) distilled in a vacuum giving:

Fraction I (2.0 g.). Mainly monosaccharides, b. p. 130° (bath temp.)/0.001 mm.; n_D^{20} 1.4495.

Fraction II (0.69 g.). Methyl heptamethyl aldobionate, b. p. 180° (bath temp.)/0.001 mm.; n_D^{20} 1.4680; $[\alpha]_D^{20} +40^\circ$ (c. 1.3 in water) (Found: OMe, 51.3; equiv., 470. Calc. for $C_{20}H_{38}O_{12}$: OMe, 53.0%; equiv. 468).

The methyl heptamethyl aldobionate (Fraction II) (0.67 g.) was hydrolysed by boiling it with 2N-hydrochloric acid (50 c.c.) for 10 hours. The rotation ($[\alpha]_D^{20}$) rose from $+40^\circ$ to $+46^\circ$ in 3 hours, after which the solution became too dark for polarimetric observation. The cooled solution was neutralised with silver carbonate and filtered before and after the passage of hydrogen sulphide. The solution was then neutralised with barium carbonate and filtered, and the filtrate evaporated to a syrup which was exhaustively extracted with ether. The extracts on concentration gave a syrup (0.27 g.; $[\alpha]_D^{20} +65^\circ$ (c. 1.97 in water); OMe, 41%) which was mainly 2:3:4-trimethyl *d*-galactose, since after heating a portion of it with alcoholic aniline, the characteristic 2:3:4-trimethyl *d*-galactose anilide, m. p. and mixed m. p. 169° , was isolated. The rotation of the isolated sugar is low, probably because of contamination with a little 2:3:5-trimethyl *d*-galactose due to methyl furanoside formation on boiling the aldobionic acid with methyl alcoholic hydrogen chloride (cf. Challinor, Haworth, and Hirst, *loc. cit.*). The

sugar on oxidation with bromine water gave a lactone, $[\alpha]_D^{20} +95^\circ$ in water (initial value), which with liquid ammonia gave 2 : 3 : 4-trimethyl *d*-galactonamide, m. p. and mixed m. p. 165°.

The barium salt remaining after ether extraction was dissolved in water and barium removed as sulphate. The trimethyl *d*-glucuronic acid remaining in solution was oxidised with bromine water and the 2 : 3 : 4-trimethyl *d*-saccharic acid isolated in the usual manner and esterified with methyl alcoholic hydrogen chloride, and the dimethyl ester distilled in a vacuum; b. p. 120° (bath temp.)/0.01 mm. The distillate crystallised on standing. After separation on a tile, the methyl ester of 2 : 3 : 4-trimethyl *d*-saccharolactone was obtained, m. p. 110° not depressed on admixture with an authentic sample. This aldobionic acid was therefore *d*-glucuronosido-1 : 6-*d*-galactose.

Oxidation of the Gum with Potassium Periodate.—(a) The neutral gum (0.25 g.) was dissolved in water (250 c.c.) containing potassium chloride (1 g.) and sodium periodate (20 c.c.; 0.3M) and shaken for 10 days at 15°. Portions (10 c.c.) were taken out at intervals, ethylene glycol was added to destroy excess of periodate, and the formic acid was titrated with 0.01N-barium hydroxide [Titre: 0.65 c.c. (24 hrs.); 0.85 c.c. (72 hrs.); 0.9 c.c. (96 hrs.); 0.9 c.c. (192 hrs. constant)].

(b) The gum (1.399 g.) was dissolved in water (250 c.c.) containing potassium chloride (5 g.) and shaken for 8 days at 17° with sodium periodate (50 c.c.; 0.236M). At the end of this time titration showed that periodate equivalent to 125.6 c.c. of 0.1N-arsenite had been used in oxidising the gum.

In a similar experiment the gum (0.504 g.) required for oxidation periodate equivalent to 47.0 c.c. of 0.1N-arsenite. If, as indicated above, the gum contains four mols. of pentose, three mols. of hexose and one mol. of uronic acid per repeating unit of equivalent 1190, these figures show that an average of 1.07 mol. of formic acid is produced and an average of 5.2 mols. of periodate are consumed per repeating unit.

(c) The gum (0.5 g.) was oxidised in the usual manner for 200 hours. The solution was then cooled to 0° and filtered from potassium periodate. Slight excess of a solution of barium chloride was then added, and the precipitated barium iodate and periodate filtered off. The last traces of periodate and iodate were destroyed by bubbling sulphur dioxide through the filtrate which was then concentrated in a vacuum to a dry solid. A furfuraldehyde determination was then carried out in the usual manner.

In a second experiment the gum (0.5 g.) was oxidised as described above and the salts were then removed by dialysis [Found: Furfuraldehyde, 10.0 and 11.6. Calc. (for the loss of two pentose units and one uronic acid unit by periodate oxidation), 10.9; (for the loss of two pentose units only), 14.6%].

Hydrolysis of the oxidised gum. The oxidised gum (2.864 g.; see above for preparation) was hydrolysed by boiling with N-sulphuric acid (50 c.c.) for 48 hours. Since the solution became very dark and since the polysaccharide did not completely dissolve it was not possible to tell when the hydrolysis was completed. Sulphuric acid was precipitated by the addition of barium hydroxide, and the solution, after filtration, was concentrated in a partial vacuum to a solid. This residue was extracted exhaustively with methanol, and the extracts were concentrated under diminished pressure, to a syrup which was made up to 10 c.c. with water.

A galactose estimation on the solution (4 c.c.) gave 387 mg. of phenylmethylhydrazone, m. p. 186°. This is equivalent to approximately 1.5 mols. of galactose (per repeating unit of equiv. 1220) in the oxidised gum.

An arabinose estimation on the solution (2 c.c.) gave *l*-arabinose benzoylhydrazone (20 mg.), m. p. 180° (decomp.), equivalent to 33 mg. of *l*-arabinose, corresponding to 0.5 mol. of *l*-arabinose residues (per repeating unit of equiv. 1200) in the oxidised gum. This value is certainly low owing to the conversion of arabinose into furfuraldehyde during the hydrolysis, and the true figure is probably nearer one mol.

No xylose could be detected (as the dibenzylidene dimethyl acetal, Breddy and Jones, *J.*, 1945, 738).

Estimation of $-\text{CH}_2\text{OH}$ Groups in the Gum. (Method of Lindstedt, *Arkiv Kemi, Min. Geol.*, 1945, 20 A, No. 13.)—The gum (1.65 g.) was suspended in pyridine (30 c.c.) and triphenylmethyl chloride (5 g.) added, and the mixture heated on a water-bath at 100° for 12 hours. The mixture was then poured into cold water (200 c.c.) and the product filtered off and washed with alcohol and ether. The last traces of triphenylmethylcarbinol were removed by exhaustive extraction with alcohol and the product dried in a vacuum (yield 2.46 g.).

This product was shaken with concentrated sulphuric acid (10 c.c.) for 12 hours. The resultant thick black solution was poured into water and the crude triphenylmethylcarbinol filtered off, washed with water and dilute ammonia, and weighed. The weight of pure triphenylmethylcarbinol was then obtained by exhaustive extraction from the filtered solid with alcohol (Found: 1.05 g. A polysaccharide containing four primary alcohol groups per repeating unit of 1220 requires 1.04 g.).

202. The Hydrogenation of Furfuraldehyde to Furfuryl Alcohol and Sylvan (2-Methylfuran).

By JOHN G. M. BREMNER and RICHARD K. F. KEEYS.

Both sylvan and furfuryl alcohol are formed in the hydrogenation of furfuraldehyde in the vapour phase at atmospheric pressure with a copper catalyst. The alcohol is formed in the lower temperature range ($\leq 200^\circ$) and sylvan at intermediate temperatures ($\sim 250^\circ$). At higher temperatures ($\geq 300^\circ$) furfuryl alcohol tends once more to be the main product, but operation under these conditions leads to a rapid decline in catalyst activity. A regular change from the predominance of sylvan to that of furfuryl alcohol occurs with an increase in the amount of

alkali added to the catalyst. The presence of chromium oxides, on the other hand, favours the formation of sylvan. A theory of hydrogenation is proposed to account for these effects.

THE hydrogenation of furfuraldehyde in the vapour phase at atmospheric pressure is reported to give sylvan (2-methylfuran) in excellent yield (Burnette, *Iowa State Coll. J. Sci.*, 1944, 19, 9; Wilson, *J.*, 1945, 61) but other workers find that furfuryl alcohol may be the main product (Ricard and Guinot, F.P. 639,756; U.S.P. 1,739,919; D.R.-P. 528,820; Lazier, U.S.P. 2,077,422). Where this is so, an increased overall conversion of furfuraldehyde into sylvan may be obtained by the further passage of the alcohol over the catalyst or by working at a higher catalyst temperature:

The present work aimed at a more detailed and systematic investigation of the catalytic hydrogenation of furfuraldehyde in the vapour phase. The emphasis was placed on those factors which determine the main product to be furfuryl alcohol or sylvan. The results obtained in this and related work are considered from the standpoint of a theory of catalysis involving the intermediate formation of radicals.

EXPERIMENTAL.

Furfuraldehyde.—The commercial material was distilled at 30–40 mm. The colourless distillate had d_{20}^{20} 1.160, n_D^{20} 1.525, b. p. 161–162°, and contained 0.003% of sulphur.

Hydrogen.—Electrolytic cylinder gas was used containing about 0.001% of carbon monoxide.

Catalysts.—Five different copper catalysts were used.

Copper–aluminium alloy catalysts were prepared from chill castings. The casting was crushed to give $\frac{1}{4}$ – $\frac{1}{2}$ " diameter granules and then activated by treatment with 0.4% aqueous sodium hydroxide at 100°: this removes aluminium from the surface layers but leaves the granule size unchanged (cf. Bag and Egupov, *Uspekhi Khimii*, 1945, 14, No. 1, 56). In these catalysts both the original alloy composition and the amount of aluminium extracted may be varied. The alloys examined contained 34, 55, and 62% of copper and the aluminium extracted varied from 5 to 35%. After activation, the granules were washed with water to remove alkali. The catalyst may be stored under water until required.

Three copper–alumina catalysts were prepared. (A) Cu–Al₂O₃ was prepared by dehydrating alumina trihydrate to the monohydrate, moulding it into $\frac{1}{8}$ " \times $\frac{1}{8}$ " cylinders, and then dehydrating it to γ -Al₂O₃ by heating to 750°. The pellets were impregnated with copper nitrate to give 20% of Cu calculated on Al₂O₃. (B) Cu–Al₂O₃ was prepared by impregnating the commercial activated alumina supplied by the Aluminium Ore Company of America with copper nitrate to give a 20% copper content. (C) Cu–Al₂O₃ was a co-precipitated catalyst formed by addition of sodium carbonate to the mixed metal nitrates. The precipitate, after being washed, was heated to 350°, and then made into cylindrical pellets as above.

A copper chromite catalyst, magnesium promoted, was prepared in similar fashion to that described by Adkins, Connor, and Folkers (*J. Amer. Chem. Soc.*, 1932, 54, 1138). The Cu:Cr:Mg atom ratio in this catalyst was 1:1.05:0.04. The catalyst was used in the form of $\frac{3}{8}$ " \times $\frac{3}{8}$ " pellets.

The copper–alumina and copper–chromite catalysts were reduced by hydrogen before use. Care was taken in this operation not to exceed 400°, the maximum reduction temperature normally being 350°.

The pelleted catalysts may be modified by impregnation with soluble salts. This is readily accomplished by adding to the pellets a volume of aqueous solution such that complete absorption occurs.

Apparatus.—Experiments were carried out in a continuous manner by passage of furfuraldehyde vapour and hydrogen downwards through the catalyst mass. Two types of apparatus were used, in both of which the catalyst tube was vertical. In one, the catalyst, supported on silica granules, was contained in a "Pyrex" glass tube (42" \times 1½") (Fig. 1). The space above the catalyst was packed with silica granules, and acted as a vaporising and pre-heating zone. The temperature through the contact material was measured by a movable iron–constantan thermocouple held in a glass sheath disposed axially down the tube. The catalyst volume was normally 200 ml. The catalyst tube was surrounded by an iron tube heated by three electrical windings independently controlled. In the absence of a pronounced heat of reaction, this arrangement enables a uniform temperature to be maintained throughout the catalyst mass. This apparatus will subsequently be referred to as the "standard" one.

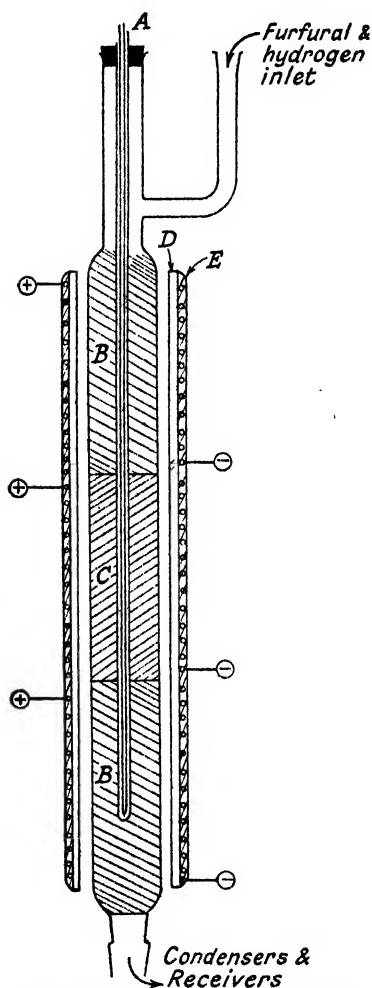

The other apparatus comprised a "Staybrite" metal catalyst tube (45" \times 1") to which was welded a metal jacket (Fig. 2). The catalyst arrangement was as in the glass tube but with the thermocouple sheath of "Staybrite" metal. The jacket was filled with liquid of b. p. suitable to maintain the reaction temperature. The vapour arising from the boiling liquid was condensed and returned. The liquid was heated to the b. p. by electrical windings on the exterior of the jacket. In exothermic reactions the heat evolved is removed by vaporisation of the surrounding liquid. The exterior surface of the catalyst tube is, in this way, held at a constant temperature regardless of the thermal nature of the reaction. This apparatus will subsequently be referred to as the "jacketed" type.

For both catalyst tube arrangements, furfuraldehyde was fed from a calibrated vessel by displacement with hydrogen evolved electrolytically. Hydrogen was admitted to the tube through an integrating rotary gas-meter capable of measuring rates up to about 100 l./hr. The products from the catalyst tube passed through a water-cooled double-surface condenser to a glass receiver. Unreacted hydrogen was passed through two receivers immersed in ice and water and two receivers immersed in solid carbon dioxide–methanol. Material entrained by the gas was recovered in these receivers. The volume of

unreacted hydrogen was measured by an integrating rotary gas-meter. The volume of hydrogen absorbed during the hydrogenation gives an excellent indication of the course of the reaction.

Analysis of Products.—Gaseous products were analysed in an Orsat apparatus. The liquid products were homogeneous if the furfuraldehyde were largely unchanged or if furfuryl alcohol was the main product. With sylvan as the main product, a lower aqueous layer was obtained. Small amounts of aqueous top layer were observed when the product was a mixture of sylvan, furfuryl alcohol, and some

unreacted aldehyde. In addition to sylvan and furfuryl alcohol, furan and pentanone-2 (Burnette, *loc. cit.*) were sometimes formed in small amount, and a pentanol in traces. Sylvan appears to be the precursor for pentanone-2.* Furfuraldehyde may suitably be estimated in a homogeneous product by titration of the acid liberated on reaction with hydroxylamine hydrochloride. This determination is carried out at room temperature, for, under reflux conditions, furfuryl alcohol also reacts with hydroxyl-

* Sylvan can be hydrogenated in good yield to pentanone-2 by using a copper catalyst (unpublished work).

amine hydrochloride liberating approximately 1 mol. of hydrochloric acid per mol. of alcohol. This effect is presumably due to a ring opening reaction (Pummerer, *Ber.*, 1923, 56, 999). Although both furfuraldehyde (Hughes and Acree, *Ind. Eng. Chem. Anal.*, 1934, 6, 123; *Cereal Chem.*, 1941, 18, 572) and furfuryl alcohol may react with bromine, the use of pyridine sulphate bromide as reagent (Fitelson, *J. Assoc. Off. Agric. Chem.*, 1943, 26, 499; Wilson and Nisbet, *Analyst*, 1946, 71, 183) limits the attack almost completely to furfuryl alcohol. (A fuller description of these analytical methods will shortly be published.)

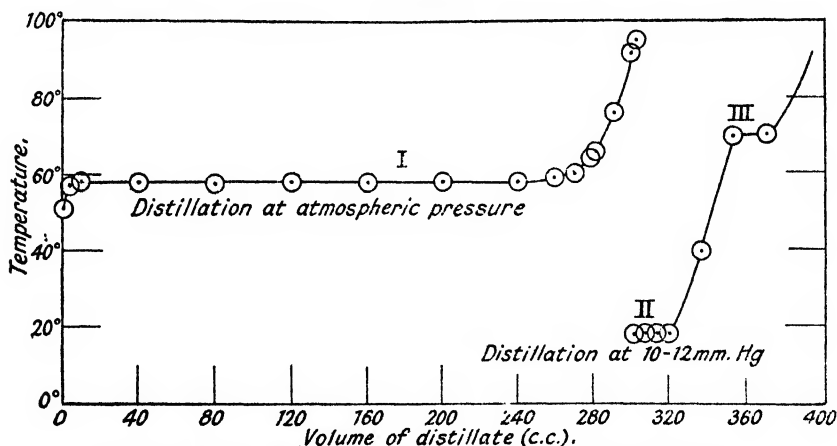

In addition to the chemical analysis of a homogeneous product, both it and the heterogeneous one were fractionated in a column equivalent to about 20 theoretical plates. When 100° was reached, the distillation was continued at about 20 mm. to separate unreacted furfuraldehyde from furfuryl alcohol (Dunlop and Trimble, *Ind. Eng. Chem.*, 1940, 32, 1000). Distillative analysis is not straightforward, for furan, sylvan (Pranishnikov and Genin, *J. Appl. Chem. U.S.S.R.*, 1940, 13, 140), pentanone-2, and furfuraldehyde all form azeotropes with water. As the water content of these azeotropes exceeds the water miscibility at room temperature the distillates separate into two layers (see Table I).

TABLE I.
Water azeotropes: boiling point and composition.

Compound.	B. p.	Water azeotrope.	
		B. p.	Water content (wt. %).
Furan	32°	30.5°	1.2
Sylvan	63	58	4.9
Pentanone-2	102.3	82.9	13.5
Pentanol-2	119.3	92.5	38.5
Furfuraldehyde	162	98	64
Furfuryl alcohol	171	—	—

The low b. p.s of furan and sylvan make their complete recovery during distillation difficult unless cooled condensers and receivers are used. A loss of 5% of sylvan under normal distillation conditions

FIG. 3.

I, Sylvan-water azeotrope; II, Furfuraldehyde-water azeotrope; III, Furfuryl alcohol.

readily occurs. When distilled, furfuraldehyde and furfuryl alcohol tend to polymerise, particularly where impregnated catalysts are used which decompose to give acid vapours on heating. This effect was minimised by addition of sodium carbonate to the receiver in which the liquid products were collected. The results of a typical distillation are given in Fig. 3.

It is clear that where a mixture of products is obtained a rigorous analysis is difficult. When either sylvan or furfuryl alcohol alone is formed the interpretation is greatly simplified.

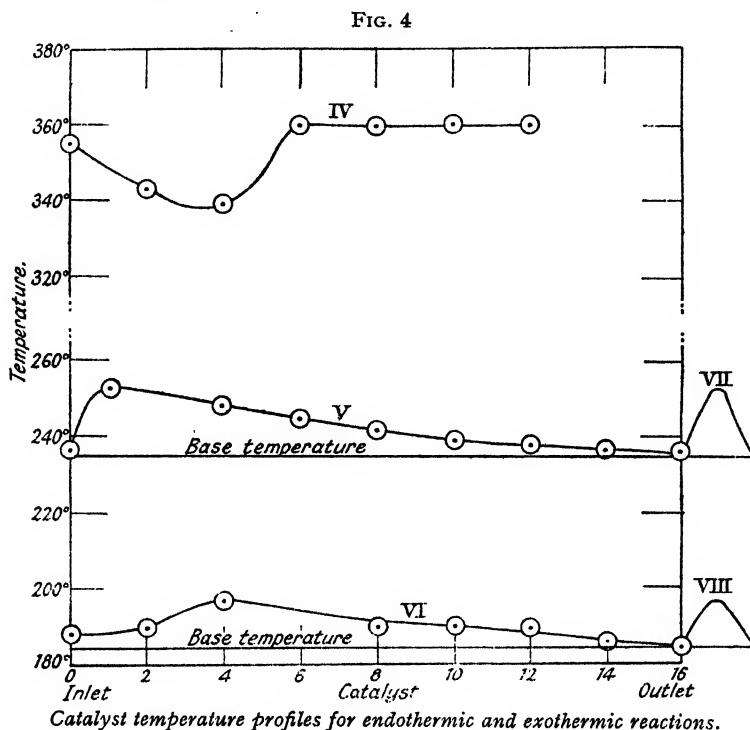

Results.—The terms pass conversion and yield are used to denote, respectively, the percentage of furfuraldehyde used in a single passage over the catalyst and the per cent. of the theoretical yield based on the amount of furfuraldehyde converted. As some 100–150 g. of furfuraldehyde were used in a normal experiment, yields were calculated on the weight and analysis of product obtained so as to counteract the large effect that small weight losses would otherwise have.

The small-scale experiments here described were, in part, the basis for the large-scale preparation of sylvan and furfuryl alcohol. The yields obtained equalled any now given.

Space velocity refers to the volume of furfuraldehyde fed per unit bulk volume of catalyst space per hour.

There is frequently some ambiguity in published work on catalytic reactions as to the interpretation to be placed on the temperature measurements. Normally, only one temperature is given, although it is

evident that the catalyst is not being worked under isothermal conditions. In this work the reaction temperature given is the maximum or peak temperature of the catalyst averaged from recorded half-hourly readings during experiments of a normal duration of 6 hours. In exothermic reactions the catalyst temperature rises rapidly at the beginning of the catalyst mass and then falls off slowly to a steady value which we term the "base" temperature. Typical temperature profiles measured longitudinally down the catalyst mass are given in Fig. 4. Curve VI shows the peak temperature to be only a few degrees above the base temperature for the hydrogenation to furfuryl alcohol ($\Delta H_{298}^0 = -18,500$ cal.). The higher exothermicity accompanying sylvan formation ($\Delta H_{298}^0 = -34,000$ cal.) is evident from curve V,

Longitudinal profiles: IV, Dehydrogenation and dehydration of isopropanol; V, Hydrogenation of furfuraldehyde to sylvan; VI, Hydrogenation of furfuraldehyde to furfuryl alcohol. Radial profiles: VII and VIII, Reactions as for V and VI.

Fig. 4, in which the temperature increment is about 20° . The peak temperature is the important one from the standpoint of reaction rate, while the base temperature controls the pass conversion in those reactions which are reversible under the conditions of the experiment. Reaction (1) is reversible in this sense, but not reaction (2). In addition to the longitudinal temperature profile there is a corresponding radial gradient at right angles. The radial gradient is a maximum at the peak temperature and becomes almost zero in the region of the base temperature. The maximum radial gradients are shown alongside curves VI and V in Fig. 4.

In an endothermic reaction the temperature falls at the beginning of the catalyst mass and rises slowly to the base temperature. This is shown in curve IV, Fig. 4.

DISCUSSION.

(1) *Equilibria in the Conversion of Furfuraldehyde into Furfuryl Alcohol and Sylvan.*—Only the scantiest of thermodynamic data are available for furfuraldehyde and furfuryl alcohol, and none has been published for sylvan. Early work by Landrieu, Bayloq, and Johnson (*Bull. Soc. chim.*, 1929, 45, 36) gives the heat of combustion of liquid furfuraldehyde and furfuryl alcohol. Miller (*Iowa State Coll. J. Sci.*, 1936, 10, 91) gives the free energy of formation of the liquids as -32 and -45.2 kcal., respectively, at 298°K . The latent heat of furfuraldehyde alone has been published (Crawford, *Ind. Eng. Chem.*, 1940, 32, 1280).

For the hydrogenation in the vapour phase of furfuraldehyde to furfuryl alcohol, we derive $\Delta H_{298}^0 = -18.5$ kcal. from the combustion data. In making this calculation we have taken the latent heat of the alcohol to be 1 kcal. greater than that of the aldehyde. From bond energies (Pauling, "The Nature of the Chemical Bond," 1939, Chaps. 2 & 4) we obtain $\Delta H_{291}^0 =$

—17.6 kcal. Both these values are higher than those given for similar reactions (Cubberley and Mueller, *J. Amer. Chem. Soc.*, 1946, **68**, 1149). The resonance energy of sylvan being taken as 24.5 kcal. (Pauling, *J. Amer. Chem. Soc.*, 1939, **61**, 1778), the hydrogenation heat of furfuraldehyde vapour to sylvan is found to be $\Delta H_{291}^0 = -34$ kcal.

The Nernst approximate theorem gives 98 and 60% pass conversion for reaction (1) at 0° and 300°, respectively, but the use of five times the theoretical amount of hydrogen raises the conversion to 96% at 250° at 1 atm.

The Nernst theorem applied to reaction (2) shows conversion to be substantially complete up to 300° at atmospheric pressure even with a stoichiometric ratio of hydrogen.

(2) *The Effect of Catalyst Temperature on the Course of Hydrogenation.*—Experiments carried out with copper-aluminium alloy catalysts (Table II) show the activity of the activated alloy to vary little with composition in the range 34–62% of copper (S.118, S.240, and S.244). The activity is, however, dependent on the amount of aluminium removed during the activation procedure. While it is very small for the original alloy (S.198), the removal of only 5% of aluminium (S.155) gives an active catalyst. Somewhat greater activity is apparent at higher extractions (S.118 and S.162), where, however, the copper surface tends to be removable by abrasion. A convenient extraction is 10–20% and, particularly with the lower value, a catalyst which has become inactive in use may be further extracted to restore the activity. When the activity declines owing to a deposition of carbonaceous material, a high activity results from treatment with air at about 400° followed by reduction with hydrogen (S.126).

The results in Table II show sylvan to be the major product with the alloy catalyst operated in the region of 250° regardless of either the alloy composition or the amount of aluminium extracted. The treatment with air of a catalyst whose activity has declined in use, due to the deposition of carbonaceous material (S.124), leaves unaffected the formation of sylvan in high yield, as does the exposure of the catalyst to air before reaction (S.123). Although these changes in catalyst composition and treatment failed to affect the formation of sylvan, yet experiments conducted at temperatures below about 250° effected a marked change in the products of hydrogenation. At about 200° (S.270) furfuryl alcohol becomes the major product. Whilst this behaviour is not unexpected from previous work, it was surprising to find that at 300° (S.124) the activity of the catalyst declined steadily during operation. Further, this decline in activity was accompanied by an increase in the yield of furfuryl alcohol and a decrease in that of sylvan. The activity of the catalyst could be completely restored by careful treatment with air at a

* The standard apparatus was used in all experiments except S.270, for which the jacket apparatus was used.

maximum temperature of about 400°. The peak temperature reached during such treatment is important since the alloy containing 55% of copper melts at 590°. A catalyst which has been worked at such temperatures shows obvious signs of fusion and is rendered permanently inactive.

The effect of temperature on the relative yields of sylvan and furfuryl alcohol was also examined

with the three Cu-Al₂O₃ catalysts A, B, and C. The results are shown graphically in Fig. 5. The hydrogenations were carried out under similar conditions of space velocity and hydrogen : furfuraldehyde ratio to those of Table II. To facilitate the temperature control in the lower range around 200° the jacketed apparatus with decahydronaphthalene (b. p. 190°) as temperature-control liquid was used in these experiments. The results closely resemble those of the alloy catalyst. At around 250° sylvan is formed in high yield, but at 200° furfuryl alcohol is the major product. In the region of 300° fairly rapid catalyst deterioration occurs, and with it a change from sylvan to furfuryl alcohol as the major product. The effect of temperature on pass conversion is shown in Fig. 6. At 200° conversion is not quite complete at a space velocity of 0.27 hr.⁻¹ (S.86) and falls from 80 to 48% (S.101) with an increase in space velocity to 0.66 hr.⁻¹, showing catalyst activity to be the limiting factor. At 250° and the normal space velocity of about 0.2 hr.⁻¹, conversion is practically complete. In the region of 300° the catalyst activity

FIG. 5.

The variations in yield of sylvan and furfuryl alcohol with temperature.

falls away progressively, so the pass conversion depends on the duration of the experiment. Catalysts which have deteriorated in this way may be restored in activity by treatment with air at about 400°, followed by reduction in hydrogen.

The variation in the ratio of sylvan to furfuryl alcohol with temperature is very similar for both the alloy and copper-alumina catalysts. The behaviour of the copper chromite catalyst is qualitatively similar. It is, however, very much less sensitive to temperature variations with regard both to the relative yields of furfuryl alcohol and sylvan and to the onset of deterioration.

The results for this catalyst, given in Table III, show sylvan to be the main product at both 250° and 300°. Even around 200° sylvan is still formed in high yield. A significant increase in the yield of furfuryl alcohol was obtained only by working at even lower temperatures, achieved by substituting furfuraldehyde (b. p. 162°) in the jacket for decahydronaphthalene as temperature-control liquid. In the higher temperature range, the onset of catalyst deterioration with the accompanying formation of furfuryl alcohol occurred only at temperatures near 350°. The results given by the copper chromite catalyst are included in Fig. 5.

(3) *The Effect of Alkalisng the Catalyst on the Ratio of Sylvan to Furfuryl Alcohol.*—At temperatures around 250° different preparations of alkali-precipitated copper catalysts gave sometimes

furfuryl alcohol and sometimes sylvan as the main product. It was considered that this might arise from a variation in the extent of washing of the precipitate, an appreciable amount of alkali being left in the final catalyst in some cases. To test this view, alkali additions were made to a 55% copper alloy catalyst. The results given in Table IV show the presence of alkali markedly to affect the course of the hydrogenation reaction.

Simple immersion of the activated alloy in sodium carbonate solution gave on hydrogenation a mixture of sylvan and furfuryl alcohol, and an almost complete change in the course of the action was achieved only by immersion under reduced pressure, to remove occluded gases. As the amount of alkali added under these conditions is not readily assessed, the A type Cu-Al₂O₃ was modified by successively increasing additions of sodium carbonate. This was accomplished by adding an alkaline solution of the requisite concentration to the pellets of volume such that complete absorption occurred, drying them, and then charging them into the catalyst tube. In this way catalysts containing 0.5, 2.5, 4, and 5% of Na₂CO₃ were prepared and examined at space velocities of about 0.2 hr.⁻¹ and a temperature of about 250°. The results obtained

are shown graphically in Fig. 7. Successive additions of alkali change the product from one consisting almost solely of sylvan, to a mixture of sylvan and furfuryl alcohol. At the higher

FIG. 7.

The effect of alkalis on the yields of sylvan and furfuryl alcohol.

alkali additions the alcohol is practically the sole product. That the formation of furfuryl alcohol in this way is due to a high degree of catalyst selectivity was shown by the passage of the alcohol over the catalyst. Sylvan was present in the product to the extent of only 4.8%.

As with temperature variations, the copper chromite catalyst was much less sensitive to alkali addition than the alloy and copper-alumina type catalysts (see Table V).

* Standard type apparatus.

The addition of 20% sodium carbonate gave some furfuryl alcohol in addition to sylvan. A striking transformation occurred during the experiment (S.280) in which the alkali content was increased to 40%. At the end of half the time projected for the experiment, during which sylvan was formed in excellent yield, a sudden change occurred and a homogeneous product was obtained containing 88.5% of furfuryl alcohol and 4.5% of furfuraldehyde. There is evidently a conditioning period for such a catalyst.

(4) *The Effect of the Presence of Carbon Monoxide in the Hydrogen on the Ratio of Sylvan to Furfuryl Alcohol.*—It was found that the presence of 7.2% of carbon monoxide in the reacting hydrogen left unchanged the formation of sylvan in high yield with a copper alloy catalyst at 250° and of furfuryl alcohol with an alkalisied A type copper-alumina catalyst at 257°. These results are to be considered with the known strong adsorption of carbon monoxide on copper (Pease, *J. Amer. Chem. Soc.*, 1923, 45, 2296) and its prevention at super-atmospheric pressure of the hydrogenation of aldehydes to alcohols in the Roelen reaction (U.S.P. 2,327,066). We conclude that under appropriate conditions both furfuraldehyde and furfuryl alcohol are strongly adsorbed on the catalyst surface.

(5) *Furfuryl Alcohol as Intermediate in the Formation of Sylvan.*—To show that furfuryl alcohol is an intermediate in the formation of sylvan it is necessary to work at incomplete conversion. The previous experiments show the alcohol to be formed in significant amount where conversion is incomplete owing either to a fall in catalyst activity with low operating temperature or to the incidence of catalyst deterioration at higher temperatures. Incomplete conversion may be achieved at the optimum temperature for the formation of sylvan either by using less than the stoichiometric amount of hydrogen or by working at high space velocities. To investigate the former, a copper alloy catalyst was operated at 250° using hydrogen to furfuraldehyde molar ratios of 1.3 and 0.93 (Expt. Nos. S.273 and S.269). The pass conversions were 78% and 32%, respectively. While for the former the sylvan : furfuryl alcohol ratio was 2 : 1, equal amounts of each were formed at the lower conversion.

A pass conversion of 87% was obtained at 258° by working the copper alloy catalyst at the high space velocity of 1.15 hr.⁻¹ (Expt. No. S.281). Under these conditions furfuryl alcohol constituted 26% of the product. This result is similar to that obtained by working with less than the stoichiometric amount of hydrogen (Expt. No. S.273).

The formation of furfuryl alcohol depends on the pass conversion in the manner to be expected of an intermediate product. Furthermore, the passage of the alcohol over the alloy catalyst gave sylvan in 86% yield (S.278).

(6) *Comparison of Furfuraldehyde with Acetone in Ease of Hydrogenolysis.*—Adkins recognises that carbonyl and hydroxymethyl groups are readily reducible to methylene and methyl groups only when attached to an aromatic nucleus (Gilman, "Organic Chemistry," 2nd Edition, I, 804, 820). This conclusion was based, in the main, on work carried out in the liquid phase at super-atmospheric pressure. That it also holds under the experimental conditions used in this work was demonstrated with acetone. Two experiments (S.164 and S.172) in which hydrogen and acetone were passed over a copper alloy catalyst at 249° and 246° gave liquid products which constituted 93.6 and 100% by weight of the acetone fed. *iso*Propanol and acetone dehydration products were present in the liquids. Evidently the extent of hydrogenolysis of acetone to propane is small.

(7) *Analysis of the Products of Hydrogenation of Furfuraldehyde.*—Sylvan and furfuryl alcohol, prepared in the course of this work, were redistilled to give samples for analysis (see

Table). The unsaturation of the alcohol was measured with the pyridine sulphate-bromine reagent (Found : 304 g. bromine/100 g. Calc. for C₅H₆O₃ : 325 g.).

Small amounts of pentanone-2 formed in some of the experiments were bulked together. The once-distilled material had d_4^{20} 0.809; n_D^{20} 1.393. It reacted with hydroxylamine hydrochloride under pressure (Found : CO, 30.0. Calc. for C₅H₁₀O : CO, 32.5%) (Smith and Bryant, *J. Amer. Chem. Soc.*, 1935, 57, 57).

(8) *General Discussion of Results.*—An interpretation of the results obtained in this work must account for the following facts : (a) The ease with which the carbonyl group in furfur-

aldehyde may be reduced to the methylene group. (b) The promotion of the formation of sylvan by chromium oxides and its suppression by the presence of alkali. (c) The probable formation of furfuryl alcohol as intermediate in the formation of sylvan. (d) The formation of furfuryl alcohol in the region of 200° and of sylvan at 250°. (e) The decline in catalyst activity when it is operated at temperatures of 300° or higher.

Observations related to some of those given above have been mentioned in the literature. Reduction of the carbonyl and the nitro-group by chemical means gives products whose nature depends on the acidity or alkalinity of the medium. Acid conditions result in complete removal of oxygen to give methylene and amino-groups. Reduction is less complete under alkaline conditions (Hickinbottom, "Reactions of Organic Compounds," Chaps. IV and VIII), thus qualitatively resembling item (b) above.

In the catalytic field the use of alkalis catalysts has received frequent mention in reactions involving the hydroxyl and the amino-group. Where an alcohol is a product or reactant the former group may be removed by a process of dehydration (3) or hydrogenolysis (4):

The dehydrogenation of alcohols to aldehydes and ketones is accompanied by little olefin formation if alkalis catalysts are used (B.P.P. 313,093, 318,124; U.S.P.P. 1,895,528, 1,984,884). Conversely the yield of alcohol formed by hydrogenation of aldehydes or ketones is not decreased by dehydration if alkali is present (F.P. 671,705; U.S.P. 1,895,515). In addition to suppressing the dehydration of alcohols, addition of alkali can increase the rate of hydrogenation of aldehydes and ketones to alcohols (Delépine and Horeau, *Compt. rend.*, 1935, 201, 1301; Reasenberg, Lieber, and Smith, *J. Amer. Chem. Soc.*, 1939, 61, 384) and of phenols to cyclohexanols (Armstrong and Hilditch, *Proc. Roy. Soc.*, 1922, 102, A, 21; McLaren, "Microfilm Abstracts," University Microfilms, Ann Arbor, 1944, V, No. 2, 39). The hydrogenation of furfuraldehyde in the liquid phase at super-atmospheric pressure is of interest as the presence of alkali causes the reaction to go smoothly in stepwise fashion through furfuryl alcohol to tetrahydrofurfuryl alcohol (U.S.P.P. 1,906,873, 2,082,025; and unpublished work). In the absence of alkali the hydrogenation rate is slow and the by-product formation large.

The addition of alkali to the chromite catalyst used in the hydrogenation of carbon monoxide improves the yield of alcohols higher than methanol (Morgan, Hardy, and Proctor, *J. Soc. Chem. Ind.*, 1932, 51, 1r).

That the loss of a hydroxyl group by the mechanism of equation (4) may also be suppressed by the presence of alkali has been shown by Griffith ("Contact Catalysis," Oxford Univ. Press, 1936, 69) in the case of phenol.

The apparently unrelated observations by Wilson (*J.*, 1945, 55, 61) that the copper chromite catalyst which hydrogenated furfuraldehyde to sylvan in good yield also catalysed the dehydration of tetrahydrofurfuryl alcohol to dihydropyran do, in fact, show the similarity of the two reactions depicted by equations (3) and (4). In demonstrating this similarity we should compare the activity of the catalyst for the dehydration of furfuryl alcohol with its ability to hydrogenolyse this alcohol to sylvan. For simplicity we have, however, examined the behaviour of the catalysts used in this work with isopropanol. The extent of its dehydration to propylene ($\Delta H = 16,200$ cal.) would be expected to be large with those catalysts that favour sylvan formation. The formation of acetone by dehydrogenation ($\Delta H = 13,700$ cal.) is to be expected with those catalysts that favour furfuryl alcohol formation. The results of these experiments carried out at 350° and a space velocity of 10 hr.⁻¹ are given in Table VI. Only 10 c.c. of catalyst were used to give approximately isothermal conditions, and the high space velocity was chosen so as to give incomplete conversion. These conditions tend to minimise effects due to the different activation energies of the dehydration and dehydrogenation reactions. The amounts of acetone and propylene formed are expressed by pass yield, i.e., pass conversion \times yield.

The effect of alkalisation in suppressing the dehydration of isopropanol is evident from the results given in Table VI. The alkalis catalyst, however, shows exceptional behaviour in that it suppresses the dehydration of isopropanol while catalysing the hydrogenolysis of furfuraldehyde. This observation is probably connected with the relative ease of dehydration of isopropanol and furfuryl alcohol, the former occurring the less readily (cf. Storch, *J. Amer. Chem. Soc.*, 1935, 57, 1395).

The use of alkali in the hydrogenation of compounds containing the amino-group includes the hydrogenation of nitrogen to ammonia (Larson and Brooks, *Ind. Eng. Chem.*, 1926, 18,

have a relatively long residence time on the catalyst, during which it will acquire a hydrogen atom to form sylvan.

As is to be expected, hydrogenolysis of tetrahydrofurfuryl alcohol which is much less stabilised by resonance does not, in fact, give tetrahydrosylvan (unpublished work). It seems probable that an appreciable proportion of the hydrogen required for this step is provided by adsorbed furfuryl alcohol molecules as represented by equation (9). A deficiency of hydrogen on a catalyst surface is probable in hydrogenations at atmospheric pressure, more especially where the reaction is carried out in the liquid phase.

The hydrogen atoms of adsorbed alcohol molecules are known to exchange readily (Farkas, *Trans. Faraday Soc.*, 1937, 33, 678). The hydrogen-transfer reaction represented by equation (9) may most simply be regarded as involving a free furfuryl radical formed by the reverse of reaction (5) (Waters, *J.*, 1946, 409; Hey, *Nature*, 1945, 156, 36). That the dehydration of furfuryl alcohol does, in fact, give sylvan and furfuraldehyde by a disproportionation reaction similar to (9) has been shown by Paul (*Bull. Soc. chim.*, 1935, 2, 2220):

Reaction (8) involving an electron transfer is regarded as a rate-determining one. The presence of chromium oxides will confer greater oxidising power or electron-acceptor characteristics to the catalyst and consequently make reaction (8) more likely. Conversely, alkali will increase the electron-donor characteristics of the catalyst and reduce the rate of the carbonium-ion formation. In these circumstances the alcohol formed will tend to be desorbed from the catalyst. The increased rate at which carbonyl compounds are hydrogenated by alkali addition in the liquid phase may be due to the increased catalyst area made available in this way.

The decreased effectiveness of alkali addition with copper chromite catalysts may be accounted for by the counterbalancing action of the chromium oxides. Conversely, we would expect the effects produced by alkalis on a catalyst to be minimised by addition of chromium oxides. This prediction has, in fact, been demonstrated experimentally for the dehydration of ethanol with an alumina catalyst at 350°. The reduction in pass conversion arising from the presence of 2% of sodium carbonate on the alumina is practically eliminated by the subsequent addition of 2% of chromium sesquioxide.

We account for the change in the main product from furfuryl alcohol to sylvan with rise in temperature by the rate-determining nature of reaction (8). The fall in activity observed by operating at even higher temperatures is due to the accumulation on the catalyst surface of non-volatile material of high molecular weight, presumably formed by the interaction of free radicals or ions with the furyl nucleus (Hammett, *op. cit.*, pp. 307, 373; Hey, *loc. cit.*). Such condensation reactions are particularly evident where stabilisation of the intermediates by resonance is possible. Such an explanation may suitably account for the deterioration in catalyst activity observed by Baljassny during his hydrogenation of acetophenone.

It is hoped to publish an account of the implications of this theory to a wide variety of catalytic reactions.

Some of the work described in this paper has formed the subject of patent applications.

The authors wish to express their appreciation to Dr. K. B. Hutton, Miss M. Allan, Dr. S. Beaumont, Dr. R. R. Coats, and especially Dr. D. G. Jones for their part in the early stages of this work. The preparation and examination of some of the catalysts used was carried out by Dr. P. W. Reynolds, Mr. D. M. Grudgings, and Mr. J. A. Mackenzie. Many helpful discussions on theories of catalytic action were held with Mr. D. A. Dowden.

203. *The Preparation, Properties, and Chlorination Products of Carbon Diselenide.*

By D. J. G. IVES, R. W. PITTMAN, and W. WARDLAW.

The action of methylene chloride vapour on heated selenium readily provides a good yield of carbon diselenide, which thus becomes accessible in considerable quantities for the first time. The vapour pressure of pure carbon diselenide has been measured over a range of temperatures and its behaviour with various reagents and solvents has been given preliminary study. It reacts vigorously with chlorine, giving a variety of products, of which selenium tetrachloride, *perchloromethylselenol*, *hexachlorodimethyl selenide* and *diselenide* have been isolated and characterised. Attempts to prepare selenocarbonyl chloride have not been successful.

THE only practical method hitherto available for the preparation of carbon diselenide depends on the interaction of hydrogen selenide with carbon tetrachloride in a hot tube (Grimm and Metzger, *Ber.*, 1936, **69**, 1356), but, contrary to the statement of these authors, this has been found to give an exceedingly poor yield of diselenide dissolved in excess of carbon tetrachloride, with which it forms an azeotrope. It has been found that methylene chloride vapour reacts with molten selenium with copious production of carbon diselenide, which has thus been prepared in the pure state in considerable quantities. It possesses interesting physical and chemical properties and presents a number of chemical problems which call for further investigation.

Methylene chloride vapour, carried in a stream of nitrogen, begins to react with molten selenium at 500° and produces carbon diselenide smoothly and rapidly at 550–600°. The deposition of carbon in the reaction zone tends to slow down and eventually stop the reaction, but this can be avoided by arranging for the supply of selenium in small quantities at a time to the reaction system. Copious evolution of hydrogen chloride occurs and some selenium is lost as a red, particulate cloud carried over in the gas stream: this difficulty may be partly obviated by the use of a fractionating column kept at about 200°. In a laboratory apparatus designed to meet these difficulties, the best yield of pure diselenide was 52% of the selenium used, without allowance for the considerable amounts of the element which should be easily recoverable from the reaction residues. In the routine preparation, however, a simpler apparatus giving a rather lower yield was found to be advantageous. Attempts to carry out the reaction solely in the vapour phase were unsuccessful, and the impression was gained that it occurs on the surface of liquid selenium.

Other hot-tube experiments of similar type gave no significant results. Methylene chloride gave no carbon disulphide with sulphur at 420°: carbonisation occurred and small amounts of hydrogen sulphide and hydrogen chloride were produced. No carbon sulphoselenide was formed by the interaction of methylene chloride with a mixture of selenium and ferrous sulphide at 425–560°, or by the action of methylene chloride and sulphur vapours on selenium at 500°: small amounts of carbon diselenide were produced in each case. Carbon ditelluride was not produced by the action of methylene chloride on tellurium at 450–680°. Methyl chloride with selenium at 400–550°, in addition to hydrogen selenide and hydrogen chloride, gave traces of a foul-smelling, lachrymatory, yellow liquid, which appeared to be different from carbon diselenide, but was not obtained in amount sufficient for characterisation.

Crude carbon diselenide was readily purified by distillation in steam, followed by distillation under either atmospheric or reduced pressure. It is a bright yellow, non-inflammable, highly refractive liquid (Grimm and Metzger, *loc. cit.*, report n_D^{20} 1.845) which does not wet glass. It has an intolerable odour, causes nose and lung irritation and lachrymation, and has a slight irritant action on the skin. On standing, it darkens, becoming brown, then black and deposits dark polymerisation products: loss of material due to this amounts to about 1% per month. The following physical properties were determined, values in parentheses being those previously recorded by Grimm and Metzger (*loc. cit.*): b. p. 125–126°/760 mm. (124°/760 mm.), m. p. (pentane thermometer) –40° to –45° (–45.5°), d_4^{20} 2.6824 (2.679), d_4^{25} 2.6626. Vapour pressures of the pure diselenide were determined, using a "spoon gauge" incorporated in a high-vacuum apparatus, care being taken to ensure the complete "outgassing" of the sample used and to avoid any possibility of decomposition of vapour during the usual sealing-off procedure. Manometric readings were corrected to 0°, sea-level, and latitude 45°. The results are shown in the table, together with vapour pressures calculated from the equation $\log_{10} P$ (mm.) = 7.9153 – 1987.4/ T , where T is the absolute temperature.

Temp.....	0.00°	5.07°	10.07°	15.07°	20.07°	25.06°	30.04°	35.04°	40.02°	50.01°
$P_{\text{obs.}}$, mm.	4.7	5.7	7.7	10.4	13.6	17.9	23.3	29.6	37.0	58.2
$P_{\text{calc.}}$, mm.	4.4	5.9	7.9	10.4	13.7	17.8	22.9	29.3	37.1	58.3

It will be seen that the vapour-pressure equation fits the experimental points with a mean deviation of ± 0.2 mm. and leads to an average latent heat of evaporation over this temperature range of 9092 cal./mole. Comparison with carbon disulphide has been made by Othmer's method (*Ind. Eng. Chem.*, 1940, **32**, 841), leading to an approximate latent heat of evaporation at the b. p. of 7855 cal./mole and an entropy of evaporation of 19.7 cal./deg./mole. Hildebrand's constant has been calculated as 28.5 (cf. carbon disulphide, 27.1).

Various observations have been made of the behaviour of carbon diselenide with solvents and reagents, in addition to those already recorded by Grimm and Metzger (*loc. cit.*). It is completely miscible with carbon tetrachloride, with which it forms a constant-boiling mixture

containing about 40% of the latter; it is also miscible in all proportions with carbon disulphide and toluene. These solvents appear to retard the polymerisation of the selenide. It is readily soluble in light petroleum (b. p. 60—80°), but in this case the polymerisation does not appear to be retarded. Medicinal paraffin dissolves carbon diselenide to about 25% by volume and the components show an upper critical solution temperature. The diselenide is very sparingly soluble in glacial acetic acid and also in ethanol, which appears to promote decomposition. It is insoluble in water and appears to suffer loss of stability under moist conditions: the upper aqueous layer rapidly becomes turbid. White phosphorus dissolves to a very large extent. Selenium oxychloride reacts violently with carbon diselenide, much elementary selenium being deposited with liberation of unidentified volatile products. Selenium monochloride reacts briskly after a period of induction, giving selenium and a volatile product of intolerable odour. Bromine reacts with a "quenching" sound, giving a clear red liquid which deposits a dark brown solid on standing. Dry hydrogen chloride has no apparent reaction and neither has the concentrated aqueous acid, from which the diselenide steam-distills on boiling. Concentrated nitric acid has little action in the cold, but destroys the diselenide on boiling, although the compound distills in the vapour of the boiling acid for a considerable time. Concentrated sulphuric acid has a more rapid action, but again unchanged selenide can be distilled from admixture for some time. Oleum produces rapid decomposition. Concentrated aqueous sodium hydroxide has little action in the cold, but dissolves carbon diselenide on heating, giving an orange solution. Alcoholic potash dissolves and destroys the diselenide rapidly and affords the best means of decontaminating apparatus which has contained it. Dry bleaching powder produces a vigorous exothermic reaction accompanied by the evolution of most aggressive vapours. It is apparent that there is a wide field of investigation still open in the chemistry of carbon diselenide, but the only reaction which opportunity has allowed us to study is that with chlorine.

Chlorine is absorbed rapidly in large amounts by carbon diselenide, with evolution of much heat. A great variety of interesting products appears to be formed: bright red and yellow solids, white red and black sublimates, red, yellow, and green liquids. Some of these are very unstable; a yellow solid deliquescing rapidly in air, with evolution of pink fumes, provides a striking example. Simplification of this complex reaction was achieved by carrying out chlorination in carbon tetrachloride, in which selenium tetrachloride is sparingly soluble, removal of the latter product by filtration, removal of carbon tetrachloride by distillation, rapid washing of the residue with water, and high-vacuum distillation. Four products were thus characterised with reasonable certainty, the chief of which was selenium tetrachloride. The others were *perchloromethylselenol*, $\text{CCl}_3\cdot\text{SeCl}$, a deep red liquid, b. p. 62°/23 mm., with a biting odour, fuming in air and hydrolysing fairly rapidly with water. *Hexachlorodimethyl selenide*, $(\text{CCl}_3)_2\text{Se}$, was obtained in small amount. It is a white, crystalline solid, m. p. 37°, with an odour resembling that of hexachloroethane. It is soluble in benzene and carbon tetrachloride, and is intermediate in volatility between the above selenol and *hexachlorodimethyl diselenide*, which was obtained in very small yield as a yellow oil, b. p. 126°/0.5 mm., with a camphoraceous odour and an irritant action on the skin. Further treatment with chlorine appears to convert the diselenide into the selenol and selenium tetrachloride.

It is remarkable that no success was achieved in obtaining selenocarbonyl chloride as a product of this chlorination reaction, and although high volatility would not be expected in this compound, it is noteworthy that a volatile selenium compound with a most aggressive and quite intolerable odour has been produced in a number of ways which might conceivably lead to this compound. Such a substance was present in the carbon tetrachloride distilled from the carbon diselenide chlorination mixture, was produced by the interaction of selenium monochloride with carbon diselenide and by the reaction of the latter with dry bleaching powder, and also by the reduction of perchloromethylselenol with anhydrous stannous chloride in carbon tetrachloride solution. The chlorination of selenoformaldehyde was also attempted as a source of selenocarbonyl chloride, but other products, not yet investigated, were produced in this reaction.

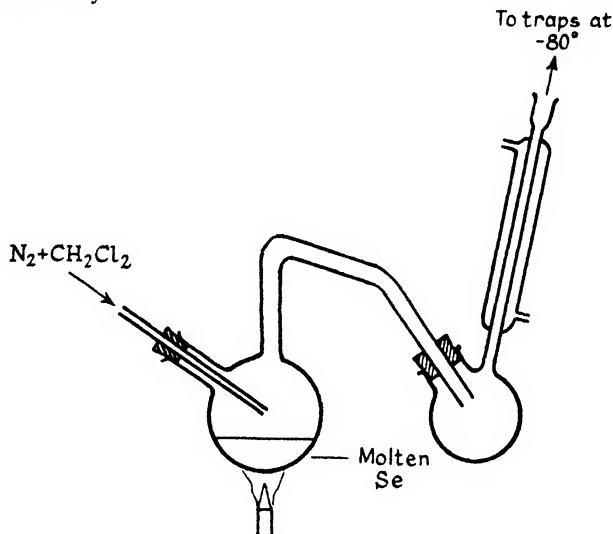

It is clear that much work remains to be done in this interesting field of selenium chemistry, but it is attended by the disadvantage of the rather toxic and highly disgusting nature of the products obtained.

EXPERIMENTAL.

Carbon Diselenide.—Various experimental conditions and types of apparatus indicated the desirability of removing the reaction products as rapidly as possible from the zone of reaction between methylene chloride and molten selenium in order to minimise the deposition of carbon. Too high a temperature

and too extensive a heated zone were also to be avoided from this point of view. These requirements, and the desirability of a reasonable production rate, made unavoidable the loss of considerable amounts of selenium in the form of red smoke, which could ultimately, however, be recovered. The simplest satisfactory apparatus consisted of a Pyrex retort, delivering into a receiver, as indicated in the figure. Methylene chloride vapour, provided by a vessel containing the liquid maintained at a suitable fixed temperature, was delivered above the surface of molten selenium in a stream of dry nitrogen. The crude product was steam-distilled directly from the receiver, separated from the aqueous layer, dried (CaCl_2), and, for purposes of the physical measurements, fractionated through a 30-cm. vacuum-jacketed Dufton column under reduced pressure (b. p. $46^\circ/50$ mm.) (Found: Se, by combustion, 92.77; by Kjeldahl, 92.96. Calc. for CSe_2 : Se, 92.93%).

Chlorination of Carbon Diselenide.—Preliminary attempts at separation of the products of reaction indicated the importance of analyses for selenium and chlorine at frequent intervals. The most rapid and satisfactory methods were found to be as follows: for selenium, digestion with oleum and perhydrol (Kjeldahl), followed by dilution, reduction with sulphur dioxide and then with hydroxylamine hydrochloride, and gravimetric estimation as elementary selenium; for chlorine, treatment with sodium in liquid ammonia, followed, after evaporation of ammonia, by treatment with alcohol, boiling with dilute sulphuric acid, treatment with sulphur dioxide, further boiling, filtration, and precipitation with silver nitrate in the usual way.

The course of a chlorination experiment was as follows. Carbon diselenide (50 g.), dissolved in carbon tetrachloride (300 c.c.) in a 1-l. flask fitted with a mechanical stirrer and reflux condenser, was treated with dry chlorine until an increase in weight of 81 g. was reached (approx. 4 moles of Cl_2). A large precipitate of whitish solid was produced, together with red and yellow sublimes. The reaction mixture was set aside for two days, and darkening occurred. The solid was removed by filtration, washed at the pump with carbon tetrachloride, and proved to be selenium tetrachloride (Found: Se, 35.9; Cl, 64.0. Calc. for SeCl_4 : Se, 35.8; Cl, 64.2%). The filtrate was carefully fractionated, a vacuum-jacketed Dufton column being used with controlled reflux-ratio head. The first distillate, consisting mainly of carbon tetrachloride, was yellow-brown, contained considerable amounts of selenium, and had an intolerable odour reminiscent of carbonyl chloride, but no definite compound could be isolated from it. The residue from this fraction was completely distilled at 200 mm. The second distillate was shaken with water, separated, dried (CaCl_2), and redistilled in vacuum. The first fraction consisted of *perchloromethylselenol* (17 g.), b. p. $62^\circ/23$ mm. (Found: Se, 33.75; Cl, 60.7; *M*, cryoscopic, in C_6H_6 , 247. CCl_3SeCl requires Se, 33.9; Cl, 60.9%; *M*, 233). Further distillation yielded a pale yellow oil which solidified in the condenser. This and the residue in the distillation flask were removed and examined separately. The liquid residue was removed to a smaller apparatus and redistilled (b. p. $124\text{--}129^\circ/2$ mm.). Admission of air to the apparatus caused oxidation, with production of green and red substances. In view of this difficulty and the low volatility of the substance, redistillation was effected in a high vacuum. A small homogeneous fraction consisting of *hexachlorodimethyl diselenide* was obtained (Found: Se, 40.2; Cl, 53.8; *M*, cryoscopic in C_6H_6 , 392. $\text{C}_2\text{Cl}_6\text{Se}_2$ requires Se, 40.0; Cl, 53.9%; *M*, 395). The solid condensate from the previous distillation was recovered by dissolving in carbon tetrachloride. The solvent was removed, and the residue sublimed in a high vacuum, giving a small yield of *hexachlorodimethyl selenide* (Found: Se, 25.3; Cl, 67.4; *M*, cryoscopic in C_6H_6 , 317. $\text{C}_2\text{Cl}_6\text{Se}$ requires Se, 25.0; Cl, 67.4%; *M*, 316).

204. The Relation of Yttrium to the Lanthanons: A Study of Molecular Volumes.

By JOSEPH K. MARSH.

When yttrium concentrates near samarium or neodymium in the lanthanon series, molecular and not ionic states are believed to be involved. The molecular volume of yttrium acetylacetone is found to approximate to that of neodymium, and to be larger than those of the lanthanons similar to yttrium in ionic size. Nevertheless, yttrium basic nitrate and ferricyanide were found to give molecular volumes indicating a polar crystalline state, though they accumulate at the position of No. 61 on fractionation. The basic nitrate will be un-ionised in nitrate solution, and triply ionised ferricyanide is unlikely to reach the solubility product with Y^{+++} or Ln^{+++} . The reaction to form these ferricyanides is therefore believed to be molecular in character, thus accounting for the behaviour of yttrium. This reasoning can be extended to other slightly soluble yttrium salts with multivalent anions (e.g., phosphate, chromate, and ferrocyanide) showing similar behaviour.

IN a previous communication (Marsh, this vol., p. 118) the suggestion was made that yttrium on passing from the ionic to the covalent state underwent a relatively larger increase in size on comparison with the lanthanon elements. For instance, yttrium and holmium ions are approximately of the same size, but sometimes yttrium shows behaviour indicating a resemblance to neodymium and samarium, which elements have larger ions than holmium. Certain sparingly soluble and basic salts incline to show yttrium associating with elements larger than holmium. A reason for this behaviour is now sought.

It is firmly established that a progressive fall in ionic radius with increasing atomic number occurs between lanthanum and lutecium. This is found by X-ray determination of the crystal-lattice size, and is confirmed by determination of the molecular volumes of the sulphate octahydrates (von Hevesy, *Z. anorg. Chem.*, 1925, **147**, 217; **150**, 68), though in both these instances the first two or three members of the rare-earth group lack isomorphism with the remainder. In the oxide series the yttrium ion falls in size between those of dysprosium and holmium, and in the sulphate series between holmium and erbium ions. The latter is the position usually taken by yttrium in a fractional crystallisation series, indicating an important correlation between ionic and molecular sizes and chemical properties in the lanthanon series. Generally, yttrium is isomorphous with holmium and erbium, but exceptions are known. For example, the 2-bromo-5-nitrobenzenesulphonates of yttrium crystallise with $10H_2O$ similarly to those of samarium and gadolinium and in contrast to the dodecahydrates of erbium and ytterbium. Direct evidence of yttrium having at times a larger volume than holmium is now sought by measurement of molecular volumes: it has already been reported in the case of the atomic volumes of the metals (Bommer and Hohmann, *Z. anorg. Chem.*, 1939, **241**, 268). The crystalline basic nitrates and the ferricyanides have been examined throughout a representative series of earths. These are two good examples of salts by the formation of which rapid accumulation of yttrium with neodymium and samarium, and separation from the "yttrium earths", is brought about, but in both instances the molecular volume of the yttrium salt proved to have a value which placed yttrium in sequence in the usual ionic position among the other elements, i.e., near to holmium. The crystals must therefore be regarded as polar in type. The acetylacetones, however, gave evidence that this covalent yttrium compound has in fact a larger molecular volume than that of the usual associates of yttrium in its ionic state.

The basic nitrates are obtained by crystallisation from hot concentrated nitrate solutions. They are decomposed by water, but in nitrate solution they appear to be stabilised by suppression of ionisation by a common-ion effect, on removal of which they hydrolyse. They may be regarded as existing in a non-ionising solvent only. If, then, they exist in solution in a non-ionised form, it is not surprising to find that the solubility of yttrium basic nitrate has a value interpolating in the lanthanon series at the position of No. 61, the same as is found in the case of the atomic volume, or the acetylacetone molecular volume. We must then postulate a transition from a non-ionic to an ionic state upon crystallisation, based on the evidence of the crystal molecular volumes. The precipitate produced by boiling a nitrate solution with sodium nitrite, being chiefly the basic nitrate $Y_8O_{14}(NO_3)_4 \cdot 17H_2O$ (Fogg and James, *J. Amer. Chem. Soc.*, 1922, **44**, 397), appears to be a similar case to the basic nitrate $Y_6O_8(NO_3)_6 \cdot 20H_2O$ produced by crystallisation (James and Pratt, *ibid.*, 1910, **32**, 873).

In the case of the ferricyanides, high concentrations of potassium ferricyanide and up to 200 g./l. of yttrium oxide in the form of chloride can be brought together in cold solution without any precipitate forming, yet the solubility of $YFe(CN)_6$ at 20° is represented by only

0.602 g./l. of Y_2O_3 (Prandtl and Mohr, *Z. anorg. Chem.*, 1938, **236**, 243). Seeding is ineffective in producing a precipitate. Indeed, the seed may dissolve, but on gentle warming a precipitate forms slowly, which has a molecular volume indicative of an ionic state of yttrium. An irreversible reaction takes place, since the precipitate will not redissolve appreciably on cooling. The formation of yttrium ferricyanide according to the simple equation $Y^{+++} + 3Cl^- + 3K^+ + Fe(CN)_6^{---} = YFe(CN)_6 + 3KCl$ cannot be expected to take place, since triple ionisation of ferricyanic acid is necessitated. Thus, in general, it will be seen that molecular reactions may be expected where the alternative involves the existence of a multivalent anion or the production of a series of unknown intermediates. Ferrocyanide, chromate, and phosphate are other examples of salts of yttrium showing closer resemblance to neodymium than to holmium in fractionations. All are compounds having low solubilities and are salts of multivalent acids incapable of complete ionisation.

A series of acetate molecular volumes have been measured, and as anticipated yttrium takes an ionic position in the series. The densities and molecular volumes of the four series of salts examined are presented in Table I. The values for the acetylacetonates might be doubled, since the molecules are known to be double in solution. No high degree of accuracy for the molecular volume determinations can be claimed for these last compounds, but the results are sufficiently reliable to prove the point that the value for yttrium does not lie in the sequence close to those of the other yttrium earths, but is larger and more nearly equal to that of neodymium. The fused acetylacetonate compounds were usually somewhat basic as indicated by high oxide contents on ignition. The densities found must therefore tend to be high and the molecular volumes low. For Table I, data have been selected from the italicised data of Table II,

sometimes by averaging, but more often by selection of the value relating to the acetylacetonate sample which showed the nearest approach to theoretical oxide content. A fairly constant density increment of 0.03 between even-numbered elements from neodymium to dysprosium inclusive is found, and the excess oxide, except in the case of neodymium but with the addition of yttrium, is also fairly constant, so that this sequence of elements is comparable, and they lend mutual support. It was found that lanthanum acetylacetonate was slightly volatile. Its true oxide content cannot therefore be determined by ignition and the low contents recorded in Table II are suspect. On the other hand, the low densities for the acetylacetonate leading to an unexpectedly high value for the molecular volume are consistent with the presence of excess acetylacetonate, but the melts were not gummy, as would be expected in that event, but quite vitreous. This in other instances accompanied deficient acetylacetonate.

If we examine the molecular volumes of isomorphous compounds of neodymium and ytterbium, we find the values for the latter smaller than those of the former by the following percentages: sulphates 7.0, ferricyanides 6.5, acetates 5.6, ethyl sulphates 3.0. The fall in the case of the acetylacetone compounds appears to be under 2%.

EXPERIMENTAL.

Densities.—In the case of the acetates, suspension of crystals in mixtures of chloroform and bromoform and determination of the density of the liquid by a Westphal balance proved very satisfactory. With basic nitrates and ferricyanides, determinations of the loss of weight in chloroform was more satisfactory, and the acetylacetones were weighed in water. A platinum bucket of 2 ml. capacity and about 0.5 g. of substance were used in these three cases. The accuracy of the method depended chiefly on the proper release of air bubbles before weighing in liquid.

Acetates, $E(C_2H_3O_2)_3 \cdot 4H_2O$.—The neodymium salt was prepared by evaporation of a solution in a desiccator. It is rather efflorescent, but large crystals may be grown. The other acetates crystallised readily from warm neutral solutions, and are stable.

Basic Nitrates, $E_2O_5(NO_3)_8 \cdot 20H_2O$ (James and Pratt, *loc. cit.*).—The normal slightly acid nitrates were boiled to dryness and heated till some decomposition had occurred. The vitreous melts were then poured into cold water and gave clear hot solutions which deposited crystals overnight. It was found possible to prepare the samarium basic nitrate if only slight decomposition of the melt was permitted, for its range of stability is small. The melt was vitreous like the others. Neodymium gave no vitreous melt or basic nitrate crystals. The nitrate creamed at once when decomposition began.

The density of the erbium salt as given in Table I is an extrapolation from the experimental value using material containing 2% of yttrium. Only a very small sample of dysprosium basic nitrate was available, and the single determination of the molecular volume appears low. Other values are believed to be correct within ± 2 . Three determinations for yttrium were within 1 part in 500.

Ferricyanides, $EF_6(CN)_6 \cdot 4H_2O$.—Neutral chloride solutions containing 100 g./l. of oxide were treated at 40–50° dropwise with cold saturated potassium ferricyanide with mechanical stirring and the precipitate which formed was collected, washed, and dried. The precipitates of samarium and gadolinium could not be obtained as coarsely crystalline as in the other cases. Prandtl and Mohr (*Z. anorg. Chem.*, 1938, **236**, 243; **237**, 160) found some variation in the amount of water of crystallisation in the different salts but apparently without loss of isomorphism: e.g., for the lanthanum salt they found $4.5H_2O$, but the molecular volumes shown in Table I are calculated for $4H_2O$ in all cases.

Acetylacetone Compounds, $E[CH(CO \cdot CH_3)_2]_3$.—Acetylacetone (3 g. in 10 ml. of alcohol) was added to an equivalent of lanthanum acetate in 50 ml. of cold water, and ammonia added dropwise with stirring, excess being avoided. The acetylacetone compound soon separated and was collected with suction. Especially in the case of ytterbium, acetylacetone washing appeared to decompose the precipitate. Washing was therefore omitted or kept to a minimum, but the products were well pressed on filter-paper and dried in a desiccator. Melting points were found to be close to known values without further purification.

Lanthanum acetylacetone. The precipitate appeared to be basic and did not give a clear melt unless one or two drops of acetylacetone were added before fusion; then clear melts giving a vitreous, pale amber solid were obtained.

Neodymium acetylacetone. This, m. p. 150–152°, like the lanthanum compound, appeared basic (Found: Nd_2O_3 , 39.04. Calc.: Nd_2O_3 , 38.11%) and failed to give a clear melt without additional acetylacetone.

Gadolinium acetylacetone. This compound, m. p. 140°, was likewise basic (Found: Gd_2O_3 , 40.53. Calc.: Gd_2O_3 , 39.83%). Unlike preparations previously reported it did not appear to contain any water of crystallisation (1 and 2 H_2O , Jantsch and Meyer, *Ber.*, 1920, **53**, 1594; 3 H_2O , Sarkar, *Bull. Soc. chim.*, 1926, **39**, 1390). If damp acetylacetones were heated to their m. p. they reacted with water to form the hydroxides and failed to give satisfactory melts.

Ytterbium acetylacetone. This had m. p. 114° but the melt was not clear. It did not gas at the m. p., as occurred with the higher-melting acetylacetones melting near the b. p. of free acetylacetone. It was not considered likely that satisfactory density determinations by weighing the finely crystalline compounds in water could be made, nor could organic liquids be used, since they have solvent action. Quantities of about 1 g. were therefore fused in an oil-bath in thin 10-mm. specimen tubes with, when necessary, the addition of one or two drops of acetylacetone to give clear melts. Loss of acetylacetone occurred at the m. p. Unless a slight loss did occur, the fused mass cooled to a stiff gum which would quickly crystallise if kneaded. But when slightly basic, a vitreous resin was obtained in one or more large pieces on breaking the tubes, and the densities of these pieces could be obtained with a fair degree of accuracy by weighing in water. There was, however, always some devitrification or hydroxide formation on the surface in contact with water, with loss in weight. The surface deposit was removed so far as possible after determining the density, and the percentage of oxide contained in the material was obtained by ignition. In some cases burning the oxide free from carbon was difficult. The char required to be broken down with a glass rod in the silica crucible before final ignition. Particular care was taken to obtain reliable data for yttrium. The three analyses are in satisfactory agreement but the third shows a high density and high oxide content and low molecular volume. The final figure adopted in Table II for the molecular volume of yttrium acetylacetone is therefore likely to be a little low.

Dr. A. S. Russell is thanked for permission to use this laboratory.

205. *The Preparation and Ultra-violet Light Absorption of Some Substituted Phenylpropenyl- and Styrylmethyl-carbinols and 1-Phenylbutadienes.*

By ERNEST A. BRAUDE, E. R. H. JONES, and E. S. STERN.

In connexion with kinetic studies on anionotropic rearrangements (see following paper), carbinols of the type $C_6H_4R \cdot CH(OH) \cdot CH:CHMe$, where $R = o\text{-Me}, m\text{-Me}, p\text{-Me}, p\text{-F}, p\text{-Cl}, p\text{-Br}$ and $p\text{-MeO}$, have been prepared by Grignard condensations of appropriate aromatic halides with crotonaldehyde. Quantitative conversions into the isomers $C_6H_4R \cdot CH:CH \cdot CH(OH)Me$ are effected by treatment with hydrochloric acid in aqueous dioxan. Dehydration of the carbinols by distillation from potassium hydrogen sulphate yields the dienes $C_6H_4R \cdot CH:CH \cdot CH:CH_2$, which are characterised by their adducts with maleic anhydride and with benzoquinone. The ultra-violet light absorption properties of the various compounds are discussed and provide evidence for the smaller polarisability of the phenyl nucleus as compared with the ethylenic bond.

THE extension of the kinetic studies on anionotropic rearrangements carried out in these laboratories (cf. Braude and Jones, *J.*, 1946, 122, 128; Braude, Jones, and Stern, *ibid.*, p. 396) required the preparation of substituted phenylpropenylcarbinols (I) and of the isomeric styrylmethylcarbinols (II). Only the parent carbinols (I and II, $R = H$) have been described

hitherto. A number of substituted phenylvinylcarbinols have been prepared by Burton and Ingold (*J.*, 1928, 904) and Burton (*ibid.*, p. 1650), but the lower mobility of phenylvinyl- as compared with phenylpropenyl-carbinol (Braude, Jones, and Stern, *loc. cit.*) indicated that the vinylcarbinols would be less valuable for kinetic studies than their propenyl homologues.

The simplest route to phenylpropenylcarbinols is by the Grignard condensation of the appropriate aryl halides with crotonaldehyde. Qualitative data in the literature (cf. Runge in Schmidt, "Chemie in Einzeldarstellungen," Vol. 16, Part I, Stuttgart, 1932) indicate that the reactivity of aryl halides towards magnesium varies in the order $ArCl < ArBr < ArI$. Furthermore, it is said to be enhanced by methyl substituents, decreased by halogen and methoxyl substituents, and completely destroyed by substituents, such as the nitro-group, exerting only electron-attracting effects. The range of compounds accessible by this method is therefore limited. In the present work it was found that the bromotoluenes and *p*-bromofluorobenzene all reacted readily with magnesium in the presence of a small amount of ethyl bromide. *p*-Dibromobenzene and *p*-bromoanisole reacted somewhat less readily, while with *p*-dichlorobenzene the reaction was incomplete even after four days. With *p*-diiodobenzene the metal slowly disappeared after prolonged treatment, but in contrast to the findings of Bruhat and Thomas (*Compt. rend.*, 1926, 183, 297; cf. Mihailescu and Caragea, *Chem. Zentr.*, 1930, I, 2248) no significant yield of condensation product with crotonaldehyde could be obtained, some of the diiodobenzene being recovered unchanged, together with iodobenzene, and intractable residues. Attempts to make *p*-bromonitrobenzene react with magnesium, using Grignard's technique (*Compt. rend.*, 1934, 198, 625) of adding an equimolecular proportion of ethyl bromide simultaneously with the unreactive halide, only yielded unchanged starting material and small amounts of *pp'*-dibromo-azo- and -hydrazo-benzenes (cf. Werigo, *Annalen*, 1873, 165, 190; Hepworth, *J.*, 1920, 117, 1004; Slotta and Heller, *Ber.*, 1930, 63, 3030). Again, the bromomagnesium derivative of *p*-bromophenol, though soluble in anisole at 100°, failed to react with magnesium.

The Grignard derivatives of the first eight halides mentioned were condensed with crotonaldehyde, special attention being paid to temperature control during the addition of the aldehyde and during the decomposition of the complex with ammonium chloride, in order to avoid the formation of the isomeric styryl derivatives. Thus, even in the preparation of the much less readily isomerised phenylvinylcarbinol, the product contains some cinnamyl alcohol unless the last two stages are carried out below 20°. It is known that, *vice versa*, cinnamylmagnesium chloride reacts partly in the form of phenylvinylcarbiniylmagnesium chloride (Gilman and Harris, *J. Amer. Chem. Soc.*, 1927, 49, 1825) and it may well be, therefore, that the Grignard derivatives themselves undergo some equilibration.

The substituted phenylpropenylcarbinols were isolated in good yields as viscous liquids or low-melting solids. In view of their ready isomerisation in the presence of acids, traces of the latter were excluded by drying over, and distilling from traces of, potassium carbonate.

In the absence of these precautions, some of the rearranged styrylmethylcarbinols and phenylbutadienes are invariably produced, and considerable resinification occurs. This is particularly noticeable with the highly mobile *p*-anisylpropenylcarbinol.

Rearrangement of the phenylpropenylcarbinols was effected by treatment with hydrochloric acid in aqueous dioxan, the corresponding styryl isomers being obtained in almost quantitative yields. In aqueous alcohol a mixture of the carbinols and their ethyl ethers is produced (cf. Braude, Jones, and Stern, *loc. cit.*) and kinetic data (see following paper) indicate that with the chloro- and bromo-carbinols some etherification occurs before, as well as during, rearrangement.

Treatment of the phenylpropenylcarbinols with α -naphthyl isocyanate in the absence of solvent gave the naphthylurethanes of the corresponding styrylmethylcarbinols. In petrol solution and in the presence of traces of pyridine, mixtures of the isomerised and unisomerised naphthylurethanes were obtained. The latter could not be isolated pure, however, as they readily rearrange to the former on attempted recrystallisation. The two types of derivatives are distinguished by their characteristic ultra-violet light absorption (see below).

It has long been known that methylstyrylcarbinol can readily be dehydrated to phenylbutadiene (Klages, *Ber.*, 1902, **35**, 2650); in fact, early workers experienced considerable difficulty in obtaining the pure carbinol by the condensation of cinnamaldehyde with methylmagnesium iodide because they omitted to eliminate traces of iodides and of acids which act as dehydration catalysts. In the present work, the rearrangement and subsequent dehydration of the phenylpropenylcarbinols were conveniently carried out in one stage by means of potassium hydrogen sulphate. The carbinol together with about one-tenth of its weight of sulphate is preheated to 80–100° at 10^{-3} mm. until the vigorous rearrangement reaction sets in (5–30 mins.). In the case of the *p*-anisyl- and *p*-bromophenyl-propenylcarbinols the solid styryl isomers are deposited on the sides of the vessel. The temperature is then raised and the phenylbutadiene distils over as the dehydration proceeds. The ease of dehydration appears to vary in the same order as that of the isomerisation of the parent carbinols. The substituted phenylbutadienes are highly refractive liquids or low-melting solids which were purified by micro-fractionation from traces of potassium hydrogen sulphate or by crystallisation, and showed the expected selective high-intensity absorption in the ultra-violet (see below). On heating or on exposure to light and air, they readily resinify, and some difficulty was experienced in obtaining correct microanalyses, particularly for the tolyl compounds.

The dienes were characterised by their reactions with maleic anhydride and with *p*-benzoquinone in benzene solution, giving respectively the phenyltetrahydrophthalic anhydrides and the phenyl-1 : 4 : 9 : 10-tetrahydronaphtha-5 : 8-quinones (cf. Diels and Alder, *Ber.*, 1929, **62**, 2081, 2337). The tetrahydro-quinones are pale yellow owing to their absorption band near 3650 Å. (see below), but slowly change on standing into the colourless phenyl-1 : 4-dihydronaphtha-5 : 8-quinols. This double prototropic change is facilitated by exposure to light, and the ease with which it occurs again appears to parallel that of the isomerisation of the phenylpropenylcarbinols. Thus the *p*-anisyl derivative does not even show the expected light absorption maximum at 3650 Å. in hexane, chloroform, or benzene solution; maxima near 3300 Å. expected for the 1 : 4-dihydronaphthalene derivative (cf. Morton and de Gouveia, *J.*, 1934, 916) appear instead, and only the colourless quinol can be recovered from the solution. Since the last two solvents are not appreciably transparent to light of wave-lengths shorter than 2350 and 3000 Å. respectively at the cell thickness used (1 cm.), the wave-length of the photochemically active light seems to be within the region of the 3650 Å. band expected for the tetrahydronaphthaquinone.

The light absorption properties of the various compounds were determined in the region 2150–4000 Å. In the phenylpropenylcarbinols (Table I), the phenyl and ethylene chromophores are in isolated positions, and would therefore be expected to contribute independently to the ultra-violet light absorption (cf. Braude, *Ann. Reports*, 1945, **42**, 105). The selective absorption of the ethylenic double bond lies well below 2150 Å., and the absorption of the carbinols in the region examined should therefore be closely similar to that of the corresponding substituted toluenes, as is found to be the case.

In the styrylcarbinols (Table II, Figs. 2 and 3), the essential chromophore is the styrene system. Styrene exhibits two bands in the region examined, at 2450 and 2920 Å. (Pestemer, Langer, and Manchen, *Monatsh.*, 1936, **68**, 326), which can be assigned to the conjugated system and to the partial phenyl chromophore respectively. The styrylcarbinols exhibit similar bands, showing small bathochromic displacements of 10–180 Å. due to the substituents, except that a *p*-fluoro-group produces a hypsochromic shift of 30 Å. In the naphthylurethanes

(Table III) the absorption originating in the naphthyl residue is superimposed on the styryl absorption and the difference in the absorption of the naphthylurethanes of the styrylcarbinols and of methanol coincides with the absorption of the styrylcarbinols themselves.

3. $\text{Ph}\cdot\text{CH}\cdot\text{CH}\cdot\text{CH}\cdot\text{CH}_3$.
4. $\text{Ph}\cdot\text{CH}\cdot\text{CHMe}\cdot\text{O}\cdot\text{CO}\cdot\text{NH}\cdot\text{Naphthyl}$.

(In ethanol.)

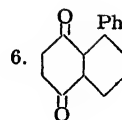

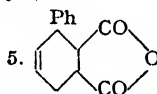

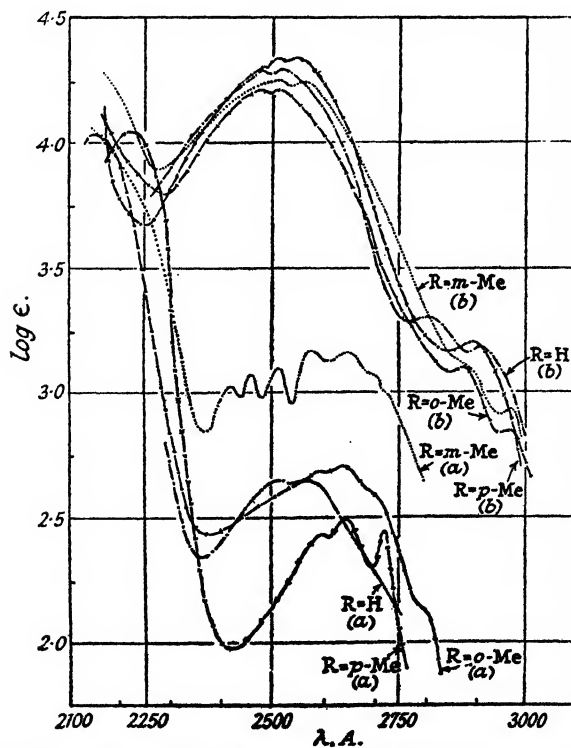

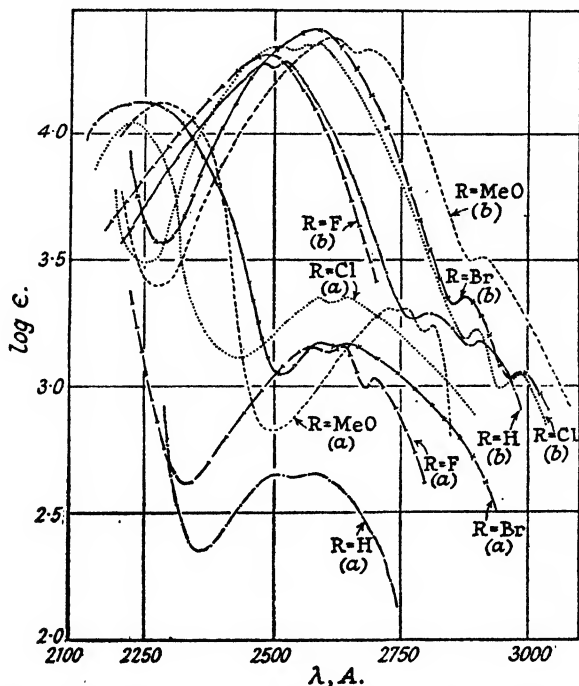

FIG. 2.

- (a) $\text{R}\cdot\text{C}_6\text{H}_4\cdot\text{CH}(\text{OH})\cdot\text{CH}\cdot\text{CHMe}$ and (b) $\text{R}\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{CH}\cdot\text{CH}(\text{OH})\text{Me}$.
(In ethanol.)

The phenylbutadienes (Table IV, Figs. 4 and 5) give rise to resolved absorption bands around 2200, 2800, and 3100 Å. The last two may be ascribed respectively to the phenylbutadiene and to the partial phenyl chromophore, while the first probably represents a summation of the low wave-length phenyl bands and absorption due to the partial butadiene chromophore. The effects of methyl, chloro-, and bromo-substituents on the 2800 Å. bands is smaller even than in the styryl system, while the fluoro-group again has a hypsochromic effect of 30 Å., and the methoxy-group a bathochromic effect of 110 Å. In the maleic anhydride

FIG. 3.

(a) $p\text{-R}\cdot\text{C}_6\text{H}_4\cdot\text{CH}(\text{OH})\cdot\text{CH}:\text{CHMe}$ and (b) $p\text{-R}\cdot\text{C}_6\text{H}_4\cdot\text{CH}:\text{CH}\cdot\text{CH}(\text{OH})\text{Me}$.
(In ethanol.)

adducts (Table V), the phenylchromophore is again isolated from the other unsaturated groups in the molecule and the absorption is very similar to that of the phenylpropenylcarbinols. The absorption curves of the benzoquinone adducts (Table VI) are a summation of those due

to their separate phenyl and dihydro-quinone systems, the latter giving rise to bands near 2500 and 3600 A., *i.e.*, displaced by *ca.* 200 A. with respect to those shown by the open-chain diacetyl-ethylene system (Braude, *J.*, 1945, 490) (Fig. 1).

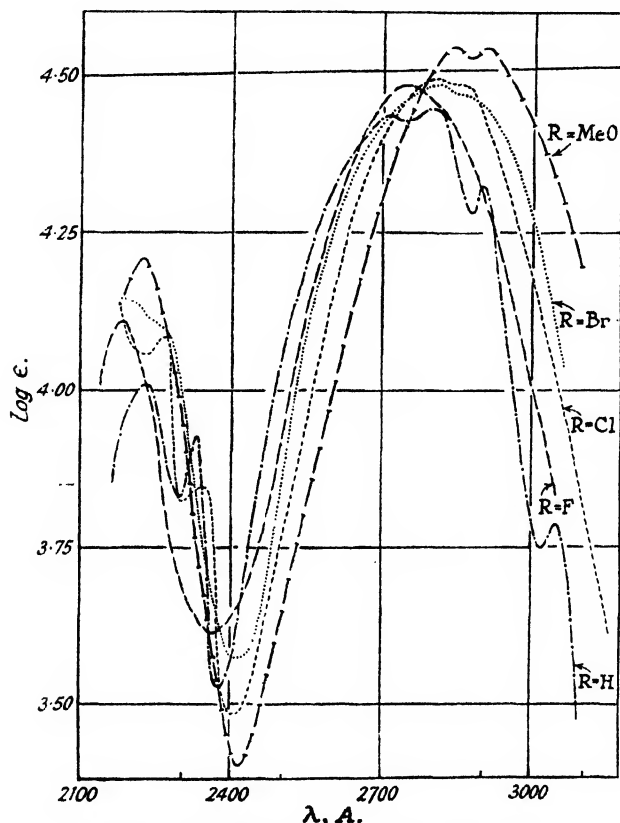

FIG. 4.

The variochromic effects of the nuclear substituents on the principal bands in the phenyl-propenylcarbinols, styrylmethylcarbinols, and phenylbutadienes are summarised in Table VII.

(The exact values of $\Delta\lambda$ are somewhat arbitrary owing to the vibrational structure. The highest peaks have been taken as characteristic of a group, and where two peaks of equal intensity are shown, the one at higher wave-length has been used for computing $\Delta\lambda$.) These effects are generally smallest (10–50 Å.) for a methyl substituent, a little larger (10–90 Å.) for the halogen groups, and largest (70–180 Å.) for the methoxyl group. A number of other regularities appear, but their generality is too limited to warrant separate discussion. The fact, however, that the variochromic effects of nuclear substituents in the styryl and phenylbutadiene systems are no greater than in the phenyl one and smaller than in corresponding

systems where the substituents are directly attached to acyclic ethylenic double bonds (cf. Bowden, Braude, and Jones, *J.*, 1946, 948) is of interest. Since the conjugating and transmitting capacity of a group is related to its polarisability (cf. Braude, *loc. cit.*), it provides spectral evidence for the lower polarisability of the phenyl nucleus as compared with an aliphatic ethylenic group.

EXPERIMENTAL.

(Light-absorption data are only given when not included in Tables I—VI.)

o-Tolylpropenylcarbinol (I; R = *o*-Me).—Freshly distilled crotonaldehyde (20 g.) in ether (40 c.c.) was added to *o*-tolylmagnesium bromide (from Mg, 6.5 g.) in ether (250 c.c.) during one hour at 0°; the solution was then stirred for 3 hours and treated with excess of ammonium chloride solution. Isolation of the product with ether, drying over anhydrous potassium carbonate, and distillation from a trace of potassium carbonate yielded *o*-tolylpropenylcarbinol (30.5 g.), b. p. 61°/0.001 mm., n_D^{20} 1.5392 (Found: C, 81.2; H, 8.7. $C_{11}H_{14}O$ requires C, 81.45; H, 8.7%).

o-Methylstyrylmethylcarbinol (II; R = *o*-Me).—Treatment of the above carbinol (1.5 g.) with 0.01M-hydrochloric acid in 60% aqueous dioxan (50 c.c.) for 12 hours at 30° yielded *o*-methylstyrylmethylcarbinol (1.35 g.), b. p. 66°/0.005 mm., n_D^{20} 1.5590 (Found: C, 81.75; H, 8.55. $C_{11}H_{14}O$ requires C, 81.45; H, 8.7%). The *α*-naphthylurethane (0.6 g.), obtained by treating the carbinol (0.33 g.) with *α*-naphthyl isocyanate (0.35 g.), crystallised from petrol (b. p. 80–100°) in needles, m. p. 104° (Found: C, 79.9; H, 6.5; N, 4.2. $C_{22}H_{21}O_2N$ requires C, 79.75; H, 6.4; N, 4.2%).

1-(*o*-Tolyl)buta-1 : 3-diene.—*o*-Tolylpropenylcarbinol (4 g.) was distilled from potassium hydrogen sulphate (0.8 g.) at 10⁻² mm. The diene after fractionation had b. p. 37°/0.01 mm., n_D^{20} 1.6008 (Found: C, 91.0; H, 8.5. $C_{11}H_{12}$ requires C, 91.6; H, 8.4%). The maleic anhydride adduct (0.65 g.) was obtained by refluxing the diene (0.5 g.) with maleic anhydride (0.25 g.) in benzene (3 c.c.) for 5 minutes. It crystallised from petrol (b. p. 80–100°) in fine needles, m. p. 92° (Found: C, 73.9; H, 5.8. $C_{15}H_{14}O_3$ requires C, 74.35; H, 5.3%).

p-Benzoquinone adduct. A solution of the diene (5.0 g.) and *p*-benzoquinone (3.5 g.) in benzene (15 c.c.) was boiled for a few minutes. On cooling, and evaporation of the solvent under reduced pressure, crystals separated which were washed with a little methanol to remove a small amount of quinhydrone. Recrystallisation from petrol (b. p. 80–100°) afforded pale yellow plates of 1-(*o*-tolyl)-1 : 4 : 9 : 10-tetrahydronaphthaquinone (3.7 g.), m. p. 93.5° (Found: C, 80.9; H, 6.25. $C_{17}H_{16}O_2$ requires C, 80.95; H, 6.4%). On allowing the quinone (1 g.) to stand overnight with acetic anhydride (25 g.) and zinc chloride (0.5 g.) and dilution with water, 1-(*o*-tolyl)-1 : 4-dihydronaphthaquinol diacetate (1 g.) was obtained; it crystallised from petrol (b. p. 80–100°) or alcohol, and had m. p. 141° (Found: C, 74.9; H, 6.1. $C_{22}H_{20}O_4$ requires C, 74.9; H, 6.0%). Light absorption in alcohol: Maxima at 2180, 2650, and 2720 Å., ϵ = 25,000, 800, and 720, respectively.

m-Tolylpropenylcarbinol (I; R = *m*-Me).—Freshly distilled crotonaldehyde (9.5 g.) in ether (50 c.c.) was added to *m*-tolylmagnesium bromide (from Mg, 3.2 g.) during one hour at 0°, and the solution stirred for 3 hours. Working up in the usual manner and distillation from a trace of potassium carbonate yielded *m*-tolylpropenylcarbinol (17 g.), b. p. 76°/0.01 mm., n_D^{20} 1.5384 (Found: C, 81.8; H, 8.7. $C_{11}H_{14}O$ requires: C, 81.45; H, 8.7%).

m-Methylstyrylmethylcarbinol (II; R = *m*-Me).—Treatment of the above carbinol (1.5 g.) with 0.01M-hydrochloric acid in 60% dioxan (50 c.c.) for 24 hours at 30° yielded *m*-methylstyrylmethylcarbinol (1.30 g.), b. p. 69°/0.005 mm., n_D^{20} 1.5608 (Found: C, 81.7; H, 8.65. $C_{11}H_{14}O$ requires C, 81.45; H, 8.7%). The *α*-naphthylurethane crystallised from petrol (b. p. 80–100°); m. p. 96° (Found: C, 79.8; H, 6.6; N, 4.2. $C_{22}H_{21}O_2N$ requires C, 79.75; H, 6.4; N, 4.25%).

1-(*m*-Tolyl)buta-1 : 3-diene.—*m*-Tolylpropenylcarbinol (2.5 g.) was distilled from potassium hydrogen sulphate (0.25 g.) at 10⁻² mm. Fractionation of the product from potassium hydrogen sulphate (0.1 g.) yielded the diene (1.8 g.), b. p. 80°/0.005 mm., n_D^{20} 1.5980 (Found: C, 89.5; H, 8.5. $C_{11}H_{12}$ requires C, 91.6; H, 8.4%). The maleic anhydride adduct was obtained by treating the diene (0.5 g.) with maleic anhydride (0.3 g.) in benzene (3 c.c.). Crystallisation from light petroleum (b. p. 60–80°) yielded the adduct (0.7 g.) in long needles, m. p. 78° (Found: C, 74.35; H, 5.8. $C_{15}H_{14}O_3$ requires C, 74.35; H, 5.8%).

p-Tolylpropenylcarbinol (I; R = *p*-Me).—Freshly distilled crotonaldehyde (35 g.) in ether (70 c.c.) was added to *p*-tolylmagnesium bromide (from Mg, 12 g.) in ether (300 c.c.) during one hour at 0°, and the solution stirred for 3 hours. Isolation of the product in the usual manner afforded *p*-tolylpropenylcarbinol (65 g.), which crystallised from light petroleum (b. p. 40–60°) in needles, m. p. 55° (Found: C, 81.55; H, 8.65. $C_{11}H_{14}O$ requires C, 81.45; H, 8.7%).

p-Methylstyrylmethylcarbinol (II; R = *p*-Me).—Treatment of the above carbinol (1 g.) with 0.001M-hydrochloric acid in 60% aqueous dioxan (50 c.c.) for 15 hours at 30° yielded *p*-methylstyrylmethylcarbinol (0.86 g.), which crystallised from light petroleum (b. p. 40–60°) in needles, m. p. 43° (Found: C, 81.3; H, 8.55. $C_{11}H_{14}O$ requires C, 81.45; H, 8.7%). The *α*-naphthylurethane crystallised from petrol (b. p. 80–100°) in needles, m. p. 135°, or from methanol, m. p. 127° (Found: C, 79.45; H, 6.4; N, 4.05. $C_{22}H_{21}O_2N$ requires C, 79.75; H, 6.4; N, 4.25%).

1-(*p*-Tolyl)buta-1 : 3-diene.—*p*-Tolylpropenylcarbinol (2 g.) was distilled from potassium hydrogen sulphate (0.2 g.) at 10⁻² mm. The diene, b. p. 78°/0.005 mm., solidified at room temperature and after crystallisation from aqueous methanol had m. p. 26° (Found: C, 90.6; H, 8.55. $C_{11}H_{12}$ requires C, 91.6; H, 8.4%). The maleic anhydride adduct was obtained by treating the diene (1.5 g.) with maleic anhydride (1 g.) in benzene (10 c.c.). Crystallisation from petrol (b. p. 80–100°) yielded the adduct (2.3 g.) in long needles, m. p. 117° (Found: C, 74.6; H, 5.8. $C_{15}H_{14}O_3$ requires C, 74.35; H, 5.8%).

p-Benzoquinone adduct. Treatment of the diene (2.2 g.) with *p*-benzoquinone (1.8 g.) in benzene (10 c.c.) afforded *p*-tolyl-1 : 4 : 9 : 10-tetrahydronaphtha-5 : 8-quinone (2.8 g.), which crystallised from

petrol (b. p. 80–100°) in pale yellow plates, m. p. 114° (Found: C, 81.4; H, 6.3. $C_{17}H_{14}O_2$ requires C, 81.0; H, 6.4%).

p-Fluorophenylpropenylcarbinol (I, R = *p*-F).—*p*-Bromofluorobenzene (58 g.) (Schieman and Pilarsky, *Ber.*, 1931, 64, 1343) in ether (250 c.c.) was added slowly to a suspension of magnesium (8.0 g.) in ether (150 c.c.) containing ethyl bromide (0.5 g.) and stirred for 4 hours in an atmosphere of nitrogen. Freshly distilled crotonaldehyde (23 g.) in ether (50 c.c.) was added to the ice-cold suspension during 2 hours, and stirring continued overnight. On working up in the usual manner, *p*-fluorophenylpropenylcarbinol (37 g.) was obtained, b. p. 59°/0.001 mm., n_D^{20} 1.5175 (Found: C, 72.2; H, 7.0. $C_{18}H_{11}OF$ requires C, 72.25; H, 6.7%). Active hydrogen (Zerewitinoff): 1.02.

p-Fluorostyrylmethylcarbinol (II; R = *p*-F).—Treatment of the above carbinol (1.5 g.) with 0.01M-hydrochloric acid in 60% aqueous dioxan (50 c.c.) for 36 hours at 30° yielded *p*-fluorostyrylmethylcarbinol (1.4 g.), b. p. 78°/0.01 mm., n_D^{20} 1.5411, which solidified on standing at room temperature and after crystallisation from light petroleum (b. p. 40–60°) had m. p. 42° (Found: C, 72.3; H, 6.95. $C_{10}H_{11}OF$ requires C, 72.25; H, 6.7%). The α -naphthylurethane crystallised from petrol (b. p. 80–100°) in needles, m. p. 116° (Found: C, 75.5; H, 5.7; N, 4.1. $C_{21}H_{18}O_2NF$ requires C, 75.2; H, 5.4; N, 4.2%).

1-(*p*-Fluorophenyl)buta-1:3-diene.—*p*-Fluorophenylpropenylcarbinol (2.5 g.) was distilled from potassium hydrogen sulphate (0.25 g.) at 10⁻² mm. The product was fractionated from potassium hydrogen sulphate (0.1 g.) and *p*-fluorophenylbutadiene (1.7 g.) was obtained, b. p. 37°/0.001 mm., n_D^{22} 1.5788, which solidified on cooling and had m. p. 16–16.5° (Found: C, 80.4; H, 6.6. $C_{10}H_9F$ requires C, 80.65; H, 6.5%). The maleic anhydride adduct (0.25 g.) was obtained by treating the diene (0.18 g.) with maleic anhydride (0.12 g.) in benzene (5 c.c.). Crystallisation from petrol (b. p. 80–100°) yielded the adduct in needles, m. p. 113° (Found: C, 68.5; H, 4.7. $C_{14}H_{11}O_3F$ requires C, 68.3; H, 4.5%).

p-Benzoquinone adduct. The diene (1.2 g.) was treated with *p*-benzoquinone (0.67 g.) in benzene (5 c.c.). Crystallisation from petrol (b. p. 80–100°) afforded 1-*p*-fluorophenyl-1:4:9:10-tetrahydronaphtha-5:8-quinone (0.93 g.) as very pale yellow needles, m. p. 90° (Found: C, 74.8; H, 5.3. $C_{18}H_{13}O_2F$ requires C, 75.0; H, 5.1%).

p-Chlorophenylpropenylcarbinol (I; R = *p*-Cl).—*p*-Dichlorobenzene (74 g.) in ether (400 c.c.) was slowly added to a suspension of magnesium (12 g.) in ether (100 c.c.) containing ethyl bromide (0.5 g.) and refluxed for 96 hours. Freshly distilled crotonaldehyde (35 g.) in ether (70 c.c.) was added during one hour at 0°, and the solution was stirred for 3 hours. Working up in the usual manner yielded unchanged *p*-dichlorobenzene (23 g.) and *p*-chlorophenylpropenylcarbinol (28 g.), b. p. 89°/0.005 mm., n_D^{21} 1.5471 (Found: C, 65.9; H, 6.2; Cl, 19.3. $C_{10}H_{11}OCl$ requires C, 65.7; H, 6.05; Cl, 19.4%). Active hydrogen (Zerewitinoff): 1.02.

p-Chlorostyrylmethylcarbinol (II; R = *p*-Cl).—Treatment of the above carbinol (1 g.) with 0.01M-hydrochloric acid in 60% aqueous dioxan (50 c.c.) for 40 hours at 30° yielded *p*-chlorostyrylmethylcarbinol (0.87 g.), which separated from light petroleum (b. p. 40–60°) in needles, m. p. 63° (Found: C, 65.95; H, 6.0. $C_{10}H_{11}OCl$ requires C, 65.75; H, 6.1%). α -Naphthylurethane. (i) A mixture of *p*-chlorostyrylmethylcarbinol (0.5 g.) and α -naphthyl isocyanate (0.5 g.) was kept in a sealed tube for 5 days. The urethane crystallised from petrol (b. p. 80–100°) in needles, m. p. 128° (Found: C, 71.5; H, 5.35. $C_{21}H_{18}O_2NCl$ requires C, 71.6; H, 5.6%). (ii) *p*-Chlorophenylpropenylcarbinol (0.5 g.) was treated with α -naphthyl isocyanate (0.5 g.). The oily product after one crystallisation from aqueous ethanol had m. p. 69°. On successive crystallisations from ethanol and finally petrol, the m. p. rose to 128° [undepressed by the product obtained under (i)], and the light absorption maximum, not originally present, at 2580 Å., ϵ = 30,000 (see Table III), appeared.

1-(*p*-Chlorophenyl)buta-1:3-diene.—*p*-Chlorophenylpropenylcarbinol (2 g.) was distilled from potassium hydrogen sulphate (0.5 g.) at 10⁻² mm., and the product fractionated. The diene (1.55 g.), b. p. 49°/0.002 mm., n_D^{20} 1.6202, solidified on cooling and had m. p. 18.5° (Found: Cl, 21.75. $C_{10}H_9Cl$ requires Cl, 21.55%). The maleic anhydride adduct, obtained by the routine method and crystallised from petrol (b. p. 80–100°), had m. p. 108° (Found: Cl, 13.3. $C_{14}H_{11}O_3Cl$ requires Cl, 13.5%).

p-Benzoquinone adduct. Treatment of the diene (1.6 g.) with *p*-benzoquinone (1.2 g.) yielded the pale yellow adduct, 1-*p*-chlorophenyl-1:4:9:10-tetrahydronaphtha-5:8-quinone (1.8 g.); after being washed with methanol and crystallised from petrol (b. p. 80–100°) it had m. p. 110° (Found: C, 70.35; H, 4.8; Cl, 12.85. $C_{18}H_{13}O_2Cl$ requires C, 70.45; H, 4.8; Cl, 13.0%).

p-Bromophenylpropenylcarbinol (I; R = *p*-Br).—*p*-Dibromobenzene (60 g.) in ether (150 c.c.) was slowly added to a suspension of magnesium (6 g.) in ether (100 c.c.) containing ethyl bromide (0.5 g.) and refluxed for 24 hours. Freshly distilled crotonaldehyde (17 g.) in ether (50 c.c.) was added during one hour at 0° and the solution was stirred for 3 hours. Working up in the usual manner yielded unchanged *p*-dibromobenzene (5 g.) and *p*-bromophenylpropenylcarbinol (26 g.), b. p. 92°/0.002 mm., n_D^{21} 1.5739, which solidified on cooling and after crystallisation from light petroleum (b. p. 40–60°) had m. p. 27° (Found: C, 52.7; H, 5.15; Br, 36.0. $C_{10}H_{11}OBr$ requires C, 52.9; H, 4.9; Br, 35.2%).

p-Bromostyrylmethylcarbinol (II; R = *p*-Br).—Treatment of the above carbinol (1.5 g.) with 0.1M-hydrochloric acid in 60% aqueous dioxan (50 c.c.) for 12 hours yielded *p*-bromostyrylmethylcarbinol (1.4 g.) as needles, from light petroleum (b. p. 40–60°), m. p. 66° (Found: C, 53.2; H, 5.0. $C_{10}H_{11}OBr$ requires C, 52.9; H, 4.9%). The α -naphthylurethane (0.55 g.) crystallised from petrol (b. p. 80–100°) in needles, m. p. 139° (Found: C, 64.0; H, 4.55; N, 3.85. $C_{21}H_{18}O_2NBr$ requires C, 63.65; H, 4.55; N, 3.55%).

1-(*p*-Bromophenyl)buta-1:3-diene.—*p*-Bromophenylpropenylcarbinol (2 g.) was distilled from potassium hydrogen sulphate (0.5 g.) at 10⁻² mm. The product was fractionated, giving the diene (1.5 g.), b. p. 88°/0.001 mm., which solidified at room temperature, and crystallised from aqueous methanol; m. p. 29° (Found: C, 57.05; H, 4.7. $C_{10}H_9Br$ requires C, 57.45; H, 4.35%). The maleic anhydride adduct, obtained as usual and crystallised from petrol (b. p. 80–100°), formed fine needles, m. p. 138.5° (Found: C, 55.0; H, 3.65. $C_{14}H_{11}O_3Br$ requires C, 54.75; H, 3.6%).

p-Benzoquinone adduct. Treatment of the diene (0.5 g.) with *p*-benzoquinone (0.25 g.) in benzene (5 c.c.) gave the adduct, 1-*p*-bromophenyl-1:4:9:10-tetrahydronaphtha-5:8-quinone (0.45 g.), which

crystallised from petrol (b. p. 80–100°) in pale yellow rectangular plates, m. p. 105° (Found : C, 60.4; H, 3.95. $C_{14}H_{14}O_2$ requires C, 60.6; H, 4.15%).

p-Anisylpropenylcarbinol (I; R = *p*-MeO).—*p*-Bromoanisole (35 g.) in ether (100 c.c.) was added slowly to a suspension of magnesium (4.45 g.) in ether (250 c.c.) containing ethyl bromide (0.5 g.) and stirred overnight in an atmosphere of nitrogen. Freshly distilled crotonaldehyde (12 g.) in ether (25 c.c.) was added during one hour at 0° and the solution was stirred for 3 hours. Working up in the usual manner and final distillation from a trace of potassium carbonate yielded *p*-anisylpropenylcarbinol (23.5 g.), b. p. 100°/0.005 mm., n_D^{20} 1.5454, which partly solidified on standing at 0°; m. p. 13–15° (Found : C, 74.45; H, 8.0. $C_{11}H_{14}O_2$ requires C, 74.15; H, 7.9%). Active hydrogen (Zerewitinoff) : 1.01.

p-Methoxystyrylmethylcarbinol (II; R = *p*-MeO).—Treatment of the above carbinol (1 g.) with 0.001M-hydrochloric acid in 60% aqueous dioxan (50 c.c.) for 3 hours at 30° yielded *p*-methoxystyrylmethylcarbinol (0.95 g.), in needles from light petroleum (b. p. 40–60°); m. p. 79° (Found : C, 73.95; H, 7.9. $C_{11}H_{14}O_2$ requires C, 74.15; H, 7.9%). Active hydrogen (Zerewitinoff) : 1.02. The *α*-naphthylurethane (0.4 g., 0.8 g. respectively) was obtained by warming (i) *p*-anisylpropenylcarbinol (0.5 g.) and (ii) *p*-methoxystyrylmethylcarbinol (0.5 g.) with *α*-naphthyl isocyanate (0.5 g.), and crystallised from petrol (b. p. 80–100°) in needles, m. p. 101° (Found : N, 4.1. $C_{22}H_{21}O_3N$ requires N, 4.05%).

1-(*p*-Anisyl)buta-1 : 3-diene.—*p*-Anisylpropenylcarbinol (1 g.) was warmed with potassium hydrogen sulphate at 10⁻² mm. for about 5 minutes, and then rapidly distilled. *p*-Anisylbutadiene (0.7 g.) solidified on standing and was crystallised from aqueous methanol, m. p. 46° (Found : C, 82.2; H, 7.45. $C_{11}H_{14}O$ requires C, 82.45; H, 7.55%). Knorr (D.R.-P. 544388; *Chem. Abs.*, 1932, 26, 2467) gives b. p. 124°/8 mm. for the diene obtained by dehydration of *p*-anisylallylcarbinol. The maleic anhydride adduct crystallised from petrol (b. p. 80–100°) in fine needles, m. p. 145° (Found : C, 70.0; H, 5.4. $C_{15}H_{14}O_4$ requires C, 69.75; H, 5.45%).

p-Benzoquinone adduct. Treatment of the diene (0.53 g.) with *p*-benzoquinone (0.33 g.) in benzene (5 c.c.) yielded 1-*p*-anisyl-1 : 4 : 9 : 10-tetrahydronaphthaquinone (0.38 g.), pale yellow plates from petrol (b. p. 80–100°); m. p. 103° (Found : C, 76.35; H, 6.0. $C_{17}H_{14}O_2$ requires C, 76.05; H, 6.0%). Light absorption in *n*-hexane : Maxima at 2280, 2680, and 3250 Å., ϵ = 23,300, 2500, and 230, respectively. The absorption may be ascribed to the isomer, 1-*p*-anisyl-1 : 4-dihydronaphtha-5 : 9-quinol (needles, m. p. 168°), which is produced on irradiation with ultra-violet light during the absorption measurements and separates from the solution on standing or evaporation.

1-Phenylbuta-1 : 3-diene.—Freshly distilled cinnamaldehyde (40 g.) in ether (120 c.c.) was added to methylmagnesium iodide (from Mg, 8 g.) in ether (200 c.c.). Decomposition of the complex with excess of ammonium chloride solution, isolation with ether, distillation from a trace of potassium hydrogen sulphate, and finally fractionation afforded pure phenylbutadiene, b. p. 45°/0.5 mm., n_D^{17} 1.6125, which solidified on cooling and had m. p. 4° (Klages, *Ber.*, 1904, 37, 2309, gives b. p. 86°/11 mm.; Muskat and Herrman, *J. Amer. Chem. Soc.*, 1931, 53, 252, give b. p. 86°/11 mm., n_D^{28} 1.5950; Emerson, *J. Org. Chem.*, 1945, 10, 464, gives b. p. 89–94°/14 mm., n_D^{25} 1.6010). The low refractive indices recorded by these authors are probably due to the presence of considerable proportions of undehydrated styrylmethylcarbinol or of polymers of the diene (cf. Stobbe and Reiss, *Ber.*, 1912, 45, 3496; Wright, *J. Org. Chem.*, 1936, 1, 457). Light absorption : see Table IV (Stobbe and Reiss, *loc. cit.*, and Smakula, *Angew. Chem.*, 1934, 47, 657, give maximum at 2800 Å., ϵ = 24,000). The maleic anhydride adduct, crystallised from petrol (b. p. 80–100°), had m. p. 120° (Diels and Alder, *Ber.*, 1929, 62, 2081, give m. p. 120°).

p-Benzoquinone adduct. Phenylbutadiene (2 g.) was treated with *p*-benzoquinone (2 g.) in benzene (20 c.c.), and the solution boiled for some minutes. On cooling and evaporation of the solvent under reduced pressure, crystals separated, which were washed with methanol to remove a small amount of quinhydrone. Phenyl-1 : 4 : 9 : 10-tetrahydronaphtha-5 : 8-quinone (2.25 g.) crystallised from petrol (b. p. 80–100°) in pale yellow rectangular plates, m. p. 101° (Found : C, 80.7; H, 5.9. $C_{16}H_{14}O_2$ requires C, 80.65; H, 5.9%).

Styrylmethylcarbinol *α*-naphthylurethane. Prepared from styrylmethylcarbinol (Braude, Jones, and Stern, *J.*, 1946, 396) (0.5 g.) and *α*-naphthyl isocyanate (0.5 g.), the urethane crystallised from petrol (b. p. 80–100°) in needles, m. p. 89.5° (Found : C, 79.25; H, 6.1; N, 4.2. $C_{21}H_{19}O_3N$ requires C, 79.45; H, 6.05; N, 4.4%).

206. The Kinetics of Anionotropic Rearrangement. Part VI. The Effects of Methyl, Methoxy-, and Halogen Substituents attached to a Phenyl Group.

By ERNEST A. BRAUDE and E. S. STERN.

The kinetics of the acid-catalysed oxotropy of substituted phenylpropenylcarbinols to the corresponding styrylmethylcarbinols (p. 1097, I \rightarrow II) have been studied. The effects of nuclear substituents in this molecular rearrangement are in accord with those observed in substitution reactions and in the dissociation constants of substituted benzoic acids. The reaction is facilitated by methyl and methoxyl substituents, and retarded by halogen substituents, first-order rate constants at one temperature varying in the order *p*-Br < *p*-Cl < *p*-F < H < *m*-Me < *o*-Me < *p*-Me < *p*-MeO. The differences in the rate constants are due to small

changes both in the isodielectric energy of activation and in the non-exponential factor of the Arrhenius equation. The results are discussed in terms of the electronic effects of the substituent groups and the unexpected sequence previously noted by other authors of tautomeric effects decreasing in the order $F > Cl > Br$, is confirmed.

IN previous papers in this series, detailed investigations have been described of rearrangements of the type where X is an acetylenic, ethylenic, or phenyl group. A reaction mechanism has

been outlined which accounts for the kinetic features of the reaction and their dependence on medium composition. The effects of many aliphatic substituents have been examined and found to be those expected for a reaction requiring electron accession at the point of reaction. It appeared worth while to extend this work to a study of the effects of aromatic substituents, data for which have hitherto been largely derived from substitution reactions and dissociation constants.

It was shown in Part V (*J.*, 1946, 396) that the rearrangement of phenylpropenylcarbinol (I, $R = H$) to styrylmethylcarbinol (II, $R = H$) proceeds smoothly in aqueous dioxan in the presence of hydrochloric acid, that the reaction follows the first-order law, and that the rate constants are practically independent of the carbinol concentration, roughly proportional to the acid concentration (c_A) when $c_A \ll 0.1M$, and decreased by increasing dioxan concentration (c_s) when $c_s \ll 80\%$ v/v. The same characteristics apply to the rearrangements of substituted

phenylpropenylcarbinols (I) where $R = o\text{-Me}$, $m\text{-Me}$, $p\text{-Me}$, $p\text{-F}$, $p\text{-Cl}$, $p\text{-Br}$, and $p\text{-MeO}$ (Tables I, II, and III). The rate constants determined at 10° intervals between 30° and 60° accurately obey the Arrhenius equation.

It was previously observed (Part V, *loc. cit.*) that in the rearrangements of phenylvinyl- and phenylpropenyl-carbinols, the highest extinction coefficients reached in kinetic runs were lower by some 3–8% than those of the pure styryl isomers isolated from the reaction mixture, and it was suggested that the formation of stereoisomers or the establishment of equilibria at 92–97% rearrangement was among the more likely explanations of the discrepancies. With

TABLE I.

The effect of carbinol concentration.

First-order rate constants (10^4k , min.^{-1}) for the rearrangement of $C_6H_4R \cdot CH(OH) \cdot CH:CHMe$ in 60% (by vol.) aqueous dioxan at 30.0° . c_{ROH} = carbinol concentration (% w/v); c_A = hydrochloric acid concentration (mols./l.).

the substituted phenylpropenylcarbinols, the ratios of "kinetic" to "preparative" end-values vary from 0.87 to 0.97, and are again temperature-independent within the experimental error ($\pm 2\%$) (see Experimental). Now, since the type and number of bonds broken and formed in the reaction is otherwise equal and opposite, the heat of reaction should be of the same order as the additional resonance energy of the conjugated (styryl) system, *i.e.* ca. 5 kg.-cals./mol. (Pauling and Sherman, *J. Chem. Physics*, 1933, 1, 606; Kistiakowsky, Ruhoff, Smith, and Vaughan, *J. Amer. Chem. Soc.*, 1936, 58, 146). This corresponds to an approximately two-fold change in the equilibrium constant for a temperature change from 30° to 60°, and to a change in conversion from 95 to 90%, *i.e.*, only just more than the limit of experimental error. The present data are thus indecisive. If equilibrium formation does take place, the over-all rate constants k actually represent the sum ($k_1 + k_{-1}$) of the rate constants of the forward and backward reactions $ROH \xrightleftharpoons[k_{-1}]{k_1} R'OH$, but the values of k_1 will only be 3–13% lower than those of k , and the values of the Arrhenius parameters will hardly be affected.

It was pointed out in Part II (*J.*, 1944, 443) that two types of solvent effect may be distinguished in considering the dependence of the rate constants, energies of activation, etc., of a catalysed reaction on the reaction medium. Those directly affecting the reactants were termed primary solvent effects, while those resulting in the first place in a change in the catalytic properties, such as the proton-donating properties, of the medium were termed secondary solvent effects. Evidence was adduced for both types of effects in oxotropic rearrangements.

It was shown that in the rearrangement of propenylethynylcarbinol in aqueous ethanol the decrease in rate constant with increasing concentration of organic solvent (c_s) could be expressed in the form $\log k = mD + n$ where D is the dielectric constant, and m and n are constants and $c_s \leq 80\%$. This was interpreted mainly as a secondary solvent effect, the decrease in dielectric constant resulting in a decrease in the proton-donating properties of the medium. It was further shown that on this basis a correction could be applied to the Arrhenius energy of activation to allow for the change in dielectric constant of the medium with temperature, the isodielectric energy of activation being given by $E_{[D]} = E_{Arr.} + RT_1 T_2 mb$ where T_1 , T_2 are the limits of the temperature range investigated, and b is a constant defined by $D = a + bt$, t being the temperature in °C. Whereas $E_{Arr.}$ varied considerably with solvent composition, $E_{[D]}$ was independent of it within the limits of experimental error. Similar observations were made (Part V, *loc. cit.*) with the rearrangement of phenylpropenylcarbinol in aqueous ethanol and aqueous dioxan, though $E_{[D]}$ in the latter case was ca. 4 kg.-cals./mol. lower than in the former, the difference being ascribed to a primary solvent effect, namely, increased solvation of the carbinol group by the dioxan.

The independence of $E_{[D]}$ of medium composition thus applies only as long as there is no appreciable change in solvating properties. Independent evidence for the occurrence of primary solvent effects was provided by the small but definite variations in the slope of the $\log k - c_A$, and $\log k - c_s$ plots with different substituted ethylenic and acetylenic carbinols (Parts III and IV, *J.*, 1946, 122, 128). These variations are presumably due to small differences in the extent of solvation of the carbinols by the solvent. If secondary solvent effects alone came into play, these slopes should be the same for different compounds undergoing the same reaction by

identical mechanisms. The data now obtained for substituted phenylpropenylcarbinols also indicate the occurrence of both primary and secondary solvent effects.

Specific k and relative rate constants, dielectric constant effects (expressed as m , the slope of the rate constant-dielectric constant plot), Arrhenius and isodielectric energies of activation, and reaction constants A (defined by $k/c_A = Ae^{-E_{(D)}/RT}$)[†] are given in Table IV; m varies somewhat for different carbinols, being lower when $R = \text{Me}$ or MeO , and higher when $R = \text{Halogen}$, as compared with $R = \text{H}$ (see I). But whereas values of $E_{\text{Arr.}}$ for any one carbinol are higher by 2–3 kg.-cals./mol. for 60% as compared with 40% aqueous dioxan, the corresponding values of $E_{(D)}$ differ by not more than 0.4 kg.-cal./mol. in seven cases, and by 0.9 kg.-cal./mol. when $R = p\text{-MeO}$. Within the range examined, the energy of activation is thus again independent, or nearly so, of the composition and hence of the dielectric constant of the medium, when allowance is made for the different temperature coefficients of the dielectric constants of different media.

* Dissociation constants of $\text{C}_6\text{H}_4\text{R}\cdot\text{CO}_2\text{H}$ in water at 25° (Dippy, *Chem. Reviews*, 1939, **25**, 206).

Regarding the correlation of rate constants, energies of activation, and reaction constants with substituents, this may be summarised as follows: (i) The rate constants are increased by methyl substituents in the order $\text{H} < m\text{-Me} < o\text{-Me} < p\text{-Me}$, strongly increased by a *p*-MeO group, and decreased by *p*-halogen substituents in the order $\text{H} > p\text{-F} > p\text{-Cl} > p\text{-Br}$. (ii) Isodielectric energies of activation are constant at 20.6 (± 0.1) kg.-cals./mol. when $R = \text{H}$, *o*-Me, *p*-Me or *p*-F, slightly increased (by 0.3–1.5 kg.-cals./mol.) when $R = m\text{-Me}$, *p*-Cl or *p*-Br and decreased (by 2 kg.-cals./mol.) when $R = p\text{-MeO}$. (iii) Reaction constants (A) are constant at 13.4 (± 0.1) sec.⁻¹ when $R = \text{H}$ or Halogen, and slightly increased by $R = \text{Me}$ in the order $o\text{-Me} < m\text{-Me} < p\text{-Me}$, and by $R = \text{MeO}$.

In aqueous-ethanolic media, the first-order law is obeyed when $R = \text{H}$, *p*-Me, *p*-F, or *p*-MeO, but with the *p*-Cl and *p*-Br substituted carbinols the first-order rate constants fall as the reaction proceeds (see Experimental) in a manner reminiscent of that previously observed with phenylvinylcarbinol (Part V, *loc. cit.*) and shown there to be due to etherification occurring before, as well as simultaneously with, rearrangement.

EXPERIMENTAL.

Materials.—The preparation and properties of the phenylpropenylcarbinols and of their styryl isomers are described in the preceding paper. Dioxan was purified by the method of Hesse and Frahm (*Ber.*, 1938, **71**, 2629).

Kinetic Measurements.—The technique was the same as described in Part V (*loc. cit.*) and preceding papers. Initial and end values are given as $E_{1\%}^{\text{inc.}}$ [$= \log (I_0/I)/cl$, where I_0 = intensity of incident light, I = intensity of transmitted light, c = concentration in % w/v, l = cell length in cm.] (Table V).

Typical runs for each carbinol, in aqueous dioxan and ethanolic media, are reproduced below. The first-order rate constants (k) are calculated by $k = (2.3/z) \log [(a - x_0)/(a - x)]$, where z = time in

* Since k is not directly proportional to c_A when $c_A > 0.1\text{M}$ in the present reaction, the specific rate constants (k/c_A) are not equal to k when $c_A = 1\text{M}$. Nevertheless for purposes of comparison of different series, specific rate constants are obviously preferable to k 's at an arbitrary acid concentration. The values given in Parts III and IV (J., 1946, 122, 128, Tables III, cols. 1) for the rearrangement of acetylenyl- and vinyl-carbinols should be divided by 10^3 to convert them into k/c_A . Although these measurements refer to 60% aqueous ethanol media, the specific constants are then comparable to the present ones, since rate constants in 60% dioxan and ethanol are not appreciably different (see below and Part V, *loc. cit.*).

† In a catalysed reaction, A depends on the catalyst concentration, and the choice of the latter is arbitrary. For purposes of standardisation it appears preferable to base A on the specific rate constant k/c_A . The values given in Parts III and IV (*loc. cit.*, cols. 3) should accordingly be increased by 1.0.

* Extrapolated.

DISCUSSION.

With regard to the reaction mechanism, this is clearly the same throughout the series, since such characteristics as reaction order, dependence of the rate constants on carbinol, acid, and solvent concentrations, and the independence of the isodielectric energies of activation of solvent composition are the same in each case. The interpretation of substituent effects can therefore be based on the mechanism already outlined and discussed for the rearrangement of the parent compound, phenylpropenylcarbinol (Part V, *loc. cit.*)*

Table IV shows that the differences in the rate constants are due to variations in both the energy of activation and the non-exponential factor A of the Arrhenius equation. Except with the *p*-methoxy-compound, however, where $E_{(p)}$ is distinctly lower, while A is only slightly higher than for phenylpropenylcarbinol, these variations are only small and mostly entail differences of the same order of magnitude as the experimental error. In view of this fact, only tentative conclusions can be based on such regularities as can be discerned, and it will be preferable at this stage of the investigation to limit the discussion mainly to a consideration of the changes in the relative rate constants brought about by substituents.

Ingold's classification (*J.*, 1933, 1120; *Chem. Reviews*, 1934, 15, 233; see also Baker, "Tautomerism," Routledge, London, 1934; Remick, "Electronic Interpretation of Organic Chemistry," Wiley, New York, 1943) of substituent effects, which is now generally accepted, recognises two principal types: (i) the general inductive (I) and (ii) the tautomeric effect (T). The former depends on the capacity of the atom or group to attract or repel electrons and is mainly electrostatic in origin, I being negative with respect to hydrogen (electron-attraction) when the electronegativity of the substituent is greater than that of hydrogen, *i.e.*, when $x_R > x_H$, and positive (electron-repulsion) when $x_R < x_H$. The tautomeric effect, on the other hand, depends on the capacity of a substituent to share an additional electron pair, *i.e.*, on its capacity for covalency increase or decrease, and on its capacity to favour resonance forms of the type $R^+ \equiv A - B^-$ or $R^- \equiv A - B^+$ in systems classically represented by $R - A \equiv B$. In the case of alkyl groups, the central atom carries no unshared electron-pair and their tautomeric effect must be ascribed to no-bond resonance in the C—H links, *i.e.*, contributions from $H^+C \equiv C - C^-$ to systems classically represented by $H - C - C \equiv C$ (Baker, *J.*, 1939, 1150).

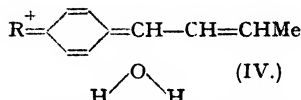

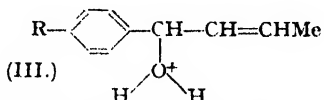

In the mechanism proposed for the present reaction, both steps require electron accession at the point of reaction and k should therefore be increased by $+I$ and $+T$ effects and retarded by $-I$ effects. This has been shown to be the case for alkyl and alkenyl substituents attached to the aliphatic part of the molecule (Parts III, IV, and V, *loc. cit.*). Similarly, the present data for the three tolylpropenylcarbinols are in accordance with expectations, the accelerating effect of the methyl substituent being least in the *m*-position ($+I$ effect only) and larger in the *o*- and *p*-positions ($+I$ and $+T$ effects). The fact that the increase in k due to an *o*-methyl group is less than that of a *p*-methyl group, although the $+I$ and probably the $+T$ effect should be greater for the former, provides yet another example of the well-known "ortho"-effect: the decrease in planarity due to the ortho-substituent inhibits the transmission of the T effect. However, even the "true" $+T$ effect is unlikely to be much larger in the *ortho*-

* The kinetic criterion given in Part V (*loc. cit.*, p. 403, lines 42 and 43) is erroneous. A valid criterion for the distinction between $ROH + H^+ \xrightarrow{\text{slow}} ROH_2^+ \xrightarrow{\text{fast}} R'OH_2^+$, and $ROH + H^+ \xrightarrow{\text{fast}} ROH_2^+ \xrightarrow{\text{slow}} R'OH_2^+$ was correctly stated in Part II (*J.*, 1944, 443) and depends on the linear relation between $\log k$ and the acidity function H_0 , rather than between $\log k$ and c_A .

than in the *para*-position, and the roughly tenfold increase in k due to a methyl substituent in the phenyl ring may be compared with its much larger effect when attached to the ethylenic double bond. Thus phenylpropenylcarbinol rearranges about 500 times faster than phenylvinylcarbinol under identical conditions (Part V, *loc. cit.*). This large difference is to be ascribed to the fact that the double-bond electron-pair moves towards the (electron-repelling) methyl substituent in one case, and away from it in the other, as well as possibly to a greater polarisability (allowing a readier transmission of the $+T$ effect) of the ethylenic double bond as compared with the aromatic system.

A p -MeO group also has the expected accelerating influence owing to its large $+T$ effect, but with the halogeno-carbinols the results are not entirely those to be anticipated from *a priori* considerations. The $-I$ effect should lead to reduction in the rate constant and to the sequence $F < Cl < Br < H$, since the electronegativity differences are in this order (F 4.0, Cl 3.0, Br 2.8, H 2.1; Pauling, "Nature of the Chemical Bond," Cornell, 1940). The $+T$ effect should counteract this diminution, but since it should be largest for Br and least for F and since it is smaller than the $-I$ effect, the actual sequence $F < Cl < Br < H$ should remain unaltered. The observed sequence is the reverse, *i.e.*, $Br < Cl < F < H$, which means that the $+T$ effects vary in the order $F > Cl > Br$ and not $F < Cl < Br$. This is unexpected, since the control of the nucleus over the valency electrons should decrease, and the capacity for covalency increase on ascending a group of the periodic table. Similar results indicating a reversed sequence of the tautomeric effects in the halogens have been observed in several other cases (Shopee, *J.*, 1933, 696; Baddeley, Bennett, *et al.*, *J.*, 1933, 261, 1112; 1935, 1827). It must be emphasised, however, that this interpretation is based on the tacit assumption that the rate constants as such, rather than the energies of activation and reaction constants separately, represent an adequate and additive measure of I and T effects.

It is noteworthy that the p -methoxyl substituent, which is the only one producing a large (*i.e.*, over 100-fold) change in rate, results in pronounced lowering of the energy of activation ($\Delta E_{[D]} = ca. 2$ kg.-cals.), just as the 500-fold increase in rate due to the β -methyl group in phenylpropenyl- as compared with phenylvinyl-carbinol is accompanied by a large decrease in $E_{[D]}$ of *ca.* 5 kg.-cals./mol. (Part V, *loc. cit.*). The data for the rearrangements of acetylenyl- and vinyl-carbinols (Parts III and IV, *loc. cit.*) also bear out that, on the whole, an increase in rate is accompanied by a decrease in the energy of activation,* and that large changes in rate depend on large changes in the energy of activation rather than $\log A$. This is readily interpreted as indicating that although the effect of substituents is exerted to a small extent by changes in the equilibrium constant of the preceding proton-transfer equilibrium, $ROH + H^+ \rightleftharpoons ROH_2^+$, their main effect lies in altering the energy requirements of the rate-determining isomerisation $ROH_2^+ \rightarrow R'OH_2^+$. An electron-repelling substituent increases the electron-density at the point of reaction, through increased contribution from resonance forms such as (IV), thereby partly neutralises the positive charge at the reaction centre, and decreases the energy of separation of the carbonium ion and the dipolar water molecule. The existence of extended conjugation in the resonance form of the oxonium ions of phenylpropenylcarbinols may also explain why substituents exerting $+T$ effects enhance the tendency for equilibrium formation: rearrangement to the styryl isomer results in increased conjugation, and hence, lowering in potential energy, only in the "ordinary" form (III), but not in the resonance form (IV).

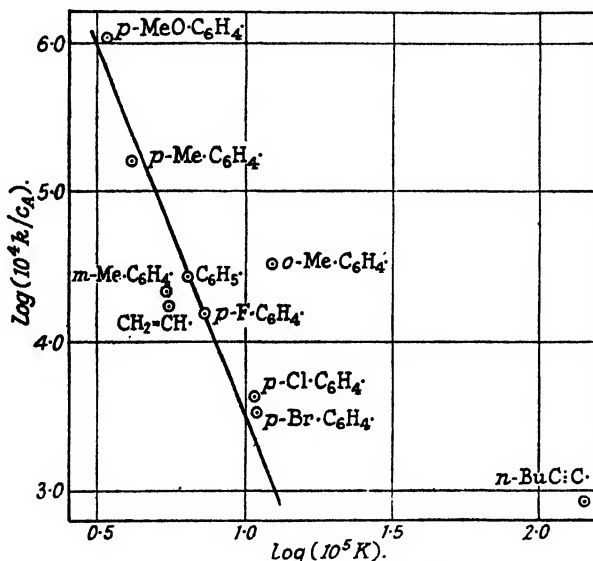

From a qualitative study of the rearrangement-acetylation of p -methylstyrylphenyl- and p -chlorostyrylphenyl-carbinols, and of p -tolyl- and p -chlorophenyl-vinylcarbinols, Burton and Ingold (*J.*, 1928, 904) and Burton (*J.*, 1928, 1650) concluded that the reaction is facilitated in the order $p\text{-Cl-C}_6\text{H}_4 > p\text{-Me-C}_6\text{H}_4 > \text{Ph}$, and that this was the expected order of reactivity. However, since the mechanism postulated by these authors, though different from the one adopted here, also requires electron-accession at the point of reaction, and since the overall electron-attracting effect of the halogens ($-I > +T$) is well known from aromatic substitution and other reactivity

* This conclusion was not drawn in the two papers referred to and only holds if the uncertain values of E (marked ~) for a few of the carbinols are disregarded. It now appears probable that the possibility, already envisaged in Part III, of equilibria being set up in these cases does apply, and that the E values derived from the temperature coefficients of the over-all rate constants do not represent real energies of activation in these cases.

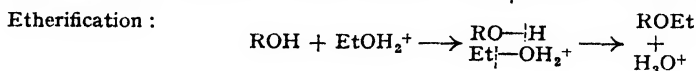

data, this expectation is clearly incorrect, and the expected sequence should be $\text{Me}\cdot\text{C}_6\text{H}_4 > \text{Ph} > \text{Cl}\cdot\text{C}_6\text{H}_4$ as confirmed by the present data. Moreover, inspection of the experimental results of Burton and Ingold also appears to indicate this sequence of reactivity and not the one deduced by their authors. Thus phenylvinyl- and *m*- and *p*-tolylvinyl-carbinols are stated to be converted completely into the corresponding styrylcarbiny acetates by treatment with boiling acetic anhydride for six hours, while identical treatment of *p*-chlorophenylcarbinol is stated to lead to a mixture containing only *ca.* 70% of the rearranged acetate. It may well be that the probable equilibrium formation in the rearrangements of *p*-chloro- and *p*-bromo-phenylpropenylcarbinols (see above) is enhanced in the less reactive phenylvinyl homologues.

The electron-attracting effect of the chloro- and bromo-substituents is also well illustrated by the fact that they appear to facilitate ether formation in ethanolic acid solution sufficiently for it to occur before rearrangement; with a fluoro-substituent the effect is not sufficiently great to lead to a falling first-order constant. Unlike the rearrangement reaction, which depends on the fission of the carbon-oxygen bond and electron accession at the point of reaction,

k = Rate constant of $\text{R}\cdot\text{CH}(\text{OH})\cdot\text{CH}:\text{CHMe}$.
 K = Dissociation constant of $\text{R}\cdot\text{CO}_2\text{H}$ (see Table IV).

ether formation probably depends on the bimolecular fission of the hydrogen-oxygen bond, *i.e.*, on electron recession at the point of reaction.

The ease of etherification of phenylvinylcarbinol (Part V, *loc. cit.*) is similarly to be ascribed to the strong electron-attraction ($-I$ effect) of the free vinyl group; in phenylpropenylcarbinol this is counteracted by the electron-repelling ($+I$, $+T$) effects of the β -methyl group and no etherification occurs prior to rearrangement.

Some correlation might again be expected between the specific rate constants of the carbinols and the dissociation constants (K) of the corresponding benzoic acids (cf. Parts IV and V, *loc. cit.*). The plot of $\log k/c_A$ against $\log K$ does in fact approximate to a straight line (Table IV; Fig.), except when $\text{R} = o\text{-Me}$. This is another instance of the "ortho"-effect (cf. Hammett, "Physical Organic Chemistry," McGraw Hill, New York, 1941). The point for vinylpropenylcarbinol (Part IV, *loc. cit.*) also falls on the straight line, but the points for ethynylpropenyl- and hexynylpropenyl-carbinols do not, and thus both the acetylenic groups and not the ethynyl group only, as previously thought, behave differently in this respect from the other groups so far examined.

The authors of this and the preceding paper are indebted to Professor Sir Ian Heilbron, D.S.O., F.R.S., for his interest, to the Rockefeller Foundation for financial assistance, and to the Chemical Society for a grant.

207. Studies in Light Absorption. Part IV. Nitro-olefins.

By ERNEST A. BRAUDE, E. R. H. JONES, and G. G. ROSE.

The ultra-violet light absorption of a number of compounds containing the conjugated chromophoric systems $C:C\cdot X$, $C:C\cdot C:C\cdot X$, and $Ph\cdot C:C\cdot X$ where $X = NO_2$ has been examined, and found to be similar to that of the corresponding systems where $X = C:C$, $C:N$, $C:O$, etc.

It is well known that chromophoric systems of the type $C:C\cdot X$, where X is a covalently unsaturated group such as $C:C$, $C:N$, or $C:O$, all exhibit selective high-intensity absorption in the 2200 Å. region (cf. Braude, *Ann. Reports*, 1945, 42, 105). The spectral properties of nitro-olefins ($X = NO_2$) have not hitherto been recorded. Since the conjugating properties of the nitro-group when attached to a phenyl group are known to resemble those of other covalently unsaturated groups (*e.g.*, nitrobenzene, styrene, benzaldehyde, and its *N*-methylimide all

Light absorption (in ethanol) of :

1. $CHMe:CH\cdot NO_2$. 2. $CHMe:CH\cdot CH:CH\cdot NO_2$. 3. $Ph\cdot CH:CH\cdot NO_2$.

exhibit similar ultra-violet light absorption due to the chromophoric system $Ph\cdot X$), the nitro-olefin system $C:C\cdot N\begin{smallmatrix} O \\ // \\ O \end{smallmatrix}$ would also be expected to absorb intensely in the 2200 Å. region. Data for a number of representative compounds (Table; Fig.) show that this expectation is fulfilled, but the maxima are situated at somewhat longer wave-lengths than in the formally related $C:C\cdot C:O$ and $C:C\cdot C\begin{smallmatrix} O \\ // \\ OH \end{smallmatrix}$ systems.

Although an isolated nitro-group, just as a carbonyl group, gives rise to a low-intensity band near 2700 Å. (Zelinsky and Rosanoff, *Z. physikal. Chem.*, 1912, 78, 629; Goodeve, *Trans. Faraday Soc.*, 1934, 30, 504; Kortüm, *Z. physikal. Chem.*, 1939, B, 43, 271), nitro-olefins exhibit no band corresponding to the displaced carbonyl band at 3200 Å. shown by $\alpha\beta$ -ethylenic carbonyl compounds. The solvent effects in the two systems are similar, λ_{max} (ethanol) being higher than λ_{max} (*n*-hexane) by an average of *ca.* 100 Å. with the nitro-olefins,

and by *ca.* 70 Å. with $\alpha\beta$ -ethylenic carbonyl compounds (Woodward, *J. Amer. Chem. Soc.*, 1941, **63**, 1123; 1942, **64**, 72; Evans and Gillam, *J.*, 1945, 432). On the other hand, in the case of the nitro-olefins, vibrational structure appears to be more pronounced in ethanol than in hexane, which is unexpected since the former is generally the more highly solvating solvent.

Lengthening of the conjugated chain as in the α -nitrobutadiene and β -nitrostyrene systems, *i.e.*, $C_6H_5C_4H_3NO_2$ and $PhC_4H_3NO_2$, respectively, results in the expected increase in λ_{max} , and the positions of the long wave-length bands are again 200–300 Å. higher than those of the corresponding bands shown by the $C_6H_5C_3H_3O$ and PhC_3H_3O systems. The persistence of shorter wave-length bands, probably to be ascribed to the partial chromophore $C_6H_5C_2H_3O$, is peculiar to the nitro-compounds.

The effects of auxochromic substituents are similar to those observed in other systems (cf. Part III, *J.*, 1946, 948); λ_{max} is increased by alkyl and halogen substituents attached to the $\alpha\beta$ -ethylenic bond, thus, $\Delta\lambda_{Me} = ca.$ 100 Å., and $\Delta\lambda_{Br} = ca.$ 300 Å. in the nitro-ethylenes. In the nitrostyrene system the effects are smaller or negative, thus, for β -substituents $\Delta\lambda_{Me} = -50$ Å., $\Delta\lambda_{Cl} = 100$ Å., and $\Delta\lambda_{Br} = 150$ Å.

208. Syntheses in the Thiopyran Series. Part I. Tetrahydro-derivatives.

By RALPH F. NAYLOR.

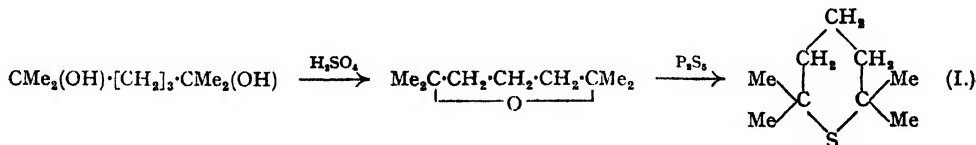

Reaction of a 1 : 5-dibromo-compound with sodium sulphide is not applicable to the synthesis of those members of the tetrahydrothiopyran series which contain tertiary carbon atoms in the 2- and the 6-position. In such cases it is possible to achieve the synthesis by cyclisation of the appropriate 2 : 6-diol to give the corresponding tetrahydropyran, followed by reaction of the latter with phosphorus pentasulphide. By this method 2 : 2 : 6 : 6-tetramethyl- and 2 : 2 : 6-trimethyl-6-ethyl-tetrahydrothiopyran have been prepared.

RECORDED investigation of compounds of the tetrahydrothiopyran series has been limited to two of the simplest members, pentamethylene sulphide and 1-methylpentamethylene sulphide, which have been readily obtained by reaction of the appropriate dihalide with sodium sulphide (Clarke, *J.*, 1912, 101, 1805; v. Braun, *Chem. Zentr.*, 1909, II, 1994; Grischkewitsch-Trochimowski, *Chem. Zentr.*, 1923, I, 1503). A few of the corresponding saturated thiopyrones have been prepared either by addition of hydrogen sulphide to a keto-diene or by cyclisation of a suitable aliphatic sulphide (Arndt and co-workers, *Ber.*, 1925, 58, 1633; 1930, 63, 313, 2393; Bennett and Scoriah, *J.*, 1927, 194), but otherwise no work has been recorded on this class of compound.

Although pentamethylene bromide reacts fairly readily with sodium sulphide, the yields of tetrahydrothiopyran are less than those reported to be obtainable with the chloride. This is in accord with the work of Bost and Conn (*Oil and Gas J.*, 1933, 32, No. 3, 17), who obtained only 30% of 2-methyltetrahydrothiopyran from 1 : 5-dibromohexane. In the present work it was desired to prepare tetra-substituted 2 : 6-derivatives, and to this end 2 : 6-dibromo-2 : 6-dimethylheptane was synthesised from ethyl glutarate :

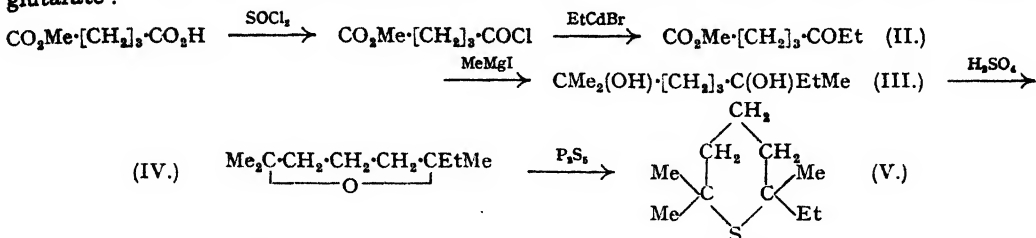

On trial, however, the lability of the bromine attached to the tertiary carbon atoms proved to be such that reaction of the bromide with sodium sulphide in alcoholic solution resulted only in the replacement of Br by OEt, and the corresponding reaction without a solvent resulted in loss of hydrogen bromide with formation of monobromodimethylheptenes and geraniolene ($\text{C}_{10}\text{H}_{18}$). This failure necessitated recourse to the less attractive method presented by conversion of a suitable pyran into the sulphur analogue. 2 : 6-Dimethylheptane-2 : 6-diol had already been observed to cyclise when it was heated in the presence of mineral acid, so giving 2 : 2 : 6 : 6-tetramethyltetrahydropyran* (Bruylants, *Rec. Trav. chim.*, 1910, 29, 130). This pyran was found to give a small yield of the desired 2 : 2 : 6 : 6-tetramethyltetrahydrothiopyran (I) when it was heated with phosphorus pentasulphide. The reaction, however, was complex, giving accompanying (resinous) products, which were not investigated.

Synthesis of unsymmetrical members of the thiopyran series presented greater difficulty, but since the essential oxide-sulphide conversion must remain the same in view of the presence of tertiary groupings, the only concern was the building up of the required carbon

* It is to be noted that no isomerisation involving shift of the -OH groups, such as has been observed by Franke and Gomolka (*Monatsh.*, 1929, 56, 331) in the case of $\alpha\omega$ -diols, $\text{CH}_3(\text{OH}) \cdot [\text{CH}_2]_n \cdot \text{CH}_2\text{OH}$, is possible in this dehydration, owing to the tertiary nature of the hydroxylated carbon atom : if water is eliminated with the formation of a double bond, the Markownikow rule will ensure that any re-addition of water will give the original alcohol $[\text{CH}_2 \cdot \text{C}(\text{OH})\text{Me}]_n \xrightarrow{-\text{H}_2\text{O}} \text{CH} : \text{CMe}_2 \xrightarrow{+\text{H}_2\text{O}} \text{CH}_2 \cdot \text{C}(\text{OH})\text{Me}_2$. In consequence only six-membered rings can arise. The six-membered nature of the subsequent thiopyran rings has been confirmed by the identity of their infra-red spectra with those of necessarily six-membered cyclic sulphides derived from hydrogen sulphide addition to di-isoprenes (Sutherland and Sheppard, in the press; Naylor, in the press).

framework. This was accomplished by the following steps, starting from methyl hydrogen glutarate :

Clutterbuck and Raper (*Biochem. J.*, 1925, 19, 393) report the preparation of methyl δ -ketoheptanoate (II) by reaction of ethylzinc iodide with the half-ester half-acid chloride of glutaric acid, but do not record yield. In the present work the zinc alkyl was replaced by ethylcadmium bromide, which reacted with the acid chloride group while leaving the ester group untouched, and a satisfactory yield (58%) of the δ -keto-ester (II) was isolated. By reaction with 3 mols. of methylmagnesium iodide (II) was converted into 2 : 6-dimethyloctane-2 : 6-diol (III), which condensed in the presence of warm dilute acid to 2 : 2 : 6-trimethyl-6-ethyl-tetrahydrothiopyran (IV). The final stage was treatment of (IV) with phosphorus pentasulphide to yield 2 : 2 : 6-trimethyl-6-ethyltetrahydrothiopyran (V).

The tetrahydrothiopyrans are quite stable towards acids and alkalis, but oxidise slowly in air. They unite with methyl iodide in the cold, but the resulting methiodides often separate as oils, which are difficult to crystallise. The rings of the sulphides (I) and (V) open when the compounds are heated with methyl iodide, the sulphur being removed as trimethylsulphonium iodide. This behaviour is in contrast to the stability of cyclic sulphides, containing primary α -carbon atoms, and is interesting in comparison with the formation of trimethylsulphonium iodide by the action of methyl iodide at 15° on compounds containing the diallylic sulphide grouping, $\cdot\text{CH}_2\cdot\text{CH}\cdot\text{CH}_2\cdot\text{S}\cdot\text{CH}_2\cdot\text{CH}\cdot\text{CH}_2\cdot$ (Selker and Kemp, *Ind. Eng. Chem.*, 1944, 36, 17). The di-iodide (VI) was not isolated and is probably too unstable to be obtained in the pure state.

EXPERIMENTAL.

(Microanalyses were carried out by Dr. W. T. Chambers, Miss H. Rhodes, and Miss E. Farquhar.)

Pentamethylene Sulphide.—Pentamethylene bromide was prepared from piperidine by the method described in *Organic Syntheses*, Coll. Vol. I, pp. 93, 419. A solution of the bromide (40 g.) and anhydrous sodium sulphide (50 g.) in ethanol (250 ml.) was refluxed for 3 hours. After addition of excess of water the product was extracted with ether and twice distilled. Pentamethylene sulphide (6 g., 34%) was obtained as a liquid, b. p. 140°/756 mm., n_D^{20} 1.5055 (Found : C, 59.0; H, 10.0; S, 31.3. Calc. for $\text{C}_5\text{H}_{10}\text{S}$: C, 58.9; H, 9.8; S, 31.4%).

Synthesis of 2 : 2 : 6-Tetramethyltetrahydrothiopyran (I).—(a) *Action of sodium sulphide on 2 : 6-dibromo-2 : 6-dimethylheptane.* Magnesium (4.5 g.) under ether was dissolved in a solution of methyl iodide (270 g.) in ether (350 ml.), and to the cooled solution of methylmagnesium iodide was introduced with stirring ethyl glutarate (64 g.) in ether (75 ml.). When the reaction moderated, the solution was refluxed for 1 hour, left overnight, and then poured slowly into aqueous ammonium chloride (200 g. in 700 ml.) containing crushed ice (2000 g.). 2 : 6-Dimethylheptane-2 : 6-diol was extracted with ether both before and after concentration of the aqueous solution, and was obtained from this extract as the monohydrate (30 g.) which was distilled at 85°/1 mm. to give the anhydrous alcohol (21 g.), m. p. 76°. Dry hydrogen bromide was bubbled through an ethereal solution of the alcohol at 0°; after neutralisation of excess acid with sodium hydrogen carbonate, 2 : 6-dibromo-2 : 6-dimethylheptane crystallised out in white needles, m. p. 34° (Found : C, 38.1; H, 6.4. Calc. for $\text{C}_9\text{H}_{18}\text{Br}_2$: C, 37.8; H, 6.3%). The dibromide lost hydrogen bromide very readily, even at room temperature, under reduced pressure. A solution of sodium sulphide (20 g.) and the dibromide (5 g.) in ethanol (50 ml.) was refluxed for 2½ hours, then diluted with water and ether extracted. The extract contained geraniolene (b. p. 40°/13 mm.) and impure 2 : 6-diethoxy-2 : 6-dimethylheptane (b. p. 70°/13 mm.; n_D^{18} 1.4452), but no sulphur-containing compounds. By heating together the dibromide (5 g.) and dry powdered sodium sulphide (25 g.) for 5 hours at 100–110° was obtained a mixture of geraniolene (b. p. 38°/12 mm.), impure bromo-2 : 6-dimethylheptane (b. p. ca. 50°/1 mm.; n_D^{18} 1.4748), and unchanged dibromide (b. p. 72°/1 mm.; m. p. 24°).

(b) *Action of phosphorus pentasulphide on 2 : 2 : 6-tetramethyltetrahydrothiopyran.* 2 : 6-Dimethylheptane-2 : 6-diol (15 g.), prepared as above, was shaken with 2N-sulphuric acid at 100° for 3 hours; the product contained unchanged diol, geraniolene, and 2 : 2 : 6-tetramethyltetrahydrothiopyran, b. p. 48°/1 mm. The last (7 g.) was sealed with phosphorus pentasulphide (24 g.) in a nitrogen-filled Carius tube, and heated for 6 hours at 110–120°. The product was extracted with aqueous alkali, dried over potassium carbonate, and distilled. After redistillation 2 : 2 : 6-tetramethyltetrahydrothiopyran (I) (2 g.) was obtained as a colourless liquid, b. p. 66°/12 mm., n_D^{18} 1.4763 (Found : C, 68.3; H, 11.6; S, 20.1. $\text{C}_{10}\text{H}_{20}\text{S}$ requires C, 68.4; H, 11.4; S, 20.2%). On standing for 1–3 days at 0° with twice its

own volume of methyl iodide, the product yielded white crystals of a *methiodide*, which recrystallised from ethanol-petrol (b. p. 60–80°) on cooling below –20°; m. p. 130° (decomposition occurred from 130° to 160°) (Found: I, 40.8. $C_{11}H_{23}IS$ requires I, 40.5%). Reaction with excess of methyl iodide for 16 hours at 100° gave crystals, which after being washed with a little methanol and recrystallised from ethanol (absolute) yielded needles of trimethylsulphonium iodide, decomp. ca. 200° (Found: I, 61.8; S, 15.5. Calc. for C_3H_7IS : I, 62.2; S, 15.7%).

Synthesis of 2:2:6-Trimethyl-6-ethyltetrahydrothiopyran (V).—Glutaric anhydride. Glutaric acid (290 g.) and acetic anhydride (400 ml.) were heated under reflux for 2 hours; the acetic acid was then distilled off, and the heating continued with a further 300 ml. of acetic anhydride. After removal of the acetic acid and anhydride, glutaric anhydride (235 g., 96%) was distilled over at 150°/10 mm. [Despite the claims of Krafft and Noerdlinger (*Ber.*, 1889, 22, 817) that glutaric acid is wholly dehydrated by refluxing alone for 2–3 hours, it was not found possible to complete the conversion into the anhydride by this method.]

Methyl hydrogen glutarate (see Clutterbuck and Raper, *loc. cit.*). Glutaric anhydride (235 g.) and methanol (132 g., 2 mols.) were refluxed for 1 hour, and the product, after removal of methanol, was distilled at 10 mm. The distillate consisted of methyl glutarate, methyl hydrogen glutarate, and some glutaric acid. The first and the last fraction were combined with glutaric acid extracted from the residue, and were reconverted into glutaric anhydride (*via* the acid) and re-esterified with methanol. The overall yield of methyl hydrogen glutarate was 240 g. (80%), b. p. 147–151°/10 mm., n_D^{20} 1.4372.

Glutaric acid half ester half chloride. A mixture of the acid ester (240 g.) and thionyl chloride (720 g.) was warmed until gas evolution started, and then very gently for one hour and refluxed for a further hour. After removal of excess thionyl chloride, the product (258 g., 97%) distilled at 98°/10 mm.

Methyl δ -Ketoheptate (II).—An ethereal solution of ethylmagnesium bromide was prepared from magnesium (42 g.) and ethyl bromide (188 g.). Powdered cadmium chloride (288 g.), rendered completely anhydrous by being heated for 1 hour on a sand-bath and allowed to cool in a desiccator over phosphoric oxide, was slowly added with stirring to the Grignard solution cooled in ice. When the solution set nearly solid it was necessary to add more ether and shake vigorously during the addition of the remaining chloride. The ice-bath was then removed, and the mixture stirred for 30 minutes. Absence of excess of Grignard reagent was ensured by testing with Michler's ketone.

To the solution of ethylcadmium bromide (10% excess reckoned on cadmium chloride) at 0° was slowly added with vigorous stirring the half ester half chloride (258 g.) in ether (300 ml.). When the mixture set solid more ether was introduced, and the addition was continued with constant shaking. After refluxing for 1 hour on the steam-bath, the mixture was diluted with ice, and then dilute sulphuric acid was added until the precipitate just dissolved. The ether layer was separated and was shaken successively with dilute aqueous ammonia, dilute sulphuric acid, dilute aqueous sodium hydrogen carbonate, and water. After drying over magnesium sulphate and removal of ether, the product was distilled at 104–110°/10 mm. Refractionation gave 144 g. (58%) of methyl δ -ketoheptate, b. p. 108°/10 mm., n_D^{20} 1.4296. On standing for several days with semicarbazide hydrochloride and potassium acetate in aqueous alcohol, the ester yielded a *semicarbazone*, which recrystallised from 95% alcohol to give colourless plates, m. p. 113° (Found: C, 50.2; H, 7.9; N, 19.6. $C_8H_{17}O_3N_2$ requires C, 50.2; H, 7.9; N, 19.6%).

2:6-Dimethyloctane-2:6-diol (III).—An ethereal solution of methylmagnesium iodide (3.25 mol.), prepared from magnesium (40.5 g.) and methyl iodide (236 g.), was stirred at 0° during the gradual introduction of methyl δ -ketoheptate (70 g.) in ether (100 ml.). When addition was complete, the solution was refluxed for 4 hours and then allowed to stand over the week-end. The product was decomposed with a solution of ammonium chloride (105 g.) in water (1500 ml.) at 0°, and the ether layer was separated. The aqueous layer was evaporated down to ca. 1200 ml., and constantly extracted with ether for 40 hours. After drying, and removal of ether, the 2:6-dimethyloctane-2:6-diol from the combined extracts was distilled at 87–90°/0.1 mm. The diol (60 g., 78%) was a colourless viscous liquid, n_D^{20} 1.4563, which at 0° slowly crystallised to give an oily white solid, m. p. 25–37°, and slowly sublimed at 20°/10⁻⁵ mm. to white crystals, m. p. 47–49.5° (Found: C, 68.1; H, 12.2. $C_{10}H_{22}O_2$ requires C, 69.0; H, 12.6%).

2:2:6-Trimethyl-6-ethyltetrahydrothiopyran (IV).—2:6-Dimethyloctane-2:6-diol (28 g.) was vigorously stirred for 30 minutes at 100° with 2*N*-sulphuric acid (250 ml.). The residual oil was combined with an ether extract of the aqueous layer, and dried over potassium carbonate. After removal of ether the product (12 g., 48%) distilled over at 65–74°/0.1 mm.; dimethyloctadiene was obtained in the lower-boiling fractions (ca. 34°/1 mm.). Refractionation of the product gave 2:2:6-trimethyl-6-ethyltetrahydrothiopyran, a mobile, colourless, sweet-smelling liquid, b. p. 89°/10 mm., n_D^{20} 1.4508 (Found: C, 76.7; H, 12.8. $C_{10}H_{20}O$ requires C, 76.9; H, 12.8%).

2:2:6-Trimethyl-6-ethyltetrahydrothiopyran (V).—An intimate mixture of 2:2:6-trimethyltetrahydrothiopyran (12 g.) and phosphorus pentasulphide (35 g.) was heated for 5 hours at 100° in a Carius tube sealed under nitrogen. The solid oily residue was extracted thoroughly with ether, then decomposed by water, and the aqueous solution extracted with ether. The ethereal extract was shaken 3 times with 10% aqueous sodium hydroxide and subsequently dried over magnesium sulphate. After removal of ether, the product (3.5 g., 26%) distilled over at 40°/0.2 mm. After 2 further fractional distillations 2:2:6-trimethyl-6-ethyltetrahydrothiopyran was obtained as a mobile, colourless liquid with a characteristic odour, b. p. 87°/13 mm., n_D^{20} 1.4849 (Found: C, 69.6; H, 11.7; S, 18.6. $C_{10}H_{20}S$ requires C, 69.8; H, 11.6; S, 18.6%). When this was kept with methyl iodide at 0°, the methiodide slowly separated as a red oil, but reaction at 100° (20 hours' reaction in a tube sealed under nitrogen) gave trimethylsulphonium iodide (Found: C, 15.7; I, 61.9. Calc. for C_3H_7IS : C, 15.7; I, 62.2%).

This paper forms part of a programme of fundamental research undertaken by the Board of the British Rubber Producers' Research Association. The author wishes to express his thanks to Dr. E. H. Farmer for his helpful advice and criticism.

NOTES.

Activating Influence of para-Groups on the Lability of Chlorine in Chlorobenzenes.

By G. M. BADGER, J. W. COOK, and (Miss) WENDY P. VIDAL.

IN another investigation, the activating influence of the azo-group on a *p*-chloro-substituent towards reaction with an anionoid reagent (compare Borsche and Exss, *Ber.*, 1923, 56, 2353) appeared to be somewhat greater than expected, and the present work was undertaken to obtain a quantitative measure of this effect. For this purpose, the percentage reaction with piperidine of various *p*-substituted chlorobenzenes has been determined, under standard conditions, by the gravimetric estimation of the halide ion in the reaction mixture, a method essentially the same as that used by Sandin and Liskear (*J. Amer. Chem. Soc.*, 1935, 57, 1304). A preliminary trial of the method of Brewin and Turner (*J.*, 1928, 332), which involves weighing the piperidine salt which separates out on cooling the reaction mixture, gave much lower results than were obtained by the method of Sandin and Liskear. This was, no doubt, due to the uncertainty as to the composition of the precipitated salt (Powell and Dehn, *J. Amer. Chem. Soc.*, 1917, 39, 1717), and also to the fact that piperidine hydrochloride is not completely insoluble in benzene.

Materials.—As solvent, sodium-dried, thiophen-free benzene, was used. Piperidine was dried over potassium hydroxide and kept over this reagent after being distilled. The *p*-chloronitrobenzene was a commercial sample, recrystallised from alcohol, m. p. 83°. *p*-Chloroaniline was also a commercial sample, recrystallised from benzene, m. p. 70°. *p*-Chloroazobenzene, prepared by the method of Jacobson and Loeb (*Ber.*, 1903, 36, 4090) and recrystallised from alcohol, had m. p. 89°. *p*-Chlorobenzonitrile was prepared from *p*-chlorobenzamide by dehydration with phosphoric oxide; recrystallised from aqueous alcohol, it had m. p. 91°. Chlorobenzene was redistilled, b. p. 130°.

Method.—The *p*-substituted chlorobenzene (0.024 mol.) was heated under reflux in an all-glass apparatus, with piperidine (0.1 mol.) in anhydrous benzene (50 c.c.) for 8 hours. The aqueous extract, after being washed with a little benzene, was acidified with dilute nitric acid (5 c.c.) and the halide precipitated as silver chloride with 0.1N-silver nitrate. The precipitate was collected in a Gooch crucible and dried at 100°.

Results.—The following percentage reactions were obtained: *p*-chloronitrobenzene, 12.9, 12.9%; *p*-chlorobenzonitrile, 5.0%; *p*-chloroazobenzene, 1.97, 1.96%; chlorobenzene, 1.29, 1.31%; *p*-chloroaniline, 1.23, 1.24%.

The activating influence of the azo-group is, under these conditions, less than that of the cyano-group, and considerably less than that of the nitro-group. The amino-group exerts little effect.

One of us (G. M. B.) has been working with an Imperial Chemical Industries Research Fellowship.—UNIVERSITY OF GLASGOW. [Received, October, 24th, 1946.]

An Improved Preparation of 1:8-Dinitronaphthalene. By HERBERT H. HODGSON and EDWARD R. WARD.

WHEREAS 1:8-dinitronaphthalene is scarcely attacked by aqueous sulphide even at 90° (Hodgson and Walker, *J.*, 1933, 1346; E.P. 392,914), it is rapidly converted in methanol suspension by a mixture of sodium sulphide and sodium hydrogen carbonate into sulphide dyes (Hodgson and Ward, *J.*, 1945, 794). When, however, the mixture of 1:5- and 1:8-dinitronaphthalene obtained by nitration of α -nitronaphthalene (Hodgson and Walker, *J.*, 1933, 721) is treated by the above sodium sulphide-sodium hydrogen carbonate mixture in methanol, in amount just sufficient to reduce the whole of the 1:5-dinitronaphthalene (about one-third, as determined by the complete removal of the 1:8-isomeride with sodium sulphite), the 1:8-dinitronaphthalene is entirely unattacked and remains behind after extraction with hydrochloric acid of the 5-nitro-1-naphthylamine mixed with it. Only one crystallisation of the residue from toluene is necessary for obtaining practically pure 1:8-dinitronaphthalene in almost quantitative amount.

The finely divided mixture (10 g.) of 1:5- and 1:8-dinitronaphthalene was suspended in boiling methanol (150 c.c.) and treated with the reducing agent (14 c.c.) [prepared by dissolution of crystalline sodium sulphide (24 g.) and sodium hydrogen carbonate (8 g.) in water (40 c.c.)] added in one batch, and the boiling was continued for 5 minutes; ice chips were then added quickly to the reddish-brown mixture before pouring it into water (total volume ca. 1 l.). No sulphide was present at the end of the reaction. The solid was filtered off, washed with water, and then extracted 4 times with boiling 8% hydrochloric acid (400 c.c. per time); the yield of extracted 5-nitro-1-naphthylamine was 8% of the original mixture and ca. 24% of the 1:5-dinitronaphthalene originally present. The acid-extracted residue, after being washed with water, was dried, and extracted twice with boiling toluene (200 c.c.); on concentration, the filtered toluene extract afforded 1:8-dinitronaphthalene (6.3 g., i.e., 63% of the original mixture and ca. 95–96% of the amount of 1:8-dinitronaphthalene present; cf. the crude yield of ca. 40% obtained by Hodgson and Walker, *loc. cit.*), m. p. 169–171.5°. Increasing the amount of reducing agent beyond that used above lowered the yield of 1:8-dinitronaphthalene and also the purity of the 5-nitro-1-naphthylamine.

The authors thank Imperial Chemical Industries Ltd., Dyestuffs Division, for gifts of chemicals, and the Department of Scientific and Industrial Research for a Senior Research Award (to E. R. W.). TECHNICAL COLLEGE, HUDDERSFIELD. [Received, October 25th, 1946.]

OBITUARY NOTICE.

BEVAN LEAN.

1865—1947

BEVAN LEAN received his early education at Ackworth School, near Pontefract, and at Bootham School, York. He proceeded in 1887 to Owens College, Manchester, to study chemistry, where his exceptional ability was soon recognised. He held the Dalton Scholarship for research in 1891 and the Berkeley Fellowship in 1893, and was appointed to the staff of the Chemistry Department as Assistant Lecturer and Demonstrator in 1894. As a student he was resident at Dalton Hall, and was Tutor in Chemistry there from 1889 to 1894.

During these years at Manchester Lean was actively engaged in research, and was author or part author of six papers in the *Transactions* of the Chemical Society, published in the years 1892—1900. The first of these, with W. A. Bone, was on the "Behaviour of Ethylene on Explosion with less than its own Volume of Oxygen", but the remainder showed that his chief interest lay in the realm of synthetical organic chemistry and dealt with butanetetracarboxylic acids, their homologues, and derived compounds. He took the external London Degrees of B.Sc. (1889) and D.Sc. (1894).

In 1897 Lean forsook an assured academic future to devote his life to school teaching. After four years as science master at Ackworth, he was appointed Headmaster of the Friends' school at Sidcot, Somerset, a position which he held for twenty-eight years. While there, he published with W. H. Perkin, Junr., in 1909 "An Introduction to Chemistry and Physics". Lean was himself a lifelong member of the Society of Friends, and was deeply religious. Under his influence the school developed greatly, and the discipline of his scientific training and his whole-hearted devotion to the welfare of the school and the individual scholars combined to make him a headmaster of outstanding ability who won the respect and affection of many generations of Sidcot scholars. He leaves a widow and two sons. The elder, Oscar B. Lean, is in medical practice, and the younger, Owen B. Lean, is an entomologist with Imperial Chemical Industries Ltd.

W. BAKER.

209. *Amidines. Part VII. Preparation of Amidines from Cyanides, Aluminium Chloride, and Ammonia or Amines.*

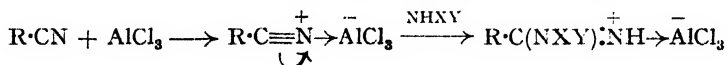

By P. OXLEY, M. W. PARTRIDGE, and W. F. SHORT.

Amidines and *N*-substituted amidines can be prepared from cyanides, aluminium chloride, and ammonia or an amine. The method gives good yields of *NN*-dialkylamidines, which are obtained in poor yield by the ammonium sulphate method.

THE preparation of amidines from cyanides and ammonium or substituted ammonium sulphates was described in Part I (Oxley and Short, *J.*, 1946, 147), in which the production of *NN*-disubstituted amidines was illustrated by a single example, namely *NN*-diphenylbenzamidine, obtained in 29% yield from phenyl cyanide and diphenylammonium benzenesulphonate. Application of the method to *p*-cyanophenyl methyl sulphate and piperidinium benzenesulphonate afforded *NN*-*pentamethylene-p*-methylsulphonylbenzamidine (27%), but our initial attempts to bring about a similar reaction with diethylammonium benzenesulphonate were unsuccessful. On raising the reaction temperature to 280°, however, *N*-ethyl-*p*-methylsulphonylbenzamidine was obtained in 0.8% yield, rising progressively to 4.5% at 325°. The same amidine was obtained from the cyanide and triethylammonium benzenesulphonate at 305° (0.2%), ethylammonium benzenesulphonate at 280° (41%), or ethylammonium chloride at 250°. (We find that it is essential to use the ammonium salt of a sulphonic acid or ammonium thiocyanate in order to obtain reasonable yields of unsubstituted amidines, but mono- and dialkylammonium chlorides may give good yields of substituted amidines.) Ammonium benzenesulphonate (81%) was obtained when diethylammonium benzenesulphonate and phenyl cyanide were heated at 350° and little cyanide was recovered. Similarly, piperidinium benzenesulphonate and phenyl or benzyl cyanide at 300° gave ammonium benzenesulphonate and benzamidinium or phenylacetamidinium benzenesulphonate. These dealkylations recall the progressive dealkylation of trialkylammonium chlorides on heating (Hofmann, *Proc. Roy. Soc.*,

1860, 10, 595; Fileti and Piccini, *Ber.*, 1879, 12, 1508) and Werner's observation (*J.*, 1914, 105, 2769) that whereas ammonium methyl sulphate rearranges to methylammonium hydrogen sulphate and undergoes some demethylation above 240°, ammonium ethyl sulphate is completely decomposed on heating into ammonium hydrogen sulphate and ethylene. We ultimately found that a 7% yield of *NN*-diethyl-*p*-methylsulphonylbenzamidinium could be obtained from the cyanide and diethylammonium benzenesulphonate at 224° and was identical with a specimen prepared by the Pinner method. *NN*-Diethylbenzamidinium was prepared by the Pinner method and its *toluene-p*-sulphonate was almost completely decomposed at 215–250° into phenyl cyanide and diethylammonium *toluene-p*-sulphonate. These observations indicate that the sulphonate method is unlikely to be generally suitable for the preparation of *NN*-dialkylamidines.

The few cyanides which are known to combine directly with ammonia or amines to yield amidines contain polar groups which stimulate the additive capacity of the cyano-group (Part I, *loc. cit.*), and it seemed probable that the reactivity of cyanides could be stimulated, as is the case with carbonyl compounds, by combination with a catalyst having strong kationoid properties. A number of alkyl cyanide-aluminium chloride complexes have been described (Genvresse, *Bull. Soc. chim.*, 1888, 49, 341; Perrier, *Compt. rend.*, 1895, 120, 1424; *Bull. Soc. chim.*, 1895, 13, 1031), and it seemed likely that catalysts of the Friedel-Crafts type might enhance the dipole condition of the molecule and with it its reactivity:

On the other hand, aluminium chloride and similar kationoid compounds readily yield amines with ammonia and amines, so that the efficiency of the catalyst would be reduced by the presence of the competitive anionoid centre in the base and would also depend upon the solubility of the respective complexes in the reaction mixture. Thus, *p*-cyanophenyl methyl sulphone and aluminium chloride yielded an insoluble brown complex which gave only traces of amidine (Fuller reaction; *Nature*, 1944, 154, 773) when heated with ammonia in various solvents, but *p*-methylsulphonylbenzamidinium was obtained in 54% yield when the cyanide and aluminium chloride were heated with excess of molten urea, which acts as a source of ammonia and as a solvent. A number of amidines have been prepared by heating a cyanide and aluminium chloride with a base, and the scope of the method is illustrated by the examples in the Table. It will be noted that the method affords good yields of *NN*-dialkylamidines and is therefore a useful supplement to the ammonium sulphonate method.

Amidine (a).	Yield, %.	Amidine (a).	Yield, %.
Benzamidinium (b)	57	<i>N</i> -2-Pyridyl- <i>p</i> -methylsulphonylbenz-

<i>N</i> -Phenyl-2 : 4-dichlorobenzamidinium ...	74	<i>NN</i> -Diphenylpicolinamidinium	76

(a) The product was isolated as base, hydrochloride, picrate, or benzenesulphonate (see experimental section): the yields recorded refer to the pure compound first isolated and are based on the cyanide employed.

(b) Gaseous ammonia used.

(c) Urea (16 mols.) employed as source of ammonia.

(d) *NN*-Diphenylacetamidinium (3.9%) was also formed.

We have made a cursory examination of the use of other catalysts for the production of amidines since it might be desirable to avoid the use of aluminium chloride in certain cases. Several catalysts used in reactions of the Friedel-Crafts type, such as ferric chloride, zinc, chloride, and stannic chloride, have been found to promote the formation of amidines, and other compounds exhibiting kationoid activity were also effective (see Table below). Boron trifluoride failed to promote the union of benzyl cyanide and cyclohexylamine at 140°; this may be due to the stability of monoaminoboron trifluoride.

(a) Urea used as source of ammonia.

(b) Tribenzyl borate was ineffective.

EXPERIMENTAL.

Cyanides and Substituted Ammonium Benzenesulphonates.

Benzamidinium.—Phenyl cyanide (10 g.) and piperidinium benzenesulphonate (25 g.; 1.06 mols.) were heated at 300° for 14 hours and afforded benzamidinium benzenesulphonate, m. p. and mixed m. p. 175—175.5° (5 g., 18.5%), and ammonium benzenesulphonate, m. p. and mixed m. p. 283—285° (6.2 g., 36.5%).

Phenylacetamidinium.—Benzyl cyanide (10 g.) and piperidinium benzenesulphonate (12.5 g.; 1 mol.) similarly gave phenylacetamidinium benzenesulphonate, m. p. and mixed m. p. 186—186.5° (2.4 g., 16%), and ammonium benzenesulphonate, m. p. and mixed m. p. 283—285° (2.7 g., 30%), after 14 hours at 300°.

***N*-Ethyl-*p*-methylsulphonylbenzamidinium.**—(a) A mixture of *p*-methylsulphonylphenyl cyanide (9.05 g.) and ethylammonium benzenesulphonate (10.15 g.; 1 mol.) was heated at 275—280° for 80 minutes and the residue was recrystallised from hot water (100 c.c.), giving recovered cyanide (2 g.), m. p. and mixed m. p. 140—141°. The aqueous solution was extracted with chloroform and made alkaline with 5*N*-sodium hydroxide, and the amidine (4.6 g.; 41%) was collected in chloroform. This amidine was obtained as a gum, but *N*-ethyl-*p*-methylsulphonylbenzamidinium picrate had m. p. 155.5—156° (Found: N, 15.4. C₁₈H₁₇O₆N₃S requires N, 15.4%). The toluene-*p*-sulphonate had m. p. 242° (Found: C, 51.2; H, 5.6; N, 7.2; S, 15.9. C₁₇H₁₈O₃N₂S₂ requires C, 51.25; H, 5.5; N, 7.0; S, 16.1%).

(b) A mixture of the cyanide (5 g.) and ethylammonium chloride (5 g.; 2.2 mols.) was heated at 250° for an hour and afforded 1.3 g. of recovered cyanide and 3.5 g. (56%) of crude amidine which gave 3.7 g. (34%) of pure toluene-*p*-sulphonate, m. p. and mixed m. p. 242°. After 3½ hours at 224° a mixture of the cyanide (5.43 g.) and ethylammonium chloride (9.8 g.; 4 mols.) afforded 27.6% of recovered cyanide and 43% of amidine, isolated as toluene-*p*-sulphonate. The following experiments with 5.43 g. of cyanide and 2.45 g. (1 mol.) of ethylammonium chloride illustrate the influence of experimental conditions on the yield of amidine.

Temp.	200—202°	224°	224°	224°	230°
Time, hrs.	1	2	4	14	1
Recovered cyanide, %	92	51.6	44.2	38.7	64.5
Yield of amidine, %*	2.85	15.9	26.7	32.3	17.9

* Isolated as toluene-*p*-sulphonate, m. p. 242°.

(c) *N*-Ethyl-*p*-methylsulphonylbenzamidinium was also produced when the cyanide (5.5 g.) and diethylammonium benzenesulphonate (7 g.; 1 mol.) were heated at temperatures within the range 280—326°. The reaction mixture was worked up as described in (a), and the principal basic product was identified by the analysis and mixed m. p. of its toluene-*p*-sulphonate. Before purification this salt gave a faint Fuller reaction and therefore probably contained traces of *p*-methylsulphonylbenzamidinium toluene-*p*-sulphonate. The mother liquors may have contained *NN*-diethyl-*p*-methylsulphonylbenzamidinium toluene-*p*-sulphonate as a minor constituent. The results are summarised in the following table.

Temp.	280°	295°	310—312°	325—326°
Time, hrs.	2	½	½	½
Recovered cyanide, %	85	82	71	42
<i>N</i> -Ethyl- <i>p</i> -methylsulphonylbenzamidinium toluene- <i>p</i> -sulphonate (m. p. 242°), %	0.83	1.65	3.6	4.55

(d) Triethylammonium benzenesulphonate, prepared from its constituents and crystallised from isopropanol to constant m. p., formed hexagonal plates, m. p. 119° (Found: N, 5.5. Calc. for C₁₂H₂₁O₃NS: N, 5.4%). Norton and Westenhoff (*Amer. Chem. J.*, 1888, 10, 133) record m. p. 120—121°. A mixture of this salt (12.95 g.; 1 mol.) and *p*-methylsulphonylphenyl cyanide (9.05 g.) was heated at 305—306° for 30 minutes. Gas evolution began at ca. 240° and continued throughout, the odour first resembling that of ethylamine but subsequently changing to that of a heterocyclic base. The product, which solidified on cooling, afforded 6.3 g. (70%) of recovered cyanide, m. p. 141—142°, and 0.55 g. of a crude base, from which only 0.04 g. (0.2%) of *N*-ethyl-*p*-methylsulphonylbenzamidinium toluene-*p*-sulphonate, m. p. and mixed m. p. 242°, was obtained.

***N*-Methyl-*p*-nitrobenzamidinium.**—A mixture of *p*-nitrophenyl cyanide (7.4 g.) and methylammonium chloride (3.9 g.; 1.2 mols.) became homogeneous after an hour's heating at 224° and after a further

3 hours at this temperature afforded 4.3 g. of recovered cyanide, m. p. 147°, and 0.7 g. (8%) of *N*-methyl-*p*-nitrobenzamidinium, m. p. 137.5° (Found: N, 23.4. $C_8H_8O_2N_3$ requires N, 23.5%). The picrate crystallised from isopropanol in needles, m. p. 174.5° (Found: N, 20.6. $C_{14}H_{11}O_9N_4$ requires N, 20.6%).

NN-Diethylbenzamidinium.—Benziminoethyl ether (10 g.; b. p. 106–108°/16 mm., Wheeler, Walden, and Metcalf, *Amer. Chem. J.*, 1898, 20, 71), diethylammonium benzenesulphonate (15.5 g.; 1 mol.), and anhydrous ethanol (20 c.c.) were kept at 50° for 21 hours, then cooled and filtered to recover diethylammonium benzenesulphonate (6.5 g.). The filtrate was evaporated under diminished pressure and the residue was shaken with 2*N*-sodium hydroxide and chloroform. The dried chloroform solution was evaporated and the residue distilled. The first fraction, b. p. 65–85°/3 mm. (1 g.), smelled of phenyl cyanide, and the amidine, b. p. 85–90° (almost entirely at 88–89°/3 mm.) (6.1 g., 51.6%), then distilled leaving a residue (1.5 g.) of 2 : 4 : 6-triphenyl-1 : 3 : 5-triazine, m. p. 236° (Found: C, 81.5; H, 5.1; N, 13.6. Calc. for $C_{21}H_{15}N_3$: C, 81.55; H, 4.9; N, 13.6%). Robin (*Ann. Chim.*, 1921, 16, 113) records m. p. 235°. *NN*-Diethylbenzamidinium picrate crystallised from methanol in plates, m. p. 161° (Found: N, 17.35. $C_{17}H_{19}O_7N_5$ requires N, 17.3%), and the toluene-*p*-sulphonate had m. p. 126° (Found: N, 8.1. $C_{18}H_{21}O_3N_3S$ requires N, 8.05%). When the imino-ether, benzenesulphonate, and ethanol were refluxed for 14 hours (internal temperature 90°), the yield of amidine was 5.1 g. (43%).

NN-Diethylbenzamidinium toluene-*p*-sulphonate began to decompose with evolution of phenyl cyanide at 215–220°, and after $\frac{1}{2}$ hour at 250° the residue afforded diethylammonium toluene-*p*-sulphonate, m. p. and mixed m. p. 103°, after being washed with ether and crystallised from isopropanol-ether (Found: N, 5.7. Calc. for $C_{11}H_{13}O_3NS$: N, 5.7%). Norton and Otten (*Amer. Chem. J.*, 1888, 10, 140) record m. p. 88°.

Considerable pressure was developed when phenyl cyanide (8.5 g.) and diethylammonium benzenesulphonate (19 g.; 1 mol.) were heated in a sealed tube for 22 hours at 345–350°. The resulting mixture of brown oil and colourless plates was triturated with chloroform and gave ammonium benzenesulphonate, m. p. and mixed m. p. 283–285° (11.6 g., 81%). The oil isolated from the chloroform solution distilled over a very wide range and afforded neither fractions of constant boiling point nor crystalline picrates.

NN-Diethyl-*p*-methylsulphonylbenzamidinium.—(a) A solution of *p*-methylsulphonylphenyl cyanide (9.05 g.) in ethanol (2.5 g.; 1.1 mols.) and chloroform (60 c.c.) was treated with a current of hydrogen chloride until 2.3 g. (1.3 mols.) had been absorbed. The imino-ether hydrochloride (8.4 g.), m. p. 220–225° (decomp.), was collected after being kept for 60 hours at room temperature (cf. Fuller, Tonkin, and Walker, *J.*, 1945, 636; Andrewes, King, and Walker, *Proc. Roy. Soc.*, 1946, B, 133, 46). The imino-ether (5.6 g., 49%), obtained as a viscous gum by shaking the hydrochloride with 5*N*-sodium hydroxide and chloroform, was heated with diethylammonium benzenesulphonate (6 g.; 1.05 mols.) for $\frac{1}{2}$ hours at 140°. Alcohol was evolved, and trituration of the crystalline product with chloroform afforded an almost insoluble solid (0.35 g.) which separated from pyridine in colourless needles, m. p. >360°, and was probably 2 : 4 : 6-tris-*p*-methylsulphonylphenyl-1 : 3 : 5-triazine (Found: N, 8.0. $C_{24}H_{21}O_6N_3S_3$ requires N, 7.7%). Concentration of the chloroform solution afforded recovered cyanide (1.3 g., m. p. and mixed m. p. 141°) and then the crude amidine (2 g., 32%) which gave a picrate, m. p. 184.5°, identical with that obtained from *NN*-diethyl-*p*-methylsulphonylbenzamidinium prepared by the aluminium chloride method (below).

(b) The cyanide (4.5 g.) and diethylammonium benzenesulphonate (23.1 g.; 4 mols.), heated at 224° for 14½ hours, afforded 3.5 g. of recovered cyanide and the crude amidine (0.5 g., 8%) which afforded the pure picrate, m. p. and mixed m. p. 184.5° (0.83 g., 7%). Almost the same yields were obtained when diethylammonium chloride (11 g.; 4 mols.) was used in place of the benzenesulphonate and the mixture heated at 224° for 2½ hours.

(c) The preparation of this amidine by the aluminium chloride method is described below.

NN-Pentamethylene-*p*-methylsulphonylbenzamidinium.—*p*-Methylsulphonylphenyl cyanide (4.5 g.) and piperidinium benzenesulphonate (24.3 g.; 4 mols.) were heated at 230° for 4 hours and gave 2.4 g. of recovered cyanide and 1.8 g. (27%) of *NN*-pentamethylene-*p*-methylsulphonylbenzamidinium, m. p. 97°. The amidine afforded a toluene-*p*-sulphonate, m. p. 230–231°, and there was no depression in m. p. on admixture of the amidine and its salt with preparations made by the aluminium chloride method (see below).

Preparation of Amidines from Cyanides, Bases, and Kationoid Reagents.*

Except where otherwise indicated, the cyanide and the base were employed in the proportion of one mol. of base per cyano-group, and one mol. of aluminium chloride (reckoned as $AlCl_3$) or of zinc chloride was added to the mixture. The experimental conditions used varied considerably and did not appear to be critical. The yields recorded are not necessarily the highest obtainable since a systematic examination of the effect of conditions on the yield of amidine was made in only a few cases. The reaction product, consisting of a complex of the amidine with the catalyst, was carefully decomposed with water and, when the amidine hydrochloride was sparingly soluble in water, it separated on cooling from the hot, filtered solution. Usually, however, the amidine was liberated from the solution by excess of aqueous sodium hydroxide, collected in chloroform, and then isolated as base, picrate, or hydrochloride. The methods employed follow closely those described in previous parts of this series, to which reference is made for earlier descriptions of many of the amidines (Part I, Oxley and Short, *J.*, 1946, 147; Part II, Oxley, Robson, Partridge, and Short, *ibid.*, p. 763; Part III, Oxley and Short, this vol., p. 382; Part IV, Partridge and Short, *ibid.*, p. 390; Part V, Hullin, Miller, and Short, *ibid.*, p. 394).

Benzamidinium.—(a) A mixture of phenyl cyanide (2.1 g.) and aluminium chloride (5.3 g.; 2 mols.) was heated at 100° for 30 minutes in an atmosphere of dry ammonia, and the amidine was isolated as picrate, m. p. and mixed m. p. 239–240°. Yield, 3.95 g.

(b) Phenyl cyanide (2.06 g.), ammonium benzenesulphonate (3.5 g.; 1 mol.), and triphenyl borate

* See also B.P. Applns. 22748 and 22749 (4.9.1945).

(5.8 g.; 1 mol.) gave a 60% yield of benzamidinium benzenesulphonate, m. p. and mixed m. p. 175—175.5°, when heated at 160° in a stream of dry ammonia for 5 hours.

o-Nitrobenzamidinium.—*o*-Nitrophenyl cyanide (5.6 g.), aluminium chloride (5 g.), and urea (36 g.; 16 mols.) were heated at 180° for 2 hours with vigorous stirring. The amidine was isolated as picrate, m. p. 228—229° (Found : N, 21.4. Calc. for $C_{13}H_{10}O_6N_6$: N, 21.3%). Yield, 1.9 g. The m. p. of *o*-nitrobenzamidinium picrate is recorded in Part I as 232—233° (decomp.).

p-Nitrobenzamidinium.—(a) This amidine was prepared from *p*-nitrophenyl cyanide (1.5 g.), aluminium chloride, and urea in the proportions used in the previous example, and was isolated either as base, m. p. 216° (decomp.), or as picrate, m. p. 239—240° (Part I). After 15 minutes at 180° the yield was 26% and rose to 60% after 30 minutes. When only 8 mols. of urea were employed, the reaction mixtures solidified after 20 minutes and the yield of *p*-nitrobenzamidinium was only 4%.

(b) A mixture of *p*-nitrophenyl cyanide (1.5 g.), urea (9.6 g.; 16 mols.), and zinc chloride (1.4 g.) afforded a homogeneous mixture after being stirred at 180° for 15 minutes, and after another 15 minutes at this temperature the yield of amidine, m. p. 212°, was 38%.

(c) A 9.1% yield of amidine was obtained when the cyanide (3 g.) and zinc chloride (2.8 g.) were heated at 180° for 15 minutes in a stream of ammonia. After 15 minutes at 135—140° the yield was 1.5%.

(d) When *p*-nitrophenyl cyanide (1.5 g.), urea (9.6 g.; 16 mols.), and anhydrous ferric chloride (1.6 g.) were heated to 120°, an exothermic reaction raised the temperature to 180°, and the cooled reaction mixture then afforded a 30% yield of the amidine.

(e) The cyanide (1.5 g.), urea (2.4 g.; 4 mols.), and stannic chloride (2.6 g.) afforded a 56% yield of amidine, isolated as picrate, m. p. 230—232°, after 30 minutes at 180°. Recrystallisation from methanol raised the m. p. of the picrate to 238—239°.

p-Methylsulphonylbenzamidinium.—(a) A mixture of *p*-methylsulphonylphenyl cyanide (9 g.), aluminium chloride (6.7 g.), and urea (48 g.; 16 mols.) was heated at 180° for 30 minutes. The amidine was isolated as the picrate, m. p. and mixed m. p. 263—264° (Part IV). Yield, 11.5 g.

p-Methylsulphonylphenyl cyanide (4.5 g.) and aluminium chloride (3.3 g.; 1 mol.) afforded a brown complex when heated in benzene (250 c.c.). This solid, which softened at 95—105° and decomposed at 120—125° with gas evolution, gave a trace of amidine (Füller reaction) when heated in a stream of ammonia in various solvents. A similar result was obtained when zinc chloride, ferric chloride, or stannic chloride was substituted for aluminium chloride. Only traces of amidine were formed when the cyanide and aluminium isopropoxide were heated in ammonia at 100° or 110°, 99% of the cyanide being recovered.

(b) A mixture of *p*-methylsulphonylphenyl cyanide (1.81 g.) and triphenyltin chloride (3.85 g.; 1 mol.; Kozeschkov, Nadj, and Alexandrov, *Ber.*, 1934, 67, 1348) was heated for 24 hours at 100° in a stream of ammonia, and the amidine was isolated as *p*-methylsulphonylbenzamidinium toluene-*p*-sulphonate, m. p. 292—293° (Found : N, 7.6. $C_{15}H_{18}O_6N_2S_2$ requires N, 7.6%). The yield was 2.75 g. (74%).

(c) A 40% yield of the toluene-*p*-sulphonate was similarly prepared from the product obtained by heating the cyanide (3.62 g.) and triphenyl borate (5.8 g.; 1 mol.) in a stream of ammonia for 17 hours at 100°. No amidine was obtained when tribenzyl borate (1 mol.) was used in place of triphenyl borate.

β-Naphthamidinium.—A mixture of *β*-naphthyl cyanide (1.5 g.), urea (9.6 g.; 16 mols.), and aluminium chloride (1.3 g.) evolved ammonia when heated but was not completely homogeneous after 1 hour at 180°. The product afforded *β*-naphthamidinium picrate (0.15 g.), m. p. 248°, and recrystallisation from methanol gave the pure product, m. p. and mixed m. p. 252° (Part I).

Phenylacetamidinium.—Phenylacetamidinium picrate (1.18 g.), m. p. and mixed m. p. 227—228° (decomp.), was prepared from the homogeneous melt obtained by heating benzyl cyanide (1.2 g.), urea (9.6 g.; 16 mols.), and zinc chloride (1.4 g.) at 180° for an hour. The same m. p. is recorded in Part IV.

N-Phenyl- and *NN'*-Diphenyl-acetamidinium.—Powdered aluminium chloride (66.6 g.) was added in portions during $\frac{3}{4}$ hour to methyl cyanide (20.5 g.) and aniline (46.5 g.) so that the temperature remained at 90—100°, and the mixture was kept at 100° for an hour. The mixture of bases (58.7 g.), isolated from the product in the usual way, afforded crystals (3.9%) of *NN'*-diphenylacetamidinium, m. p. 131—132°, on recrystallisation from aqueous methanol. A second recrystallisation from aqueous methanol afforded the pure amidine, m. p. 133.5—134° (cf. Part III). The original mother liquor was made acid to brilliant-yellow with ethanolic picric acid and the crude picrate was recrystallised from methanol giving *N*-phenylacetamidinium picrate, m. p. 194—195° (Found : N, 19.3. Calc. for $C_{14}H_{13}O_7N_5$: N, 19.3%), higher than the values previously recorded (Part III). Yield, 91.6 g.

N-cyclohexyl-*aa*-diethylacetamidinium.*—When powdered aluminium chloride (10.6 g.) was added in one portion to 1-ethylbutyl cyanide (7.7 g.; Ziegler and Ohlinger, *Annalen*, 1932, 495, 110) and cyclohexylamine (9.6 g.; 1.2 mols.), the temperature rose to about 200°. When the temperature had fallen to 100°, the product was mixed with ice (100 g.) and the solid was collected and washed with a little ether. Recrystallisation of the solid (12 g.) from 0.5*N*-hydrochloric acid (125 c.c.) afforded 5.1 g. of *N*-cyclohexyl-*aa*-diethylacetamidinium chloride, m. p. 240—242° (Found : N, 12.3. $C_{12}H_{25}N_4Cl$ requires N, 12.0%).

N-Benzylbenzamidinium.—Aluminium chloride (13.3 g.) was added with stirring during 30 minutes to phenyl cyanide (10.3 g.) and benzylamine (10.7 g.) so that the temperature remained below 120°. After 20 minutes' heating at 180°, the amidine was isolated, collected in chloroform, and converted in aqueous solution into the hydrochloride, m. p. and mixed m. p. 227—229° (Part V). The yield of hydrochloride was 10.6 g., and 8.6 g. of *N*-benzylbenzamidinium picrate, m. p. 162—164°, were obtained from the mother liquor and sodium picrate solution. Recrystallisation from ethanol raised the m. p. of the picrate to 169—170° (Part V).

N-*o*-Nitrophenylbenzamidinium.—*o*-Nitroaniline (13.8 g.) was dissolved in phenyl cyanide (10.3 g.) at 50°, finely powdered aluminium chloride (13.4 g.) was then added, and the mixture was stirred at 140°

* Preparation by Mr. J. Miller.

for 20 minutes. The amidine was liberated, collected in chloroform, dissolved in an equivalent of 5*N*-hydrochloric acid, and mixed with aqueous sodium picrate. Recrystallisation of the precipitate from aqueous cellosolve afforded *N*-*o*-nitrophenylbenzamidinium picrate, m. p. 208—209° (Found: N, 17.9. $C_{19}H_{14}O_6N_8$ requires N, 17.9%). Yield, 6.92 g.

N-2-Pyridylbenzamidine.—When aluminium chloride (6.7 g.) was added to a mixture of phenyl cyanide (5.15 g.) and 2-aminopyridine (4.7 g.) the temperature rose to 160° and the reaction was completed by heating at 200° for 15 minutes. Crystallisation of the crude amidine from light petroleum afforded *N*-2-pyridylbenzamidine, m. p. 99—99.5° (Found: N, 21.3. $C_{12}H_{11}N_3$ requires N, 21.3%). Yield, 6.1 g. The picrate crystallised from methanol in plates, m. p. 209° (Found: N, 19.9. $C_{18}H_{14}O_7N_8$ requires N, 19.7%), and the toluene-*p*-sulphonate had m. p. 171.5° (Found: N, 11.6. $C_{18}H_{15}O_3N_3S$ requires N, 11.4%).

N-Phenylbenzamidine.—A mixture of phenyl cyanide (5.2 g.), aniline (4.7 g.), and zinc chloride (6.8 g.) was heated at 110—115° for 30 minutes, and the temperature was then quickly raised to 210° to give a homogeneous melt, which was then cooled immediately. The crude amidine afforded 0.54 g. of *N*-phenylbenzamidine, m. p. and mixed m. p. 116° (Part I), on crystallisation from ethanol, and a second crop (2.5 g.), m. p. 112°, gave pure amidine (2.45 g.) when purified through the toluene-*p*-sulphonate.

N-Benzylanisamidine.—The temperature rose to about 200° when aluminium chloride (13.4 g.) was added to *p*-methoxyphenyl cyanide (13.3 g.) and benzylamine (11 g.). The product was crystallised from water giving *N*-benzylanisamidinium chloride, m. p. 225° (Found: N, 10.1. $C_{15}H_{17}ON_2Cl$ requires N, 10.1%). Yield, 22.8 g. *N*-Benzylanisamidine crystallised from light petroleum (b. p. 80—100°) in prisms, m. p. 89° (Found: N, 11.5. $C_{15}H_{16}ON_2$ requires N, 11.7%).

N-cyclohexylanisamidine.—*p*-Methoxyphenyl cyanide (6.65 g.), cyclohexylamine (6.0 g.), and aluminium chloride (7 g.), brought into reaction as described in the previous example, afforded *N*-cyclohexylanisamidinium chloride (12.6 g.), m. p. 275—276° (decomp.) (Found: N, 10.4. $C_{14}H_{21}ON_2Cl$ requires N, 10.4%). *N*-cyclohexylanisamidine, purified by sublimation in a vacuum, had m. p. 100° (Found: N, 12.3. $C_{14}H_{20}ON_2$ requires N, 12.1%), and the picrate crystallised from ethanol in needles, m. p. 141° (Found: N, 15.3. $C_{20}H_{23}O_8N_8$ requires N, 15.2%).

N-Phenyl-2:4-dichlorobenzamidine.—Powdered aluminium chloride (6.7 g.) was added during 10 minutes to a solution of 2:4-dichlorophenyl cyanide (8.6 g.) in aniline (4.7 g.) prepared at 50°. The temperature rose to ca. 130° during the addition and the reaction was completed by heating at 140° for an hour. The crude amidine (12.7 g.) was converted into *N*-phenyl-2:4-dichlorobenzamidinium chloride (11.1 g.), m. p. 147—149° (Found: N, 9.0. $C_{13}H_{11}N_2Cl_3$ requires N, 9.3%). Addition of sodium picrate to the mother liquors afforded the picrate (2.4 g.), m. p. 148—149° (Found: N, 13.9. $C_{19}H_{13}O_7N_8Cl_2$ requires N, 14.15%).

N-2-Pyridyl-*p*-methylsulphonylbenzamidine.—Aluminium chloride (4.5 g.; 0.7 mol.) was added with cooling to *p*-methylsulphonylphenyl cyanide (9.05 g.) and 2-aminopyridine (4.7 g.), and the mixture was then heated at 180° for 30 minutes. *N*-2-Pyridyl-*p*-methylsulphonylbenzamidine (10.1 g.) crystallised from methanol in colourless plates, m. p. 170.5° (Found: N, 15.5. $C_{13}H_{13}O_2N_3S$ requires N, 15.3%). The base afforded a monopicrate, m. p. 208—208.5° (Found: N, 16.4. $C_{18}H_{14}O_6N_8S$ requires N, 16.7%). Less than 0.1% of this amidine was produced when the cyanide and 2-aminopyridine benzene-sulphonate (4 mols.) were heated at 224° for 5 hours.

N-cyclohexylphenylacetamidine.—(a) The addition of aluminium chloride (13.4 g.) to benzyl cyanide (11.7 g.) and cyclohexylamine (9.9 g.) was regulated so that the temperature of the mixture did not exceed 140°, and the cold reaction product was decomposed by cold water (100 c.c.). The crude hydrochloride (22.7 g., m. p. 299—300° decomp.) was collected after cooling, and recrystallisation from water afforded *N*-cyclohexylphenylacetamidinium chloride, m. p. 301—302° (decomp.) (Found: N, 11.0. $C_{14}H_{21}N_2Cl$ requires N, 11.1%). *N*-cyclohexylphenylacetamidine crystallised from light petroleum (b. p. 100—120°) in needles, m. p. 122.5° (Found: N, 12.95. $C_{14}H_{20}N_2$ requires N, 13.0%). The picrate had m. p. 103—105° (Found: N, 15.9. $C_{20}H_{23}O_7N_8$ requires N, 15.7%). The effect of variations in the proportion of reactants and in the reaction conditions on the yield of amidine is shown in the table below. Each experiment was performed with 11.7 g. of benzyl cyanide, and variations in the reaction time were due to the necessity of controlling the temperature in some experiments by regulating the rate of addition of aluminium chloride and in others by heating the reaction mixture.

* Benzene (50 c.c.) was used as solvent.

† Calculated on the amine.

(b) The temperature rose to ca. 60° when anhydrous zinc chloride (13.7 g.) was added to benzyl cyanide (11.7 g.) and cyclohexylamine (9.9 g.), and after 2 hours at 200° *N*-cyclohexylphenylacetamidine (1.2 g. or 6%), m. p. and mixed m. p. 122.5°, was isolated from the reaction product. After 30 minutes at 100° the yield of amidine was 5%.

N-cyclohexyl-1-amidino-*n*-heptane.—An exothermic reaction occurred when aluminium chloride (2.7 g.) was added to *n*-heptyl cyanide (2.5 g.) and cyclohexylamine (2 g.), and the temperature rose to ca. 200°. The reaction mixture, which was allowed to cool immediately, afforded *N*-cyclohexyl-1-amidino-*n*-heptane hydrochloride (5.1 g.), m. p. 200° (Found: N, 10.65. $C_{14}H_{29}N_2Cl$ requires N, 10.75%). The picrate had m. p. 102° (Found: N, 15.6. $C_{20}H_{31}O_7N_8$ requires N, 15.45%).

1:3-Bis-(*N*-phenyl-4-amidinophenoxy)propane.—Powdered aluminium chloride (2.67 g.; 1 mol.) was added during 10 minutes with stirring to a mixture of 1:3-bis-(4-cyanophenoxy)propane (5.6 g.) and aniline (3.7 g.; 2 mols.) previously heated to 140°, and, after 20 minutes at this temperature, the mixture was cooled and decomposed with hot aqueous alcohol. The crude amidine (6.4 g.) was

liberated and converted into 1:3-bis-(*N*-phenyl-4-amidinophenoxy)propane benzenesulphonate, m. p. 219—220° (Found: N, 7.3. $C_{41}H_{40}O_8N_4S_2$ requires N, 7.2%). The amidine had m. p. 206—207° (Found: N, 12.1. $C_{22}H_{22}O_2N_4$ requires N, 12.1%), and the hydrochloride, m. p. 287—288° (decomp.) (Found: N, 10.5. $C_{22}H_{20}O_2N_4Cl_2$ requires N, 10.4%).

NN-Pentamethylenebenzamidine.—Aluminium chloride (13.4 g.) was added during 20 minutes with cooling in ice-water to phenyl cyanide (10.3 g.) and piperidine (8.5 g.), and the mixture was subsequently heated on the steam-bath for 1½ hours. *NN*-Pentamethylenebenzamidine (6.9 g.), b. p. 98°/0.5 mm., was isolated from the product and converted into the picrate, m. p. and mixed m. p. 173—174° (Part IV).

N-Phenyl-*N*-methylbenzamidine.—Aluminium chloride (6.7 g.) was slowly added to phenyl cyanide (5.15 g.) and methylaniline (5.35 g.), and, after 20 minutes at 160°, *N*-phenyl-*N*-methylbenzamidine (10.5 g.) was isolated; it crystallised from light petroleum (b. p. 60—80°) in needles, m. p. 85.5° (Found: N, 13.3. Calc. for $C_{14}H_{14}N_2$: N, 13.3%). The picrate had m. p. 187° (Found: N, 15.9. Calc. for $C_{20}H_{17}O_7N_5$: N, 15.9%). The m. p.s of the amidine and its picrate are recorded in Part V as 85° and 186—188° respectively.

NN-Diethyl-*p*-methylsulphonylbenzamidine.—A mixture prepared by slowly adding aluminium chloride (7 g.) to *p*-methylsulphonylphenyl cyanide (9.05 g.) and diethylamine (7.3 g.; 2 mols.) was heated on the steam-bath for 1½ hours, and afforded the crude amidine (12.8 g.) as a gum. *NN*-Diethyl-*p*-methylsulphonylbenzamidinium picrate had m. p. 184.5° (Found: N, 14.7. $C_{18}H_{21}O_9N_5S$ requires N, 14.5%), and the toluene-*p*-sulphonate had m. p. 162° (Found: N, 6.6. $C_{19}H_{20}O_8N_5S_2$ requires N, 6.6%).

NN-Pentamethylene-*p*-methylsulphonylbenzamidine.—(a) A mixture of *p*-methylsulphonylphenyl cyanide (9.05 g.), piperidine (8.5 g.; 2 mols.), and aluminium chloride (7 g.), prepared and heated as in the last example, afforded *NN*-pentamethylene-*p*-methylsulphonylbenzamidine (13.1 g.), m. p. 97° (Found: N, 10.4. $C_{13}H_{18}O_2N_2S$ requires N, 10.5%). The picrate was first obtained from methanol in slender needles, m. p. 199—199.5° (Found: N, 14.2. $C_{19}H_{21}O_9N_5S$ requires N, 14.5%), but a second form crystallising from the same solvent in cubic crystals, m. p. 188.5°, was subsequently obtained. The lower-melting form was converted into the needle form, m. p. 199.5°, at its m. p., and either could be obtained by inoculating a methanolic solution with a crystal of the desired form. The toluene-*p*-sulphonate crystallised from alcohol in prisms, m. p. 230—231° (Found: N, 6.5. $C_{20}H_{22}O_8N_5S_2$ requires N, 6.4%).

The following experiments, performed on a 0.025 g.-mol. scale using equimolecular proportions of the reactants, illustrate the influence of solvents on the yield of amidine. The yields are in terms of the picrate, m. p. 199.5°.

Solvent.	Nitrobenzene.	Chloroform.	Carbon tetrachloride.	Benzene.	
Vol., c.c.	20	25	25	25	25
Temp.	95°	65°	80°	85°	85°
Time, hrs.	1	2	2	2	6
Yield, %	25	15.2	25.0	56.5	60.5

(b) Triphenylaluminium, prepared from aluminium turnings (1 g., 2.7 atoms) and diphenylmercury (5 g.; 1 mol.) (cf. Hilpert and Gruttner, *Ber.*, 1912, **45**, 2828), was mixed with *p*-methylsulphonylphenyl cyanide (2.5 g.) and piperidine (1.2 g., 1 mol.). The temperature rose spontaneously to 125° and was maintained by heating for another 10 minutes. The crude amidine (1.7 g.) was isolated, and afforded the pure picrate (2.2 g., 32%), m. p. 199.5°.

(c) A solution of *p*-methylsulphonylphenyl cyanide (3.62 g.), piperidine (1.7 g.; 1 mol.), and triphenyl borate (5.8 g.; 1 mol.) in benzene (10 c.c.) was boiled for 2 hours (internal temp. 85°) and diluted with chloroform, and the amidine was extracted with dilute sulphuric acid. The yield of picrate, m. p. 199.5°, was 3.5%.

(d) The preparation of this amidine by the benzenesulphonate method is described above.

NN-Diphenylpicolinamidine.—2-Cyanopyridine (5.2 g.) and diphenylamine (8.5 g.) were warmed until a homogeneous mixture was obtained, and powdered aluminium chloride (6.7 g.) was then added with stirring, the temperature rising to 85°. The mixture was heated at 140° for 30 minutes and the amidine was then liberated and collected in chloroform. The crude amidine (10.4 g.; m. p. 116—118°) was crystallised several times from light petroleum and afforded *NN*-diphenylpicolinamidine, m. p. 129—130° (Found: N, 15.2. $C_{18}H_{15}N_3$ requires N, 15.4%). The picrate crystallised from methanol in prisms, m. p. 164.5—165.5° (Found: N, 16.5. $C_{24}H_{18}O_7N_5$ requires N, 16.7%).

[Received, November 27th, 1946.]

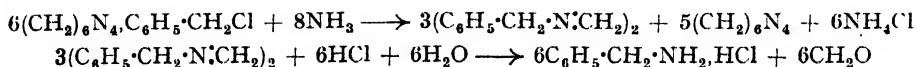

210. The Preparation of Benzylamines from Benzyl Halides and Hexamethylenetetramine.

By JOHN GRAYMORE.

A new method for the preparation of cyclic methyleneimines and thence the corresponding primary amines is described, as is also a method for the preparation of benzylmethylamine. The work also shows that these methyleneimines may be converted into the corresponding aldehydes by heating with hydrochloric acid providing the methyleneimine be in excess.

VARIOUS investigators have described methods for the preparation of primary amines from hexamine-alkyl halides (Delépine, *Compt. rend.*, 1895, **120**, 501; *Bull. Soc. chim.*, 1897, **17**, 290;

Compt. rend., 1897, **124**, 292; Galat and Elion, *J. Amer. Chem. Soc.*, 1939, **61**, 3585). The present method depends on the preparation of a methyleneimine by decomposition of an aqueous solution of a quaternary compound such as hexamine-benzyl chloride in the presence of excess of ammonia, and subsequent hydrolysis of the cyclic methyleneimine by excess of hydrochloric acid:

Hoch (D.R.-P. 139,394) showed that the oil obtained by adding excess of sodium hydroxide to hexamine-alkyl halides gave a cyclic methyleneimine when gently heated. The cyclic methyleneimine could not, however, be obtained directly by heating an aqueous solution of hexamine-alkyl halide with sodium hydroxide. Heated alone, an aqueous solution of the quaternary compound gives benzaldehyde (Sommelet, *Compt. rend.*, 1913, **157**, 852).

The ammonia serves the double purpose of ensuring the alkalinity of the solution, thus facilitating the polymerisation of the benzylmethyleamine and so preventing its isomerisation to benzylidenemethylamine, and also combines with the liberated formaldehyde.

The hydrochlorides of benzylamine and of *p*-nitro-, *p*-chloro- and *m*-methyl-benzylamine were obtained. The molecular weight (Rast) of the solid methyleneimine, obtained either by the above method or by direct condensation of benzylamine with formaldehyde, indicated it to be a mixture of the dimeride and the trimeride of $\text{CH}_2\cdot\text{N}\cdot\text{CH}_2\text{Ph}$, although it is possible that at the high temperature of melting camphor depolymerisation occurs. Analysis of the addition product of the methyleneimine with methyl iodide also seemed to indicate that the methyleneimine is a mixture. Decomposition of the addition product by heating with water at 80° gave the hydriodide of benzylmethylamine, a benzylmethyleimine, formaldehyde, and a small quantity of a substance apparently the *methiodide* of the trimeride:

The aqueous solution yields benzylmethylamine hydriodide. The method is thus suitable for providing the secondary amine pure and in good yield. The breakdown of quaternary derivatives obtained from the cyclic methyleneimines to give secondary amines has been demonstrated previously (Graymore, *J.*, 1938, 1311) but the above decomposition differs in that the secondary amine is readily recoverable by virtue of the fact that the other products, save formaldehyde, are insoluble in cold water.

It has been shown (Graymore, *J.*, 1945, 293), following a suggestion of Sommelet (*loc. cit.*), that the condensation product of benzylamine with formaldehyde, dissolved in hydrochloric acid, gave benzaldehyde when heated with hexamine. A similar result has now been achieved by heating the condensation product with two-thirds of the quantity of hydrochloric acid as required by the equation $(\text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{N}\cdot\text{CH}_2)_2 + 2\text{HCl} = 2\text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{N}\cdot\text{CH}_2\cdot\text{HCl}$, the excess of cyclic methyleneimine replacing the hexamine previously used.

EXPERIMENTAL.

Cyclic Benzylmethyleimine.—Hexamine-benzyl chloride (90 g.) was dissolved in water (400 c.c.) containing an excess of ammonia (70 c.c.; *d* 0.88) and the solution heated under reflux (1½ hours). Formaldehyde (20 c.c.; 40%) was now added to remove excess of ammonia and to precipitate any free benzylamine as cyclic methyleneimine. The oily cyclic base was allowed to settle, the greater part of the supernatant liquor decanted, and the residue poured into a large quantity of cold water; solidification of the oil was hastened by vigorous stirring. The solid was then ground, and washed well with cold sodium hydroxide and finally with cold water. The crude product (35–36 g.), *bis*(benzylmethyleimine), recrystallised from cold benzene or light petroleum, had *m. p.* 46° and was identified by comparison with sample prepared directly from benzylamine and formaldehyde [Found: *M* (Rast), 254. $(\text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{N}\cdot\text{CH}_2)_2$ requires *M*, 238]. From the decanted liquor, 50 g. of a mixture of hexamine and ammonium chloride were recovered.

Benzylamine hydrochloride. The cyclic imine (10 g., crude), dissolved in excess of concentrated hydrochloric acid, was steam-distilled to remove formaldehyde and traces of benzaldehyde, and evaporated to small bulk; benzylamine hydrochloride crystallised in large plates (11 g.), *m. p.* and mixed *m. p.* 248–249°.

Benzaldehyde from the cyclic base. To the cyclic methyleneimine (10 g.) was added concentrated hydrochloric acid (6 c.c.) and the mixture was gently heated under reflux (1 hr.). The solution was now made strongly acid with dilute hydrochloric acid, refluxed for a minute, and the precipitated benzaldehyde removed by ether and identified; yield 4 c.c. (50%).

Bis-(p-nitrobenzylmethyleimine).—Hexamine-*p*-nitrobenzyl bromide (60 g.) dissolved in water (300 c.c.) containing ammonia (60 c.c.; *d* 0.88), was heated under reflux until the semi-solid orange

1118 The Preparation of Benzylamines from Benzyl Halides, etc.

liquid which separated had formed a buff or buff-orange solid (1½ hrs.); this was cooled, removed (yield 23 g.), ground, and recrystallised from hot benzene, forming small needles, m. p. 158°. It dissolved in dilute hydrochloric acid and was reprecipitated as a buff powder. It was slightly soluble in alcohol but very soluble in ethyl acetate [Found: C, 58.5; H, 5.0; N, 16.8; *M* (Rast), 329. $(C_8H_8O_2N_2)_2$ requires C, 58.5; H, 4.9; N, 17.07%; *M*, 328].

(i) This dimer (14 g.) was dissolved in excess of hydrochloric acid (20 c.c., *d* 1.19, in 200 c.c. of water). Steam-distillation removed most of the formaldehyde, and the solution on concentration yielded *p*-nitrobenzylamine hydrochloride in yellow crystals (15 g., crude). Most of the yellow colour was extracted by washing with a small quantity of warm alcohol, and recrystallisation from water afforded needles decomposing at 256° (Found: Cl, 18.8. Calc. for $C_7H_8O_2N_2 \cdot HCl$: Cl, 18.8%).

(ii) To the cyclic methyleneimine (6 g.) was added hydrochloric acid (*d* 1.19; 2.6 c.c.) and the mixture was gently refluxed (½ hr.). After addition of an excess of dilute hydrochloric acid with cooling, *p*-nitrobenzaldehyde separated (0.8 g.); a further quantity was obtained on dilution of the filtrate with water. Recrystallised from hot water, it was obtained as a pale yellow substance, m. p. 106°, identified by conversion into its 2:4-dinitrophenylhydrazones.

Decomposition of Hexamine-p-Chlorobenzyl Chloride.—The quaternary compound (30 g.), dissolved in water (100 c.c.) containing ammonia (*d* 0.88; 30 c.c.), was heated under reflux (1 hr.). After cooling, the supernatant liquor was decanted from the oily methyleneimine, the latter washed several times with water, extracted with ether, and dried over solid sodium hydroxide. After removal of the ether, the base *p*-chlorobenzylmethyleneimine was distilled under reduced pressure and obtained as a viscous oil, b. p. 220°/100 mm. (Found: C, 62.5; H, 5.21. C_8H_8NCl requires C, 62.6; H, 5.2%). The molecular weight was not determined.

(i) This imine (6 g.) was dissolved in excess of hydrochloric acid, steam-distilled to remove formaldehyde, and evaporated to small bulk, *p*-chlorobenzylamine hydrochloride crystallising out on cooling; recrystallised from alcohol, it melted at 250° (6 g.) (Found: N, 7.9. Calc. for $C_7H_8NCl \cdot HCl$: N, 7.9%).

(ii) To the imine (6 g.) was added hydrochloric acid (*d* 1.19; 3 c.c.), and the mixture was heated gently under reflux (10 mins.). Excess of hydrochloric acid was now added, and boiling continued for 5 mins. On cooling, *p*-chlorobenzaldehyde separated as an oil which was extracted with ether. On removal of the ether it solidified (yield 2.5 g.). It was identified by oxidation to *p*-chlorobenzoic acid, m. p. and mixed m. p. 236°.

m-Methylbenzylamine Hydrochloride.—To hexamine-*m*-methylbenzyl bromide (25 g.), dissolved in water (100 c.c.), was added ammonia (*d* 0.88; 30 c.c.), and the solution heated under reflux (1 hr.). The syrupy oil which separated was removed, washed with cold water, dissolved in excess of hydrochloric acid, steam-distilled to remove formaldehyde, and the solution concentrated. *m*-Methylbenzylamine hydrochloride separated, and recrystallised from water in needles (7 g.) (Found: Cl, 22.5. Calc. for $C_8H_{12}NCl$: Cl, 22.5%).

cycloHexylmethyleneimine.—Addition of cyclohexylamine (50 g.) slowly to formaldehyde (40 c.c., 40%) precipitated an oil which solidified. From alcohol it crystallised in long prisms, m. p. 75° (Found: C, 75.1; H, 11.7; N, 12.7; *M* (Rast), 144. $C_6H_{13}N$ requires C, 75.6; H, 11.7; N, 12.6%; *M*, 111. $C_6H_{11}N \cdot CH_2$ requires *M*, 111).

Benzylmethyleneimine Methiodide.—To benzylmethyleneimine [1 mol. calculated as $(C_6H_5 \cdot CH_2 \cdot N \cdot CH_2)_3$], recrystallised from light petroleum and dissolved in dry ether, was added methyl iodide (1½ mols.). After one day the precipitated methiodide was filtered off [Found: C, 59.1; H, 5.32; N, 8.1; I, 27.4. $(C_6H_5 \cdot CH_2 \cdot N \cdot CH_2)_3 \cdot CH_3I$ requires C, 53.7; H, 5.5; N, 7.37; I, 33.4%. $(C_6H_5 \cdot CH_2 \cdot N \cdot CH_2)_3 \cdot CH_3I$ requires C, 60.1; H, 6.0; N, 8.4; I, 25.5%].

Hydrolysis of Cyclic Benzylmethyleneimine Methiodide: Preparation of Benzylmethylamine Hydroiodide.—The foregoing addition compound (18 g.) was suspended in water (250 c.c.) in an open vessel and heated at 70–80° for one hour. The methiodide slowly decomposed, a sticky oil was deposited, and formaldehyde was evolved. On cooling, the oil partly solidified and a small quantity of a white solid (A, see below) separated in needles (slightly soluble in hot water). The filtrate was evaporated on the water-bath to dryness, formaldehyde being evolved, and gave benzylmethylamine hydroiodide in yellow needles (9 g., crude). Crystallised from hot alcohol (twice), it formed white needles, m. p. 164° (Emde, *Arch. Pharm.*, 1909, **247**, 364, gives m. p. 124°) (Found: C, 38.7; H, 4.8; N, 5.3; I, 51.2. Calc. for $C_8H_{12}NI$: C, 38.6; H, 4.8; N, 5.6; I, 51.0%). It was further identified by conversion into *p*-toluenesulphonbenzylmethylamide, m. p. 92–93° (Found: S, 11.4. Calc. for $C_{11}H_{11}O_2NS$: S, 11.6%). The residue (A, above) was ground, and extracted with ether. The ethereal solution yielded cyclic benzylmethyleneimine, m. p. 46° (4 g.) [Found: C, 80.6; H, 7.6; *M* (Rast), 242. Calc. for $(C_6H_5N)_2$: C, 80.6; H, 7.6%; *M*, 238]. The residue from the ethereal extract recrystallised from hot alcohol in needles, m. p. 160–161°, of the methiodide of tris(benzylmethyleneimine) (4 g.) (Found: I, 25.3; N, 8.17. $C_{23}H_{30}N_3I$ requires I, 25.5; N, 8.4%). Heated with water at 80°, it decomposed slowly to give benzylmethylamine hydroiodide, formaldehyde, and cyclic benzylmethyleneimine. At higher temperatures under reflux a small quantity of benzaldehyde is formed.

Analysis and molecular-weight determinations were by Drs. Weiler and Strauss.

211. The Kinetics of the Reaction between Copper and Iodine in Various Solutions. Part II. Solutions of Iodine in Organic Solvents.

By L. L. BIRCUMSHAW and M. H. EVERDELL.

The kinetics of the reaction between copper and iodine when dissolved in carbon tetrachloride, chloroform, benzene, or diamyl ether has been investigated. In carbon tetrachloride and chloroform the rate appears to follow the equation $dx/dt = k(a - x)/x$, where the symbols have their usual significance. The influence of the state of the surface of the copper and the temperature coefficient has also been studied. Whereas in the work (Part I) on aqueous (potassium iodide) solutions of iodine it was shown for a large range of iodine concentrations that the rate of reaction is unaffected by the presence or thickness of the film of cuprous iodide, yet with the above solutions the rate appears to be partly controlled by the thickness of the iodide film.

IN Part I (*J.*, 1942, 598) the results of a study of the rate of reaction of copper on iodine in aqueous (potassium iodide) solution were communicated. It was shown that for a large range of iodine concentration the reaction was unimolecular with respect to the iodine concentration, and the rate was unaffected by the presence or absence of a cuprous iodide film or by the method of preparation or degree of smoothness of the copper surface. The increase in reaction rate found on increasing the potassium iodide concentrations to very high values was identified with the increase in the rate of diffusion of iodine in these circumstances. It was also demonstrated that the reaction proceeds by the diffusion of both iodine and solvent through the cuprous iodide film and not by the diffusion of copper ions.

It is well known that iodine dissolved in aqueous potassium iodide is present largely in the form of the complex ion I_3^- , the proportion of free iodine molecules being very small. In the case of organic solvents giving violet solutions the iodine is considered to exist as simple molecules, whereas in the brown solutions obtained with ethers, ketones, or esters it exists mainly as a co-ordination complex with the solvent. The great difference in the state of the iodine in aqueous solutions on the one hand, and in organic solvents on the other, might be expected to have a considerable effect on the kinetics of the reaction between copper and iodine, and it was decided to extend the work to solutions of the latter type.

This work may be divided into the following sections: (1) Experiments carried out between copper and iodine in carbon tetrachloride solution at 25°. The initial concentration of the solutions varied from 0.0025 to 0.04 g.-atom/l. (2) Experiments at 25° in chloroform, benzene, and diamyl ether, showing the effect of change of solvent. (3) Experiments at 0°, 25°, and 30°, showing the effect of change of temperature. (4) Experiments at 25°, showing the influence of the state of the copper surface on the rate of reaction.

EXPERIMENTAL.

The experimental method has been described (Part I, *loc. cit.*). Briefly it consisted in rotating strips of thick copper foil of 36 sq. cm. area in the iodine solution at about 100 revs./min. The course of the reaction was followed by titration: 5 c.c. of the solution were pipetted into an excess of N/1600-sodium thiosulphate solution, shaken until all the iodine had reacted, and then back-titrated with N/1600-iodine solution. The copper strips showed a firm film of whitish-brown cuprous iodide which exhibited no crumbling.

Carbon tetrachloride. "AnalaR" Carbon tetrachloride was distilled over calcium chloride and then repeatedly over clean, polished strips of copper to remove any traces of sulphur present. Fractions boiling at 76.7° were used for the work. The results are given in Table I, where $k = \frac{2.303v}{t_2 - t_1} \log_{10} \frac{C_1}{C_2}$ and x is given in g.-atoms $\times 10^6$, all the data relating to 25°.

Col. 7 in the readings for initial concentration N/400, contains the values of the simple unimolecular constant k (corrected for the volume change). In the reaction for copper with iodine in aqueous (KI) solution a constant is given by this equation, but in the present experiments it is seen that k falls rapidly with time. This suggests that the reaction is retarded by the cuprous iodide film. However, that the Tammann-Pilling-Bedworth equation $x^2 = kt$ is not obeyed is seen by an examination of Fig. 1, where x is plotted against time. If this relation were obeyed, values of x for a particular time t should all be equal and independent of the initial concentration of the iodine. It can also be seen that the ordinates are not proportional to the iodine concentration, which should be the case if the unimolecular relation is obeyed. It appeared probable that this reaction in organic media (a) was proportional to the iodine concentration, and (b) was inversely proportional to the thickness of the cuprous iodide film formed on the copper. Hence, if a = initial concentration of iodine and $a - x$ = concentration of iodine at time t ,

$$dx/dt = k(a - x)/x \quad \dots \dots \dots (1)$$

since x is proportional to the thickness of the cuprous iodide film. The integrated form of this equation, giving k , the velocity constant, will only hold for the reaction at constant volume. In the present work

the volume of the reacting liquid varies with each reading owing to the extraction of 5.0 c.c. for the titration. The immediate problem is to insert this volume correction into equation (1).

If m is the mass of iodine in solution, and c and v are the concentration and volume respectively, then $m = cv$ and

$$-dm/dt = -d(cv)/dt$$

If c_0 = initial concentration and v_0 = initial volume then

$$-d(cv_0)/dt = kc/v_0(c_0 - c)$$

because $v_0(c_0 - c)$ is proportional to the thickness of the cuprous iodide film at any moment during the first interval; hence

$$k_1 = \frac{v_0^2}{t_1 - t_0} (c_0 \ln \frac{c_0}{c_1} - c_0 + c_1) \quad (2)$$

At t_1 , we remove 5 c.c., and with the new volume v_1 we have

$$-v_1 \frac{dc}{dt} = \frac{kc}{v_0(c_0 - c_1) + v_1(c_1 - c)}$$

because $v_0(c_0 - c_1)$, now constant, represents the thickness of the film at the beginning of the second interval. Additional amounts of iodine added during the second stage are represented by $v_1(c_1 - c)$. Integrating between the limits c_1 and c_2 and t_1 and t_2 , we have

$$k_2 = \frac{v_1 v_0 (c_0 - c_1) \ln (c_1/c_2) + v_1^2 c_1 \ln (c_1/c_2) - v_1^2 (c_1 - c_2)}{t_2 - t_1} \quad (3)$$

This equation gives k_2 , the velocity constant for the second interval. Similarly for the third interval we have

$$-v_2 \frac{dc}{dt} = \frac{kc}{v_0(c_0 - c_1) + v_1(c_1 - c_2) + v_2(c_2 - c)}$$

which, integrated between the limits t_2 and t_3 and c_2 and c_3 , gives

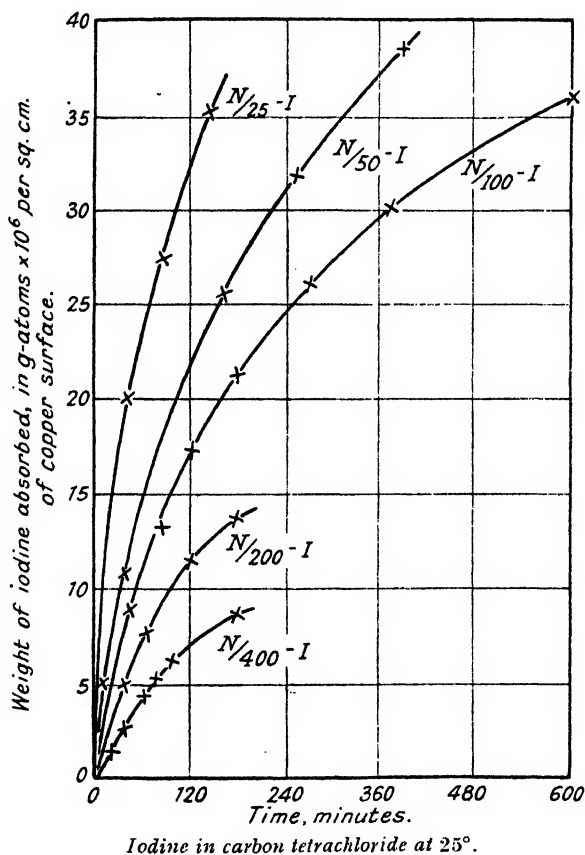

$$k_3 = \frac{v_2 \{v_0(c_0 - c_1) + v_1(c_1 - c_2)\} \ln (c_2/c_3) + v_2^2 c_2 \ln (c_2/c_3) - v_2^2 (c_2 - c_3)}{t_3 - t_2} \quad (4)$$

the velocity constant for the third interval. For the n th interval we have,

$$k_n = \frac{v_{n-1}\{v_0(c_0 - c_1) + v_1(c_1 - c_2) + \dots + v_{n-2}(c_{n-2} - c_{n-1})\} \ln(c_{n-1}/c_n) + v_{n-1}^2 c_{n-1} \ln(c_{n-1}/c_n) - v_{n-1}^2 (c_{n-1} - c_n)}{t_n - t_{n-1}} \quad (5)$$

From equation (5) we can calculate k for any interval (corrected for the change of volume). It is noteworthy that if equation (2) is used for all intervals in the reaction the differences shown in the values of the constant so obtained are small, *i.e.*, the correction term for the change of volume is small. That equation (5) is similar to equation (2), save for the inclusion of the volume changes in (5), may be shown by putting $v_1 = v_2 = v_3 \dots = v_n$ in equation (5), whereupon it reduces to equation (2). The values of k_n are given in Table I. They are fairly constant, but the agreement is not excellent. When the average values are compared for different initial concentrations of iodine they show no regular drift.

FIG. 1.

Iodine in carbon tetrachloride at 25°.

A direct contrast between the reaction in aqueous potassium iodide and that in carbon tetrachloride can therefore be made. In the former case the reaction appears to be independent of the presence or thickness of the cuprous iodide film, whereas in the latter case the reaction is directly controlled by the film thickness.

The Effect of the Solvent on the Reaction Rate.—In the determination of the effect of the solvent on the rate four organic liquids have been used.

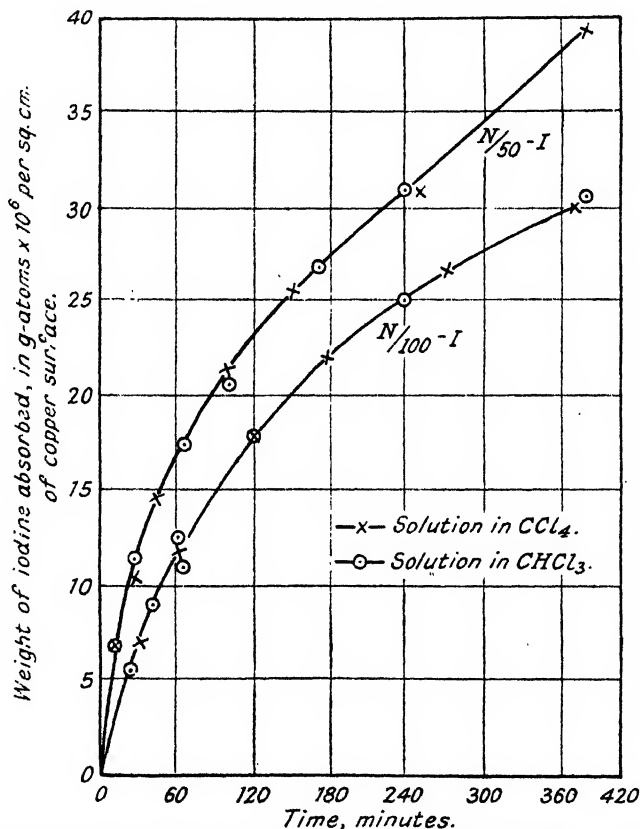

"AnalaR" Chloroform containing no foreign matter detectable by analysis (free acid, Cl^- , Cl_2 , CHO , COCl_2) was kept over calcium chloride for 36 hours, decanted, and distilled. The first fractions were discarded, and the bulk of the liquid, b. p. 60.2°, reserved for the experiments. Data were obtained for two concentrations of iodine, $N/100$ and $N/50$. The results are shown in Fig. 2, and it is seen that the rates in carbon tetrachloride and in chloroform are practically identical.

"AnalaR" Benzene containing 0.001% of thiophen and 0.002% of non-volatile matter was kept over copper foil for several days and then over fused calcium chloride. After decantation the liquid was distilled, and further purified by freezing. The m. p. of the final fraction was 5.5°, and this was used for the work. The copper surface was prepared by carborundum straight polishing (Part I, *loc. cit.*). Preliminary experiments showed that the rate in benzene is less than in carbon tetrachloride,

so experiments were carried out over a range of concentration $N/400$ — $N/25$. The results are shown graphically in Fig. 3, and it is seen that for concentrations greater than and including $N/100$ the rate of reaction in benzene is less than that in carbon tetrachloride; moreover, the difference in rate for the same concentration in the different solvents increases with increasing concentration. For solutions of $N/200$ -iodine the rate in benzene is slightly greater than in carbon tetrachloride, and this difference is more pronounced in the case of $N/400$ -solutions.

The solutions of iodine in certain oxygen-containing organic liquids, *e.g.*, ethers, esters, and ketones, show a deep brown colour when concentrated, changing to red at high dilutions. It is usually supposed that in such solutions co-ordination compounds exist between iodine and the solvent, the oxygen in the solvent acting as a donor element. It was desired to use such a solvent for this reaction. Of the common esters, ethers, and ketones, none is suitable. Acetone, which reacts with iodine in the presence of traces of alkali, was considered unsafe; diethyl ether and ethyl acetate have relatively high vapour pressures at 25° , and with the apparatus used, evaporation troubles would be encountered. The liquid

FIG. 2.

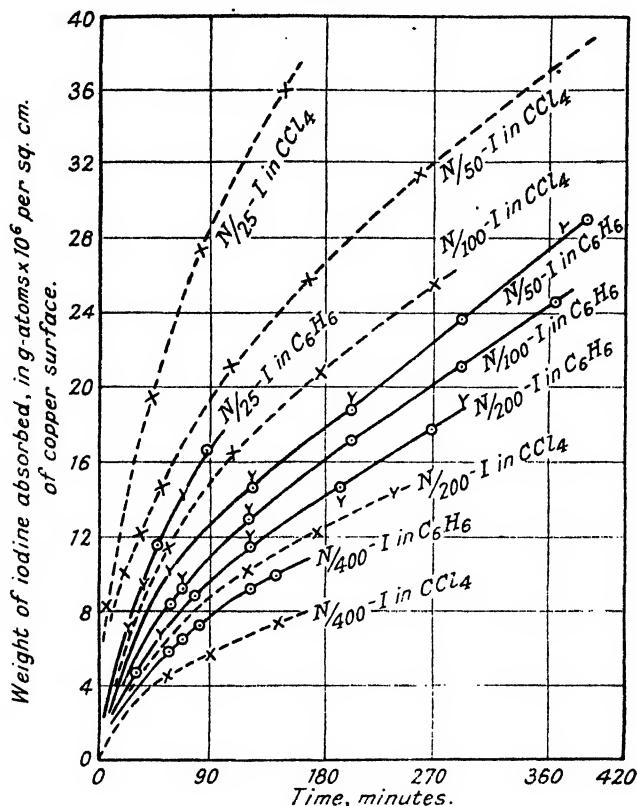

Comparison of reaction rates in chloroform and carbon tetrachloride at 25° .

eventually selected was diamyl ether. This, except for the reversible complex formation, is without action on iodine. Diamyl ether, obtained in large quantities, was purified by standing over calcium chloride, then copper foil, and by repeated distillation. The fraction of b. p. 168° was reserved for the experiments. It was intended to follow the course of the reaction in the usual way, *i.e.*, by titration, but this was found to be impossible, for the iodine in diamyl ether appears to react very slowly with sodium thiosulphate solution (possibly the dissociation of the iodine complex is very slow). On this account the rate was investigated gravimetrically. Copper strips were cut, polished, dried, and weighed. After reaction, the strip with the cuprous iodide film was washed well with diamyl ether, dried, and weighed again. The difference in weight gives the amount absorbed by the copper as cuprous iodide in time t . A new sheet of copper and a new solution of iodine were used for each experiment. The results are given in Table II, and the increases in weight are the means of two identical experiments; the iodine absorbed (col. 5) is given in terms of g-atoms $\times 10^6$ per sq. cm. of surface. The strips could be very accurately cut, and the slight variations in weight are due to slight variations in thickness. It can be seen that at all concentrations the rate in diamyl ether is much less than the rate in carbon tetrachloride.

Effect of Temperature.—The temperature coefficient of the reaction between copper and iodine in aqueous (potassium iodide) solution is small, but large enough to permit accurate measurement of the change of rate due to 5° increase to be taken. It was intended to study the reaction in organic solvents

at 20°, 25°, 30° and 35°. Preliminary experiments showed, however, that the rate of reaction at 30° was very little greater than at 25°. The increase was too small to be shown accurately, and as it was undesirable to work at temperatures much above 25° it was decided to work at 0°. In this case, extreme

care was taken to ensure the sealing of the reaction vessel, since at 0° the introduction of air would lead to water-vapour condensation. The temperature coefficient was investigated in this way with carbon tetrachloride and chloroform. The results are shown in Fig. 4, and it will be seen that the coefficient is very small.

Effect of Surface Condition of the Copper on the Rate.—The presence of an oxide film or different methods of preparing the surface of the metal have no effect on the rate of reaction in aqueous (KI) solution. It has been shown also that the rate of reaction in such solutions under the conditions studied is independent of the presence or thickness of the cuprous iodide layer on the copper. For reactions in carbon tetrachloride and chloroform it has been shown that the reaction is controlled by diffusion through the cuprous iodide layer. The structure of the film might well be influenced by the condition of the surface of the copper. It was therefore decided to investigate the effect of the condition of the surface on the rate.

Effect of temperature on rate of reaction.

| (3) N/100-I at 0°: { × in CCl ₄ , ○ in CHCl ₃ . | |

The four different methods of preparing the surface have been described in Part I (*loc. cit.*), i.e., (i) carborundum straight polishing, (ii) carborundum circular polishing, (iii) mirror finish with jeweller's rouge, (iv) etching with dilute nitric acid.

These experiments were all carried out in benzene solution, as it was considered that the films in benzene appeared rather more even and less liable to flaking than in other solvents. The results are shown in Fig. 5. Only slight differences could be detected, but it can be seen that: (1) The rates in the case of carborundum straight and carborundum circular polishing are identical; (2) the rate on the mirror surface is slightly less, (3) the acid-etched surface gives an even lower reaction rate. That is, the rate is less with the smooth surfaces, coarseness of abrasion tending to increase the velocity of the reaction.

The presence of an oxide film on the copper. Copper strips of the correct area were polished by carborundum straight polishing and heated to 100° for 30, 20, and 10 mins. as described in Part I. The oxidised copper was placed in the reaction vessel, and the reaction followed in the usual way by titration. The results are shown in Fig. 6, and it will be seen that the rate in both carbon tetrachloride and benzene is considerably decreased by the presence of an oxide film.

Films formed in Aqueous and Organic Solvents.—It has been shown that for a large range of iodine concentrations the rate of reaction in aqueous solution is unaffected by the presence or thickness of the cuprous iodide film on the copper, whereas in the case of reactions carried out in organic solvents this film controls the reaction. The question arises as to whether this difference is due to a difference in the actual films formed in the two cases or to the nature of the solutions in the two different classes of solvent.

Strips of copper foil of the usual size were polished and then rotated in a solution of N/200-iodine in N/50-potassium iodide for 30 minutes. The strips of copper covered with cuprous iodide film were then removed from the solution and washed and dried carefully. Some of the strips showed small cracks in

FIG. 5.

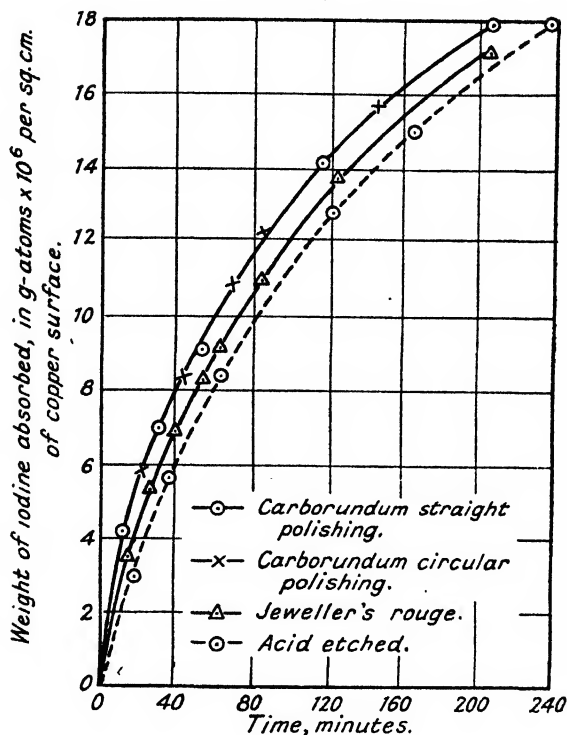

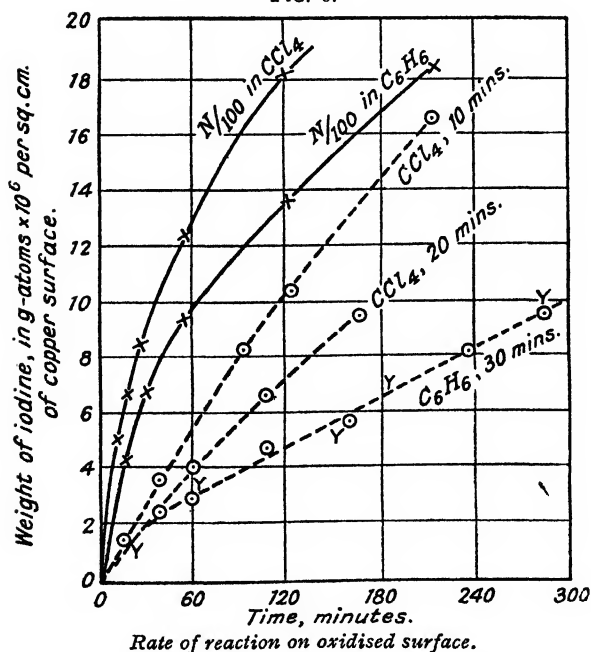

FIG. 6.

the films on drying and these were discarded. The "perfect" strips were then rotated in carbon tetrachloride, and the reaction followed by titration in the usual way. The results are given in Table III, (1) and (2), where χ is expressed as g-atoms of I $\times 10^6$.

TABLE III.

(1) *Copper covered by cuprous iodide film formed in aqueous solution rotated in N/200-iodine in carbon tetrachloride at 25°.*

Time, mins.	10	20	30	60	120	180
x_0	0.83	1.45	1.85	3.04	5.57	7.48
x (no previous film)	3.75	4.88	5.88	7.96	11.46	14.135

(2) *Copper covered by cuprous iodide film formed in carbon tetrachloride solution rotated in N/200-iodine solution at 25°.*

Time, mins.	2	5	10	15	20	30	40	50	60
x_0	1.67	4.33	8.56	12.12	15.43	20.58	24.71	27.65	30.00
x (no previous film)	1.87	4.54	8.57	12.13	15.43	20.78	24.91	28.04	30.38

The results described under (1) were not very reproducible owing to a certain amount of film-cracking, but they clearly showed that the rate in carbon tetrachloride solution is much decreased by the presence on the metal of a film deposited from an aqueous solution. The results described under (2) were easily reproducible and it is seen that the rate is unaffected by the presence of a cuprous iodide film formed in carbon tetrachloride.

DISCUSSION.

The actual rate of reaction observed in these experiments probably depends ultimately on the collisions of the iodine molecules on the copper surface, whatever the means by which the iodine travels through the cuprous iodide film. The rate of diffusion of the iodine molecules through the film will be a function of the concentration gradient of the molecules across the film, *i.e.*, the concentration of an adsorbed film of iodine on the liquid side of the cuprous iodide and the concentration, much lower, of iodine at the film (Cu_2I_2)-metal interface. The concentration of the adsorbed film of iodine will obviously depend on the state of the iodine in solution. Lachmann (*J. Amer. Chem. Soc.*, 1903, 25, 50), after an examination of iodine solutions in 60 organic solvents, distinguished two types of solution: (1) violet solutions from substances like carbon tetrachloride, chloroform, etc. (substances called saturated by Lachmann); (2) brown solutions from ethers, esters, alcohols, and ketones (substances called unsaturated by him). This subject has been investigated by a number of workers but on the whole there seems to be little doubt that Lachmann's original classification was correct.

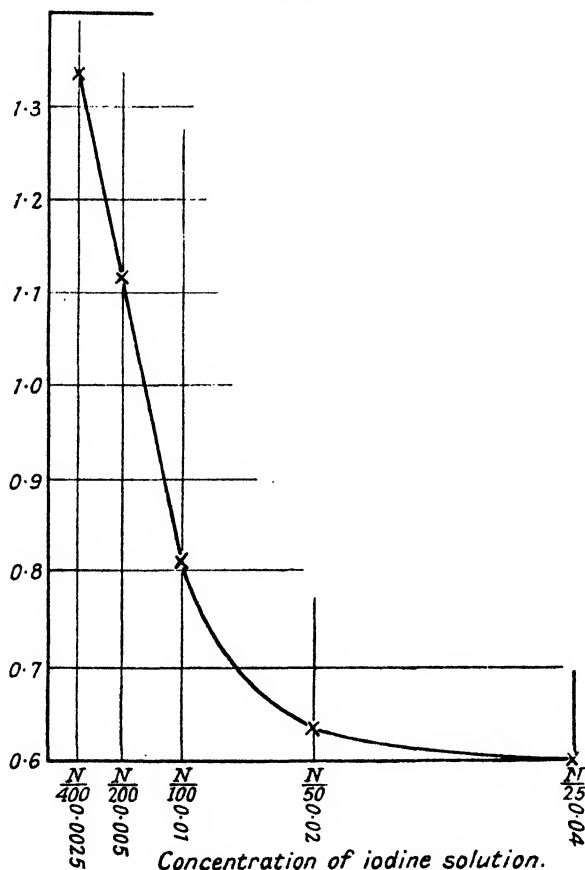

The problem of the benzene solution of iodine is not so simple, and on the collected evidence as a whole these solutions seem to fall directly into neither class. The problem has been investigated in recent years by Walker (*Trans. Faraday Soc.*, 1935, 31, 1432). This solution was placed by both Lachmann and by Getman (*J. Amer. Chem. Soc.*, 1928, 50, 2883) in the violet group, yet the colour is definitely reddish and very different from that in carbon tetrachloride, especially in concentrated solution: in more dilute solution the colours are more alike. From a study of the absorption spectrum, Walker concluded that there was some interaction between iodine and benzene. Hildebrand and Jenks (*ibid.*, 1920, 42, 2180) also showed that benzene solutions of iodine are abnormal with respect to their solubility-temperature relationships compared with other violet solutions. The problem of the possible solvation of iodine in benzene solution is made more complex by the fact that the resulting dipole moment is zero; yet when the evidence as a whole is considered some type of interaction seems to be indicated.

Some simple experiments made by the authors are not without significance. The solutions in carbon tetrachloride or chloroform can be titrated readily with sodium thiosulphate, the end-point being reached with no period of delay; but if 20 c.c. of an N/100-iodine solution in diamyl ether are titrated with N/100-thiosulphate in the presence of starch, the blue colour fades after the addition of a few c.c. of titrant. After about one hour's standing the colour returns, but is again dispersed by the addition of a small amount of thiosulphate, returning again after standing. The theoretical volume of thiosulphate solution required for titration is reached only after several days. This suggests that the thiosulphate only reacts with the free iodine, and that the restoration of the equilibrium between the latter and the complex is slow. If with benzene a solvent-iodine complex is formed in the same way and the complex is of the same nature, the same difficulty might be expected in direct titrations. No such difficulty is experienced, however, so that, although iodine and benzene may form some sort of complex, it is not of necessity of the same type or of the same degree of stability as those formed in the brown solutions.

It is seen in Fig. 2 that the rates of reaction in carbon tetrachloride and chloroform are identical. This is in agreement with Evans and Bannister's results (*Proc. Roy. Soc.*, 1929, A, 125, 370) for the reaction between silver and iodine: it might be expected, since the state of

iodine in the two solvents is believed to be the same, *i.e.*, simple molecules. Table II shows that the rate in diamyl ether is much less than the rates in carbon tetrachloride at the same concentration. This might be due to any of the following causes: (1) Only the free iodine molecules diffuse through the cuprous iodide film and react with the metal. (2) Both the free iodine molecules and the complex molecules diffuse through the film but only the free iodine molecules react. (3) Both the free iodine molecules and the complex may react with the copper, but the passage of the complex through the cuprous oxide layer will almost certainly be much slower, owing to its large molecular size.

FIG. 7.

Ratio between ordinates for benzene to ordinates for carbon tetrachloride.

Fig. 3 shows the rate of reaction in benzene compared with the rate in carbon tetrachloride at the same concentrations. Consider first the experiments at concentrations 0.01, 0.02, and 0.04N. The rate of reaction is less than in carbon tetrachloride and the difference increases with increase of iodine concentration. However, the rate of 0.0025N-iodine in benzene is slightly greater than the rate at the same concentration in carbon tetrachloride. If, in Fig. 3, the ordinates of the graph of the reaction in 0.04N-iodine in benzene are compared with those of the graph of 0.04N-iodine in carbon tetrachloride, a fairly constant value of the ratio is obtained; *e.g.*, at time 390, 300, 210, 150, and 60 minutes this ratio is 0.60, 0.61, 0.60, 0.61, and 0.60, respectively. This is, of course, a perfectly arbitrary method of comparing the reaction rates. The average values of this ratio for all the concentrations are plotted against concentration and given in Fig. 7, and show the effect of concentration on the difference in reaction rate in the two solvents. Above concentrations of approximately $N/200$ the rate in benzene is less than that in carbon tetrachloride; below $N/200$ it is greater. It is difficult to see any obvious explanation of this inversion.

Graphs for results at 0°, 25°, and 30° are shown in Fig. 4 and it is seen that the temperature coefficient is very small, much less than in the aqueous solutions.

Unlike the reaction in aqueous solution, in organic liquids the rate is affected by the nature of the metal surface; in general, coarseness of surface tends to increase the rate of reaction. The rate of reaction in both benzene and carbon tetrachloride is decreased by the presence of an oxide film, the degree of reduction increasing with the period of oxidation.

Measurements of the rate in carbon tetrachloride of specimens covered with a cuprous iodide film deposited from aqueous solution showed that the rate was much lower than that obtained with a clean metal surface. Conversely, the rate in aqueous solution of a copper specimen covered with a film deposited from a carbon tetrachloride solution was the same as with the new metal specimen. Clearly, the difference is not due to a difference in the structure of the film deposited from the two types of liquid, aqueous and organic.

When the kinetics of this reaction in aqueous and organic solutions are compared, interest centres round the fact that in aqueous solutions the rate is unaffected by the film, whereas in organic solutions the film appears to control the reaction. It is necessary to explain this difference, which cannot be traced, as we have seen, to differences in the structure of the films of cuprous iodide formed in the two cases. It has been stated (Part I) that in reactions in aqueous solution both solvent and solute are believed to pass through the iodide film. It is possible, however, that in organic solvents these do not enter the film but only the solute diffuses through the iodide. These films are readily wetted by water, but on the other hand, it was found that when a sheet of copper was removed from an organic solution of iodine and the surface liquid drained off the film appeared dry and the weight did not decrease with time as might be expected if the liquid were in the pores of the film and hence evaporated slowly. Attempts were made to remove a portion of a film, to support it on a small stand made from thin glass rod, and touch its upper surface with a drop of carbon tetrachloride. The spreading of the liquid on the solid did not take place rapidly, and for some time the under side of the film showed no signs of the liquid soaking through. Owing to cracks formed in the films, they always collapsed after about a minute, so little reliable evidence was obtained. Some evidence for the fact that organic solvents do not enter the iodide film is obtained from a consideration of the reaction in different organic solvents. If the reaction proceeds by the passage of iodine and solvent through the film, then it might be supposed that in using organic solvents of different viscosities different rates might be obtained. The rates of reaction in carbon tetrachloride and in chloroform, in both of which solvents all the evidence points to the iodine existing as simple molecules, are identical, whereas the viscosities of the two solvents are widely different. As shown above, the state of iodine in benzene and diamyl ether is complex and so prevents a consideration of the rates carried out in them with respect to the above; but the evidence from solutions in chloroform and in carbon tetrachloride alone suggests that the organic solvents do not themselves diffuse through the cuprous iodide film.

Adopting this theory, we have still to consider the mechanism by which the iodine molecules diffuse through the film. Three mechanisms appear to be possible: (1) The iodine might diffuse through large cracks in the film (a type of gaseous diffusion); (2) it might diffuse through small pores in the film, possibly in loose union with the cuprous iodide; (3) the diffusions might take place through atomic holes in the cuprous iodide crystal lattice.

The diffusion mechanism of (1) would depend on the vapour pressure of the iodine, which would increase rapidly with rise of temperature, and this would result in a relatively large temperature coefficient. The very small temperature coefficient observed is evidence against this. Mechanism (2), passage of iodine through pores little larger than the molecules themselves, is not impossible. If some type of attraction exists between the iodine and the cuprous iodide little energy would be required for the diffusion. The small temperature coefficient found is some evidence for this. (3) According to the theories developed by Jost and Schottburg "atomic holes" exist as lattice defects in any crystalline material, and it is possible that diffusion of iodine may take place in this manner. This theory of diffusion has, of course, attracted much attention during recent years. Like mechanism (2), this process would require little energy, and it is not possible to distinguish between (2) and (3) by a consideration of the temperature coefficient.

The authors thank the Chemical Society for a grant, and one of them (M. H. E.) is indebted to the Governing Body of University College, Exeter, for a grant from the Andrew Simons Fund.

212. Deoxypentose Nucleic Acids. Part I. Preparation of the Tetrasodium Salt of the Deoxypentose Nucleic Acid of Calf Thymus.

By J. MASSON GULLAND, D. O. JORDAN, and C. J. THRELFALL.

The preparation of the tetrasodium salt of the deoxypentose nucleic acid of calf thymus is described by a method in which the nucleoprotein is first isolated and then decomposed; during these processes the reaction did not vary significantly from pH 7. The analytical data support the relative proportions of nucleotides indicated by titration (Gulland, Jordan, and Taylor, Part II, this vol., p. 1131).

GULLAND, BARKER, and JORDAN (*Ann. Rev. Biochem.*, 1945, **14**, 175) have suggested that the direct isolation of nucleic acids from tissues may lead to a degraded product, and they consider that a more satisfactory procedure is to isolate and subsequently decompose the nucleoprotein. In the method which has been developed, therefore, the deoxypentose nucleoprotein of calf thymus was first isolated by making use of the remarkable difference in solubility of the nucleoprotein in sodium chloride solutions of different strengths described by Mirsky and Pollister (*Proc. Nat. Acad. Sci. U.S.*, 1942, **28**, 344; *Biol. Symposia*, 1943, **10**, 24). The deoxypentose nucleic acid was then separated from the protein by the method introduced by Sevag, Lackman, and Smolens (*J. Biol. Chem.*, 1938, **124**, 425).

The material obtained by this preparation gave satisfactory analytical figures for carbon, hydrogen, phosphorus, and sodium, but the nitrogen value was low, being 15.4% compared with the theoretical value of 15.9% based on a polynucleotide containing the four nucleotides in equimolecular quantities. Furthermore the ratio of the purine nitrogen content to that of pyrimidine nitrogen was low, a mean value of 1.6 being obtained in place of the theoretical value of 2.0. These data may be interpreted with the aid of the results of electrometric titration (Part II, *loc. cit.*), which, whilst indicating that for every four atoms of phosphorus there is 1.0 radical of thymine and 1.0 of guanine, suggest that the amount of cytosine may be as high as 1.2 radicals and of adenine as low as 0.8 radical. Re-calculation of the theoretical nitrogen analysis on this basis gives a value of 15.5%, and the purine nitrogen/pyrimidine nitrogen ratio has the value 1.6. These data are in satisfactory agreement with the observed results. The theoretical values for carbon, hydrogen, phosphorus, and sodium are not affected appreciably by this change in the nucleotide ratio in the statistical polynucleotide.

EXPERIMENTAL

Isolation of the Tetrasodium Salt of the Deoxypentose Nucleic Acid of Thymus Gland.—Fresh frozen calf thymus glands (54.5 kg.) were minced and suspended in 0.9% sodium chloride (54 l.) and milled to produce a fine suspension. This suspension was centrifuged (6300 r.p.m.) and the solid material resuspended in 0.9% sodium chloride (45.5 l.) and milled and centrifuged as before. The ribonucleoproteins, together with cytoplasmic material, were obtained from the combined extracts (120 l.) by adding an equal volume of industrial methylated spirit, and the precipitated solid was washed by decantation with 50%, then 100% industrial methylated spirit, collected, and dried in a vacuum at room temperature. Yield, 2.68 kg.

The tissues, which were now free of material containing pentose, were suspended in 10% sodium chloride (214 l.) with vigorous mechanical stirring at 0°. At this stage the viscosity of the solution increased considerably (cf. Mirsky and Pollister, *loc. cit.*). After extraction at 0° for 48 hours, the insoluble material was removed by centrifuging (6300 r.p.m.) and the deoxypentose nucleoprotein precipitated from the resultant solution (pH 6.5) by the addition of an equal volume of industrial methylated spirit. The precipitated solid was washed with 70%, then 100% industrial methylated spirit and dried in a vacuum at room temperature. Yield, 1.69 kg. of a very slightly yellow fibrous solid.

The nucleoprotein (500 g.) was powdered to assist solution and dissolved in 10% sodium chloride (45.5 l.) with vigorous mechanical stirring. The solution, which was viscous, was clarified by centrifuging (6300 r.p.m.). To the clear solution was added an equal volume of a mixture of chloroform (35 parts) and amyl alcohol (10 parts), and the mixture was emulsified by rapid mechanical stirring. The emulsion was then separated by centrifuging (DeLaval, model "500", disc type bowl, 5500 r.p.m.) into three parts: (i) the chloroform-amyl alcohol mixture, (ii) a solution containing the sodium salt of deoxypentose nucleic acid and nucleoprotein, (iii) a gel of protein hydrochloride and the chloroform-amyl alcohol mixture. The protein gel remained in the bowl of the centrifuge whereas the chloroform-amyl alcohol mixture and the solution of nucleic acid and nucleoprotein were discharged from separate outlets. The last mentioned solution was again emulsified with the chloroform-amyl alcohol mixture and the process repeated until no gel was formed on emulsification; this required nine emulsifications. The sodium salt of the deoxypentose nucleic acid was precipitated by the addition of an equal volume of industrial methylated spirit, washed free from chloride with 70% industrial methylated spirit, then 100% ethyl alcohol, and finally ether, and dried in a vacuum at room temperature. Yields from two 500 g. quantities of nucleoprotein were 130 g. and 150 g. of a white fibrous solid giving negative biuret and Sakaguchi tests [Found on sample dried at 110° in a vacuum over phosphoric oxide: C, 35.5, 35.5,

35.3; H, 3.68, 3.83, 3.56; N, 15.3, 15.3, 15.4; P, 9.35, 9.32, 9.32; Na, 6.9, 6.8 (gravimetric), 7.1 (colorimetric). Calc. for a large polynucleotide consisting of the tetrasodium salts of tetranucleotides containing on average 1 mol. each of guanine, adenine, cytosine, and thymine deoxypentose nucleotides, *i.e.* $(C_{26}H_{48}O_{24}N_{15}P_4Na_4)_x$: C, 35.4; H, 3.4; N, 15.9; P, 9.4; Na, 6.95. Calc. for a large polynucleotide consisting of the tetrasodium salts of tetranucleotides containing on average 1 mol. each of guanine and thymine, and 1.2 mols. of cytosine and 0.8 mol. of adenine deoxypentose nucleotides, *i.e.* $(C_{26.8}H_{48.8}O_{24.2}N_{14.6}P_4Na_4)_x$: C, 35.4; H, 3.4; N, 15.5; P, 9.4; Na, 6.98%. In both cases the additional HONa atoms of the two terminal nucleotides of a straight-chain polynucleotide have been ignored, since their contribution is negligible if the size of the polynucleotide is large].

Determination of Purine Nitrogen/Pyrimidine Nitrogen Ratio.—The method used was that of precipitation of purines with silver sulphate (Schmidt and Levene, *J. Biol. Chem.*, 1938, **126**, 423). The sodium salt of deoxypentose nucleic acid (*ca.* 30 mg.) was hydrolysed by boiling under reflux with 5% sulphuric acid (7 ml.) for 1 hour. When cold, the solution was diluted to 25 ml., the total nitrogen was determined on a portion (2 ml.), and 2 ml. samples were treated with an equal volume of saturated silver sulphate. The solution containing the precipitate of the silver salts of guanine and adenine was cooled at 0° for $\frac{1}{2}$ hour. The precipitate was separated by centrifuging and washed twice by stirring at 0° with a saturated solution of silver sulphate (2 ml.) followed by centrifuging. The solution was combined with the washings and analysed for pyrimidine nitrogen. The precipitate was decomposed with dilute hydrochloric acid (2 ml.), and the silver chloride removed by centrifuging and washed twice with dilute hydrochloric acid (2 ml.). The solution was combined with the washings and analysed for purine nitrogen. The purine nitrogen/pyrimidine nitrogen ratio was found to be 1.60, 1.63, 1.60, 1.58, 1.57 for five separate hydrolyses; mean, 1.60. The discrepancy between this value and the theoretical of 2 for a statistical polytetranucleotide is greater than the experimental error indicated by the Table. Nevertheless we should not have inclined to attribute undue significance to the ratio, were it not for the agreement between it, the analytical data, and the results of electrometric titration; this uniformity of trend does suggest that the purine/pyrimidine nitrogen now recorded has real meaning.

In order to confirm the accuracy of the method claimed by Schmidt and Levene (*loc. cit.*), a series of analyses of known purine and pyrimidine derivatives was performed; representative results are recorded in the Table. Determination of the purine/pyrimidine nitrogen ratio of two samples of yeast ribonucleic acid was made for comparison, the results being 1.84, 1.86; 1.84, 1.90.

Analytical Methods.—The sodium salt of deoxypentose nucleic acid is extremely hygroscopic when dried, as in this instance, at 110°/0.1 mm. over phosphoric oxide, and special technique was required in order to minimise exposure of the dried material to atmospheric moisture. Estimations of carbon by combustion presented some difficulty owing to the occlusion of carbon by the sodium metaphosphate residue in the boat, but this problem was solved by the addition of small quantities of anhydrous potassium chlorate to the fused mass at the end of the combustion. Determinations of nitrogen were made by a modified micro-Kjeldahl technique embodying the methods of Elek and Sobotka (*J. Amer. Chem. Soc.*, 1926, **48**, 501) and Friedrich ("Die Praxis der quantitativen organischen Mikroanalyse," 1933, Deuticke, Leipzig and Vienna); of phosphorus by a modification of the method of Embden (*Z. physiol. Chem.*, 1920, **113**, 138); and of sodium either gravimetrically (as sodium sulphate after removal of phosphate as barium phosphate) or colorimetrically (Hoffman and Osgood, *J. Biol. Chem.*, 1938, **124**, 347).

It is a pleasure to acknowledge our gratitude to Boots Pure Drug Company Ltd. for carrying out the large scale operations; to the British Empire Cancer Campaign for a grant which defrayed part of the cost; and to Imperial Chemical Industries Ltd. for the loan of apparatus. We wish also to record our thanks to Mr. J. E. Still, B.Sc., for the analyses for C, H, N, and P, and to Mr. H. F. W. Taylor, B.Sc., and Mr. J. M. Creeth, B.Sc., for the sodium analyses.

213. Deoxypentose Nucleic Acids. Part II. Electrometric Titration of the Acidic and the Basic Groups of the Deoxypentose Nucleic Acid of Calf Thymus.

By J. MASSON GULLAND, D. O. JORDAN, and H. F. W. TAYLOR.

The acidic and the basic groups of the tetrasodium salt of the deoxypentose nucleic acid of calf thymus and of barium thymate derived therefrom have been titrated electrometrically, employing hydrogen and glass electrodes. This polynucleotide is found to possess three amino-, two purine-pyrimidine enolic hydroxyl, four primary phosphoryl, and not more, and probably less, than 0.25 secondary phosphoryl dissociations for every four atoms of phosphorus. These data are consistent with a chain structure for this acid in which branching, if it occurs, is infrequent as compared with yeast ribonucleic acid. The main internucleotide bond is an ester linkage. For every four atoms of phosphorus it is found that there are 1.0 guanine, 1.0 thymine, 1.0 to 1.2 cytosine, and 1.0 to 0.8 adenine radicals.

The initial dissociation curves of the tetrasodium salt of the deoxypentose nucleic acid of calf thymus obtained by titrating from pH 6.9 with acid and alkali are abnormal, being displaced from the back-titration curves. This discrepancy between the forward- and back-titration curves persists in high concentrations of neutral salt. It is concluded that the purine-pyrimidine hydroxyl groups and some of the amino-groups are blocked, most probably by a hydrogen bond between these groups. The significance of this linkage in the macromolecular structure of the tetrasodium salt of the deoxypentose nucleic acid is discussed.

THE conflicting results obtained previously from investigations of the acid-base properties of thymus deoxypentose nucleic acid (Steudel, *Z. physiol. Chem.*, 1912, **77**, 497; Feulgen, *ibid.*, 1919, **104**, 189; Levene and Simms, *J. Biol. Chem.*, 1925, **65**, 519; 1926, **70**, 327; Makino, *Z. physiol. Chem.*, 1935, **232**, 229; 1935, **236**, 201; Bredereck, Köthnig, and Lehmann, *Ber.*, 1938, **71**, 2613; Bredereck and Köthnig, *ibid.*, 1939, **72**, 121; Ahlström, Euler, Fischer, Hahn, and Högberg, *Arkiv Kemi, Min. Geol.*, 1945, **20**, A, 1) may be ascribed to the different degrees of degradation of the samples studied (Schmidt, Pickels, and Levene, *J. Biol. Chem.*, 1939, **127**, 251; Cohen, *ibid.*, 1942, **146**, 471; Tennent and Vilbrandt, *J. Amer. Chem. Soc.*, 1943, **65**, 424; Gulland, Barker, and Jordan, *Ann. Rev. Biochem.*, 1945, **17**, 175). In all probability the least degraded specimens which have hitherto been examined were those prepared by the method of Bang (Hofmeister's "Beiträge chem. Physiol. Path.", 1903, **4**, 331) and studied conductimetrically by Hammarsten (*Biochem. Z.*, 1924, **144**, 383) and electrometrically by Jorpes (*Biochem. J.*, 1934, **28**, 2102) and Stenhagen and Teorell (*Trans. Faraday Soc.*, 1939, **35**, 743). They were found to possess four acid-dissociating groups per hypothetical tetranucleotide, having the very approximate pK_a' values of 2.4, 3.7, 4.3, and 5.2. The Hammarsten-Bang method of isolation, however, gave a product which on analysis was found to be very deficient in nitrogen and phosphorus (N, 11.97; P, 7.09%; Hammarsten, *loc. cit.*) when compared with the theoretical for the tetrasodium salt (N, 15.85; P, 9.37%). Furthermore, Hammarsten studied the free acid obtained from the sodium salt by the action of hydrochloric acid; as will be shown in this paper this treatment causes an irreversible change in that the free acid isolated from solutions more acid than pH 3.5 does not show the same acid-base properties as the sodium salt isolated at pH 7.0.

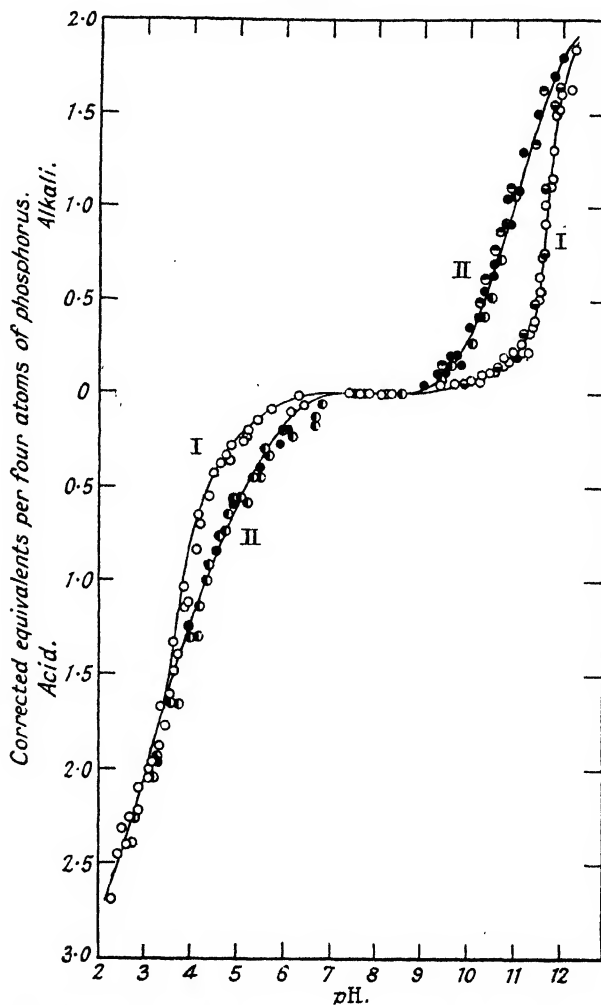

The sodium salt of calf thymus deoxypentose nucleic acid which has been studied in this investigation was isolated by a mild method (Gulland, Jordan, and Threlfall, Part I, this vol., p. 1129), throughout which the solution employed did not vary significantly from pH 7.0.* The solid was fibrous and dissolved in water to give a faintly opalescent solution, having a pH of 6.90, which exhibited marked structural viscosity and streaming birefringence (Creeth, Gulland, and Jordan, Part III, this vol., p. 1141). A second specimen, prepared by the Hammarsten-Bang procedure and supplied by Professor Caspersson through Professor Astbury in 1939, has also been studied. It was found to contain a small amount of protein which was removed by the method of Sevag, Lackman, and Smolens (*J. Biol. Chem.*, 1938, **124**, 425), and is believed to be identical with that studied with ultracentrifuge and viscosity methods by Signer, Caspersson, and Hammarsten (*Nature*, 1938, **141**, 122) and with X-ray methods by Astbury and Bell (*ibid.*, p. 747).

* It is necessary to correct a point in the paper of Tennent and Vilbrandt (*J. Amer. Chem. Soc.*, 1943, **65**, 424). The sample of "Thymonucleic acid TNA2, prepared by Gulland", referred to by these authors, was a purchased commercial sample, and the "barium thymate BT1, prepared by Gulland" was made from it by the usual method. These were given to Professor Astbury in 1939 with a warning that their purity and homogeneity was open to doubt; they were not intended for the type of investigation to which they have been put by Tennent and Vilbrandt, and in our view results obtained with them are of no value in connection with nucleic acid structure.

Results of the Present Investigation.—All electrometric titration curves have been corrected at the extremes of pH for the titration of the water by the method of Jordan and Taylor (*J.*, 1946, 994).

(i) *Titration of the sodium salt of thymus deoxypentose nucleic acid.* The titration curve of this sample is shown in Fig. 1, curve I. It will be seen that on the addition of acid or alkali to

the solution in water no groups are titrated at first between pH 5.0 and 11.0, but that outside these limits there occurs a rapid liberation of groups titrating in the ranges pH 2.0 to 6.0 and pH 9.0 to 12.0. On back titration either with acid from pH 12.0 or with alkali from pH 2.5, a curve (II) is obtained which is different from that representing the initial titration, and it is significant that the same curve (II) is obtained whether the back titration is with alkali from pH 2.5 or with acid from pH 12.0. This complete identity of the back-titration curves suggests that acid and alkali have an identical effect in liberating both sets of groups.

The back-titration curve exhibits a well-defined point of inflection in the neutral region, and shows incipient points of inflection in the regions of pH 12.0 and pH 2.0, corresponding respectively to approximately 2.0 equivalents of alkali and 3.0 equivalents of acid for each four atoms of phosphorus. There is some difficulty in interpreting electrometric titration

data above pH 11.0 and below pH 3.0 owing to the dependence of the water correction on the ionic strength (Jordan and Taylor, *loc. cit.*), which, for a polybasic substance such as nucleic acid, cannot be estimated with certainty. In obtaining the data given in Fig. 1, the assumption has been made that the acidic and basic groups contribute independently to the ionic strength. This approximation is justified by the fact that no appreciable proportion of the phosphorus

atoms carry more than one dissociating group (see below). It appeared desirable, however, to have additional confirmation of the number of groups titrating in the alkaline region, and titration of the sodium salt of thymus deoxypentose nucleic acid was therefore carried out in *m*-potassium chloride. The presence of the potassium chloride has the effect of masking all other contributions to the ionic strength (Cohn, Green, and Blanchard, *J. Amer. Chem. Soc.*, 1937, 59, 509), and the water correction is obtained from a titration of *m*-potassium chloride. The results of this titration, which are given in Fig. 2, curve III, show conclusively that the

number of groups dissociating in the range pH 8.0 to 12.0 is 2.05. Owing to the ease with which precipitation of the deoxypentose nucleic acid occurs in the presence of *m*-potassium chloride when acid is added, a complete back titration below pH 11.2 was not practicable; the data which have been obtained, however, are sufficient to indicate that the discrepancy between the forward- and back-titration curves described above persists in the presence of *m*-potassium chloride. Very similar results were obtained by titration in 2.53*M*-guanidine sulphate ($[\text{C}(\text{NH}_2)_3]_2\text{SO}_4$; Fig. 3, curve IV). Owing, however, to the existence of an unsteady liquid-

junction potential between this solution and the saturated potassium chloride bridge, the pH values were not very reproducible, especially in strongly alkaline solutions.

(ii) *Titration of the sodium salt of thymus deoxypentose nucleic acid precipitated with alcohol at pH 7.0 after treatment with alkali at pH 12.0, or with acid at pH 3.0.* The titration curves of an alkali-treated sample are shown in Fig. 4, curves V and VI; similar results were obtained with two other samples. The results of titration on the alkaline side of neutrality resemble those obtained with the original substance, in that a shift in the dissociation curve is observed

on back titration, although to a somewhat smaller extent. No such effect, on the other hand, was observed on the acid side. The back-titration curves from pH 12.0 or pH 2.5 are identical, and are very similar to the curve obtained with the original substance.

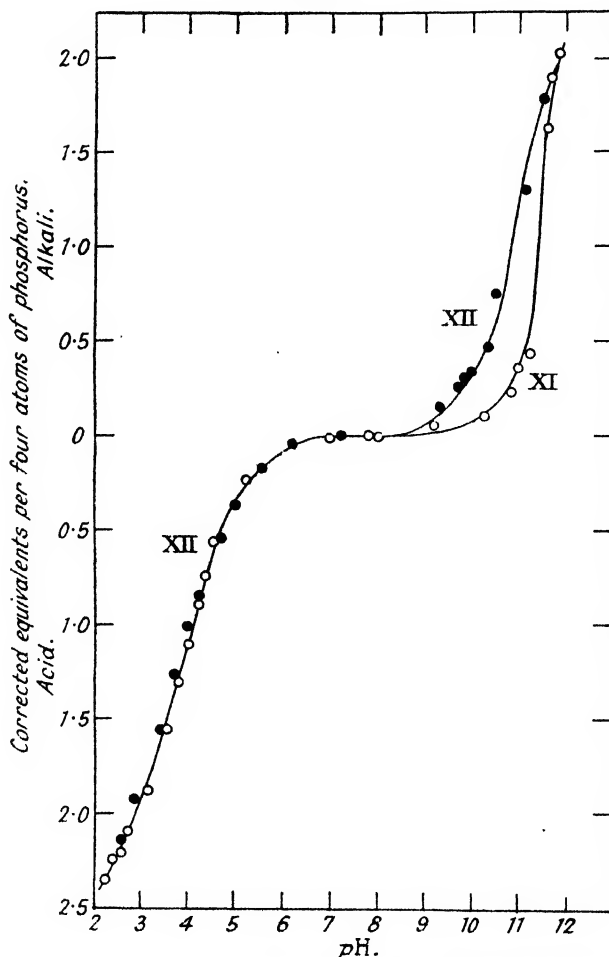

The results obtained with an acid-treated specimen (Fig. 5, curves VIII and IX) are almost identical with those described above for the alkali-treated material.

(iii) *Titration of the sodium salt of thymus deoxypentose nucleic acid supplied by Professor Caspersson.* The titration curves of this sample are shown in Fig. 6, curves XI and XII, and

are intermediate between those of the alkali- and acid-treated materials prepared by us and those of our original material. Viscosity studies (Creeth, Gulland, and Jordan, *loc. cit.*) support the view that, compared with the acid prepared by us, the sample of Caspersson exhibits different, probably less, hydrogen bonding (see below) and lower viscosity.

(iv) *Titration of the barium salt of thymic acid.* On treating thymus deoxypentose nucleic acid with dilute sulphuric acid at 80°, quantitative removal of guanine and adenine takes place (Feulgen, *Z. physiol. Chem.*, 1918, 101, 296; Feulgen and Landmann, *ibid.*, 102, 262; Brederick

and Müller, *Ber.*, 1939, 72, 115); the resulting thymic acid is isolated as its barium salt. The empirical formula weight of this substance is defined, for convenience, as the amount containing 4 g.-atoms of phosphorus, and the values obtained from the phosphorus contents of the two preparations studied were 1310 and 1315. The electrometric titration curve calculated on the basis of these formula weights is shown in Fig. 7, curve XIII, well-marked points of inflection being observed at pH 2.5, 8.0 and 11.5 after the neutralisation of 1.85 and 1.0 equivalents respectively. A titration has also been carried out in the presence of formaldehyde in order to ascertain what proportion of the more acidic dissociation represents that of an amino-group (curve XIV).

Discussion.—(i) *The nature of the acidic and the basic groups of deoxypentose nucleic acid.* The problem of the initial structure of deoxypentose nucleic acid before alkali or acid treatment will be considered in section (ii) of this discussion, and in this section the back-titration curve (Fig. 1, curve II) only will be treated.

Owing to the fact that the deoxyribonucleotides have not yet been isolated in quantities sufficient to permit an investigation by electrometric methods, it is necessary to refer to dissociation-constant data of the ribonucleotides in order to interpret this curve. This procedure is to some extent justified by the fact that the pK_a' values of the amino-groups of adenylic

FIG. 7.

(The zero of equivalents is fixed arbitrarily at pH 8.4, the titrations being carried out on two samples of slightly different barium content.)

and cytidylic acids do not differ very greatly from those of adenine and cytosine respectively, as shown by the following data :

Adenine	4.15	Adenylic acid.....	3.70 ¹
Cytosine	4.60 ¹	Cytidylic acid	4.24 ¹

¹ Data of Levene and Simms (*loc. cit.*).

It is not expected, therefore, that replacement of *d*-ribose by deoxypentose would give rise to any considerable change in the pK_a' values.

There has been some confusion in the literature between the pK_a' values assigned to the amino- and the primary phosphoryl dissociations of nucleic acids. Levene and Simms (*loc. cit.*) considered the groups dissociating in the range pH 2.0 to 6.0 to be the amino-groups, whereas Hammarsten (*loc. cit.*) and Fletcher, Gulland, and Jordan (*J.*, 1944, 33) considered them to be the primary phosphoryl dissociations. Consideration of the pK_a' values for the

nucleosides and sugar phosphates (given below) in the light of the modern theory of zwitterions points conclusively to the former view being correct.*

Adenosine	3.45	(Levene and Simms, <i>loc. cit.</i>).
Sugar phosphates...	pK_a' , 0.8 to 1.1; pK_a' , 6.0 to 6.5	(Kumler and Eiler, <i>J. Amer. Chem. Soc.</i> , 1943, 65 , 2355).
Adenylic acid	pK_a' , 0.89; pK_a' , 3.70; pK_a' , 6.01	(Levene and Simms, <i>loc. cit.</i>).

The pK_a' value of adenylic acid is clearly that of a primary phosphoryl dissociation, the pK_a' an amino-dissociation, and the pK_a' a secondary phosphoryl dissociation. At the isoelectric point, therefore, nucleic acids will exist almost entirely in the zwitterionic form.

The dissociations which will be titrated in the range pH 2.5 to 8.0 are therefore those of the amino- and the secondary phosphoryl groups. Examination of the lower portion of the back-titration curve (Fig. 1, curve II) shows that groups of both types are present, although the amount of secondary phosphoryl dissociation for every four atoms of phosphorus is relatively very small (see below). The curve is in approximate agreement with a theoretical curve constructed for 1.0 equivalent each, for every four atoms of phosphorus, of the amino-dissociations of guanylic, adenylic, and cytidylic acids, the pK_a' values of which are 2.3, 3.7, and 4.24 respectively (Levene and Simms, *loc. cit.*; Fletcher, Gulland, and Jordan, *loc. cit.*). It appears, however, that the pK_a' value of the amino-group of cytidylic acid (*viz.*, 4.24) which has been assumed for the amino-group of cytosine deoxypentose nucleotide is low, and much better agreement with the experimental curve is obtained by employing the pK_a' values of 2.5, 3.5, and 5.2 for constructing the theoretical curve; the curve shown in Fig. 1 is calculated on this basis.

The titration curve in the range pH 5.5 to 7.5 indicates the presence of a small amount of a group having a pK_a' value of 6.0 to 6.5, which is considered to be a secondary phosphoryl group. The determination of the exact quantity of this dissociation is dependent upon a precise knowledge of its pK_a' value and of the amounts of the amino-dissociations and their pK_a' values, but using 6.5 for the pK_a' value of the secondary phosphoryl dissociation, which is that observed for thymic acid, and assuming that there is no overlap of the amino- and the secondary phosphoryl dissociations above pH 6.5 (*i.e.*, no amino-dissociation greater than pK_a' 4.5), the amount of secondary phosphoryl dissociation is 0.25 equivalent for every four atoms of phosphorus. This represents the maximum amount of this group which can be present. Since, however, the pK_a' value of the weakest amino-group is of the order of 5.2, overlapping of the dissociations above pH 6.5 must occur, and thus the amount of the secondary phosphoryl dissociation present will be less than the maximum value.

The analysis of the sodium salt of deoxypentose nucleic acid shows that there are four sodium atoms for every four atoms of phosphorus, and in view of the fact that the amount of secondary phosphoryl dissociation is small, the four atoms of sodium must be combined largely or entirely with four primary phosphoryl dissociations. The deoxypentose nucleic acid of calf thymus differs in this respect markedly from the ribonucleic acids of yeast (Fletcher, Gulland, and Jordan, *loc. cit.*) and of *Calliphora erythrocephala* (Khouvine and Grégoire, *Bull. Soc. Chim. biol.*, 1944, **16**, 421), both of which show 1.0 equivalent of secondary phosphoryl dissociation (on correction for the phosphorus analysis) for every four atoms of phosphorus, and it cannot therefore possess the branched chain structure postulated for yeast ribonucleic acid by Fletcher, Gulland, and Jordan (*loc. cit.*). The data recorded are, however, consistent with the view that the thymus deoxypentose nucleic acid of calf thymus has a long, unbranched chain structure (Signer, Caspersson, and Hammersten, *loc. cit.*; Astbury and Bell, *loc. cit.*).

The groups titrating in the range pH 8.0 to 12.0 are considered to be the purine-pyrimidine hydroxyl groups of thymine and guanine deoxypentosides, and the upper part of the back-titration curve is in agreement with a theoretical curve constructed for 1.0 equivalent each of pK_a' values 10.4 and 11.4. The corresponding pK_a' value for thymine is 9.94 (Levene, Bass, and Simms, *J. Biol. Chem.*, 1926, **70**, 229; and confirmed by us) and for guanylic acid, 9.36 (Levene and Simms, *loc. cit.*), which, although of the same order of magnitude as the upper dissociations of deoxypentose nucleic acid, are nevertheless appreciably lower. The same effect is seen to a lesser extent in yeast ribonucleic acid which shows 2.0 dissociations of pK_a' 10.2 as compared with 9.36 for guanylic acid and 9.43 for uridylic acid (Levene and Simms, *loc. cit.*; Fletcher, Gulland, and Jordan, *loc. cit.*). The reason for this discrepancy is not clear,

* Acceptance of this view does not alter the main conclusions of Fletcher, Gulland, and Jordan about the structure of yeast ribonucleic acid, except that the triply-bound phosphoryl group is not necessarily that of uridylic acid.

especially in view of the better agreement which exists between the pK'_a values for the amino-dissociations of the ribonucleotides and of a yeast ribonucleic acid. It may, however, be related to the degree of polymerisation of the nucleic acid since it is not observed in thymic acid, which is considered to have a low molecular weight (see below).

The data given in Fig. 2, curve III, show that, other than the purine-pyrimidine hydroxyl groups, there are no dissociating groups titrating with alkali which have a pK'_a value in water less than at least 13.5. This confirms the absence of free sugar hydroxyl groups in this sample, since the pK'_a values of the primary hydroxyl dissociations of many sugars are in the region of 12.5 (Hirsch and Schlags, *Z. physikal. Chem.*, 1929, **141**, A, 387; Stearn, *J. Physical Chem.*, 1931, **35**, 2226; Urban and Shaffer, *J. Biol. Chem.*, 1932, **94**, 697; Urban and Williams, *ibid.*, 1933, **100**, 237), and suggests that no other sugar than a deoxypentose is present in any appreciable quantity in this sample of deoxypentose nucleic acid of thymus. Furthermore, taken in conjunction with the presence of one primary phosphoryl dissociation for every atom of phosphorus, the guanine, adenine, and cytosine dissociations and the guanine and thymine hydroxyl dissociations, this fact supports the view that the internucleotide bond is an ester linkage between the phosphoryl groups and the two hydroxyl groups of the sugar which are not involved in the glycosidic ring structure. Other types of linking may, however, exist in the nucleic acid, but the sensitivity of the titration method precludes the occurrence of such other linkages to a greater extent than one for every ten to twenty nucleotides.

The titration of thymic acid, taken in conjunction with the preceding data for deoxypentose nucleic acid, supplies information concerning the proportions of the four bases guanine, adenine, cytosine, and thymine present in this sample of nucleic acid. The titration curve for thymic acid (Fig. 7) shows 1.0 dissociation per four atoms of phosphorus in the pH range 8.0 to 12.0; this group can only be the enolic hydroxyl group of thymine. The 2.0 dissociations therefore observed in this pH range for deoxypentose nucleic acid (see above) must indicate the presence of one molecule each of thymine and guanine for every four atoms of phosphorus. It is not possible to determine with certainty the relative proportions of cytosine and adenine from the titration data of the sodium salt of deoxypentose nucleic acid, although the total amount of these groups is approximately 2.0. Thymic acid, however, possesses for every four atoms of phosphorus 1.0 to 1.2 dissociations of pK'_a 4.5 which must be the amino-dissociation of cytosine, and thus it is probable that the ratio of cytosine to adenine in the deoxypentose nucleic acid is as 1.0—1.2 is to 1.0—0.8.

The presence in barium thymate of 0.75 equivalent of a secondary phosphoryl dissociation for every four atoms of phosphorus suggests, on the basis of the straight-chain structure for deoxypentose nucleic acid, that the average number of nucleotides per molecule of thymic acid is approximately 5, and thus that the average molecular weight of the free acid is of the order of 1200.

(ii) *The macromolecular structure of deoxypentose nucleic acid.* As is shown in Fig. 1, the amino- and the enolic hydroxyl groups of thymus deoxypentose nucleic acid are partly or completely blocked until the material has been treated with acid or alkali; an irreversible change then takes place with the accompanying liberation of titratable groups. The release of the groups on treatment with alkali takes place sharply in the neighbourhood of pH 11.5, but less sharply in the range pH 3.5 to 4.5 on treatment with acid. In both cases equilibrium is established almost instantaneously, and the liberation of groups is accompanied by a marked fall in the viscosity and a disappearance of streaming birefringence (Hammarsten, *loc. cit.*; Vilbrandt and Tennent, *J. Amer. Chem. Soc.*, 1943, **65**, 1806; Creeth, Gulland, and Jordan, *loc. cit.*).

The decrease in viscosity brought about by the addition of acid or alkali was considered by Vilbrandt and Tennent (*loc. cit.*) to be caused by a depolymerisation which was slowly reversed when the solution was returned to neutrality. Our results show that such a depolymerisation cannot involve the rupture of the internucleotide ester linkages since no increase of secondary phosphoryl dissociation is observed in the back-titration curve. The complete identity of the back-titration curves from pH 2.5 and pH 12.0 strongly suggests that acid and alkali have the same effect in liberating the amino- and the hydroxyl groups. Two possibilities may be considered to explain this behaviour. It could be caused by easily hydrolysed radicals, hitherto unidentified in the breakdown products of the nucleic acid, which either substitute in the amino- and the hydroxyl groups separately or form a bridge between them. There are, however, certain limitations in the type of radical which could be involved; first, it could not contain groups which are titrated in the pH range examined in this investigation, since the back-titration curve shows no liberation of such groups and is moreover almost identical with the titration curve of the acid or alkali treated samples (Figs. 4 and 5), and secondly, the stability

to acid and alkali of the links involving the amino- and the hydroxyl groups would have to be very similar. In our opinion these restrictions make the preceding explanation of the observed behaviour improbable, and a simpler and preferable explanation is that in which the amino- and the hydroxyl groups are linked by hydrogen bonds. Bonding of this type has frequently been suggested as being important in protein structure, and our observations on the behaviour of deoxypentose nucleic acid resemble in some respects those recorded for egg albumen (Cannan, Kibrick, and Palmer, *Ann. N.Y. Acad. Sci.*, 1941, **41**, 243; Crammer and Neuberger, *Biochem. J.*, 1943, **37**, 302), which have been interpreted by postulating a hydrogen bond between a phenolic hydroxyl group and a carboxylate ion. Although it is undesirable at the present stage to speculate too far as to the macromolecular structure of deoxypentose nucleic acid, a hydrogen bond between an amino-group and either the -NH- group or the enolic -C(OH)- group of an adjacent guanine or thymine radical could explain satisfactorily our experimental results. The large number of such bonds which are possible, the maximum number being two for every four atoms of phosphorus, would give a degree of stability to the untreated deoxypentose nucleic acid, and in order to degrade the nucleic acid it might be necessary to break many of the hydrogen bonds simultaneously. Such a process would lead to an abnormal titration curve of the type shown in Fig. 1. It is not possible on the basis of these data to decide whether the hydrogen bonds unite nucleotides in the same, or in different chains; this aspect is considered in the light of viscosity and streaming birefringence by Creeth, Gulland, and Jordan (*loc. cit.*).

The increase in viscosity observed at approximately pH 7 when a solution of the nucleic acid was adjusted to that value after treatment with acid or alkali (Vilbrandt and Tennent, *loc. cit.*; Creeth, Gulland, and Jordan, *loc. cit.*) does not involve the blocking of the amino- and the enolic hydroxyl groups, since the titration curves obtained were identical with the back-titration curve shown in Fig. 1 whether the solution was titrated immediately or was allowed to remain at approximately pH 7 for 96 hours in the absence of atmospheric oxygen. During this period the viscosity had risen to a value of the same order as that observed with the original acid (Creeth, Gulland, and Jordan, *loc. cit.*).

A different behaviour was observed in samples which had been precipitated by alcohol at pH 7 after acid or alkaline treatment. Some blocking of the enolic hydroxyl groups occurred (Figs. 4 and 5), but to a much smaller extent than that found with the original material, and the properties of the precipitated material appeared to be independent of the viscosity changes, since very similar titration curves were obtained whether the product was precipitated immediately or after 96 hours. Precipitation would thus seem to be the important factor. There is no evidence from titration data that precipitation effects blocking of the amino-groups.

Greenstein and Jenrette (*J. Nat. Cancer. Inst.*, 1940, **1**, 77; *Cold Spring Harbor Symp. Quant. Biol.*, 1941, **9**, 236) have postulated on the evidence of viscosity measurements that reversible depolymerisation of thymus deoxypentose nucleic acid takes place on the addition of neutral salts. Titration of the sodium salt of thymus deoxypentose nucleic acid in $\text{M-potassium chloride}$ (Fig. 2) and in 2.53 molar guanidine sulphate (Fig. 3) showed that the changes in viscosity which occur bear no relation to the irreversible change which takes place on treatment with acid or alkali, since the discrepancy between the forward- and back-titration curves was still present in these salt solutions. The lowering of the viscosity by the addition of salt must therefore involve a different type of physico-chemical change to that occurring on treatment with acid or alkali.

EXPERIMENTAL.

Apparatus.—The electrometric titrations were carried out according to the method described by Fletcher, Gulland, and Jordan (*loc. cit.*), and the titration curves were corrected for the titration of water at the extremes of pH by the method of Jordan and Taylor (*loc. cit.*). The solutions for titration contained 100 to 200 mg. of the samples in 20 ml. of water.

Preparation of Alkali-treated Samples of the Sodium Salt of Thymus Deoxypentose Nucleic Acid.—To a solution of sodium salt of deoxypentose nucleic acid (2 g.) in water (100 ml.), 0.5N-sodium hydroxide (25 ml.) was added with mechanical stirring. The solution then had a reaction of pH 12.30. 0.5N-Hydrochloric acid (24 ml.) diluted with water (51 ml.) was added slowly with rapid stirring to avoid precipitation. The pH was finally adjusted to 7.0. The solution was added immediately or at the time required to ethyl alcohol (750 ml.). The white granular precipitate (1.6 g.) was collected, washed with alcohol, and dried in a vacuum over phosphoric oxide.

Preparation of Acid-treated Samples of the Sodium Salt of Thymus Deoxypentose Nucleic Acid.—To a solution of the sodium salt of deoxypentose nucleic acid (2 g.) in water (150 ml.), 0.08N-hydrochloric acid (50 ml.) was added slowly with constant stirring, the final reaction being pH 3.1. 0.195N-Sodium hydroxide (24 ml.) was added slowly with stirring, and the reaction adjusted to pH 7.1 with dilute hydrochloric acid. The solution was added immediately or later as required to ethyl alcohol (750 ml.).

The white granular precipitate (1.6 g.) was collected, washed with alcohol, and dried in a vacuum over phosphoric oxide.

Preparation of Barium Thymate.—A solution of the sodium salt of thymus deoxypentose nucleic acid (15 g.) in water (400 ml.) was warmed to 80° and mixed with 10% sulphuric acid (30 ml.) at the same temperature. A white solid formed and redissolved in 5 minutes. The solution was maintained at 80° for 30 minutes. Silver sulphate (5 g.) was added and the suspension shaken for 1 hour, cooled in water and then to 0°, and mixed with a solution of barium acetate (20 g.) and barium chloride (5 g.) in water (30 ml.). Next day the supernatant was decanted, and the solid collected by centrifuge and washed repeatedly with 90% alcohol and then with 100% alcohol and ether. The product (4.6 g.) was dried in a vacuum over phosphoric oxide.

Analyses.—All samples were dried at 110° in a vacuum over phosphoric oxide. Details of the analytical methods are given in Part I (*loc. cit.*). Sodium salt of deoxypentose nucleic acid of calf thymus prepared by Professor Caspersson and deproteinised by us (see text), found: C, 35.5; H, 4.14; N, 15.4; P, 9.4; Na, 7.2 (colorimetric)%. Alkali-treated sodium salt of deoxypentose nucleic acid of calf thymus (respective values for three preparations), found: C, 35.3, 35.7, 36.1; H, 3.62, 3.83, 3.79; N, 15.4, 15.6, 15.5; P, 9.30, 9.63, 9.58; Na, —, 6.42, 6.28 (gravimetric)%. Acid-treated sodium salt of deoxypentose nucleic acid of calf thymus, found: C, 35.9; H, 3.76; N, 15.8; P, 9.41; Na, 6.33 (gravimetric)%. Calc. for a large polynucleotide consisting of the tetrasodium salts of tetranucleotides containing on average 1 mol. each of guanine, adenine, cytosine, and thymine deoxypentose nucleotides, *i.e.* $(C_{29}H_{45}O_{24}N_{15}P_4Na_4)_x$, the additional HONa of the terminal groups being ignored: C, 35.4; H, 3.4; N, 15.9; P, 9.4; Na, 6.95%. Calc. for a large polynucleotide consisting of the tetrasodium salts of tetranucleotides containing on average 1 mol. each of guanine and thymine, and 1.2 mols. of cytosine and 0.8 mol. of adenine deoxypentose nucleotides, *i.e.* $(C_{38.8}H_{45}O_{24.2}N_{14.6}P_4Na_4)_x$, the additional HONa of the terminal groups being ignored: C, 35.4; H, 3.4; N, 15.5; P, 9.4; Na, 6.98%.

Barium thymate (respective values for two preparations), found: C, 27.1, —; H, 3.46, —; N, 5.44, 5.53; P, 9.47, 9.44; Ba, 23.3, 23.1%. It is a pleasure to record our thanks to Imperial Chemical Industries Ltd. for the loan of apparatus; to Professor W. T. Astbury, F.R.S., for the gift of the sample prepared by Professor Caspersson; to Mr. J. M. Creeth, B.Sc., for preparing two of the alkali-treated samples, for preliminary work on the acid treated material, and for some of the sodium analyses; to Mr. C. J. Threlfall, B.Sc., for preparing the samples of barium thymate; and to Mr. J. E. Still, B.Sc., and Mr. D. S. R. Cameron for the microanalyses.

UNIVERSITY COLLEGE, NOTTINGHAM.

[Received, November 2nd, 1946.]

214. Deoxypentose Nucleic Acids. Part III. Viscosity and Streaming Birefringence of Solutions of the Sodium Salt of the Deoxypentose Nucleic Acid of Calf Thymus.

By J. M. CREETH, J. MASSON GULLAND, and D. O. JORDAN.

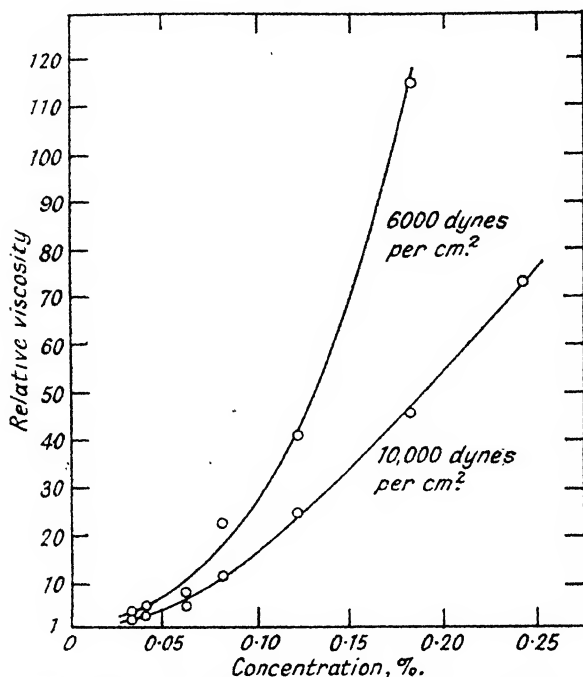

The high viscosity and marked streaming birefringence of solutions of the tetrasodium salt of deoxypentose nucleic acid of calf thymus are found to remain constant between pH 5.6 and 10.9. Outside these critical limits the viscosity falls to a very low value and the streaming birefringence disappears, but they increase again if the pH is readjusted to 7.0. The critical pH values are coincident with those at which a liberation of amino- and enolic hydroxyl groups has been observed (Gulland, Jordan, and Taylor, Part II, this vol., p. 1131) and it is considered that the two phenomena are related and are due to the fission of the hydrogen bonds postulated as linking the purine-pyrimidine hydroxyl groups and some of the amino-groups. The present data do not show whether bonding of neighbouring polynucleotide chains or of nucleotides in the same chain is involved.

The viscosities of solutions of the tetrasodium salt of deoxypentose nucleic acid of calf thymus were reduced considerably by low concentrations of neutral salt, increase of the concentration above 0.01M having relatively only a small effect on the viscosity.

THE high viscosity exhibited by aqueous solutions of the sodium salt of thymus deoxypentose nucleic acid at pH 7.0 has been shown to decrease with the addition of acid and alkali (Jones and Austrian, *J. Biol. Chem.*, 1907, 3, 1; Jones, *ibid.*, 1908, 5, 1; Hammarsten, *Biochem. Z.*, 1924, 144, 383; Vilbrandt and Tennent, *J. Amer. Chem. Soc.*, 1943, 65, 1806) and with the addition of neutral salts (Greenstein and Jenrette, *J. Nat. Cancer Inst.*, 1940, 1, 77; *Cold Spring Harbor Symp. Quant. Biol.*, 1941, 9, 236). A mechanism involving depolymerisation has been ascribed to both these processes (Greenstein and Jenrette, *loc. cit.*; Vilbrandt and Tennent, *loc. cit.*). In view of the observations (Gulland, Jordan, and Taylor, Part II, *loc. cit.*) that

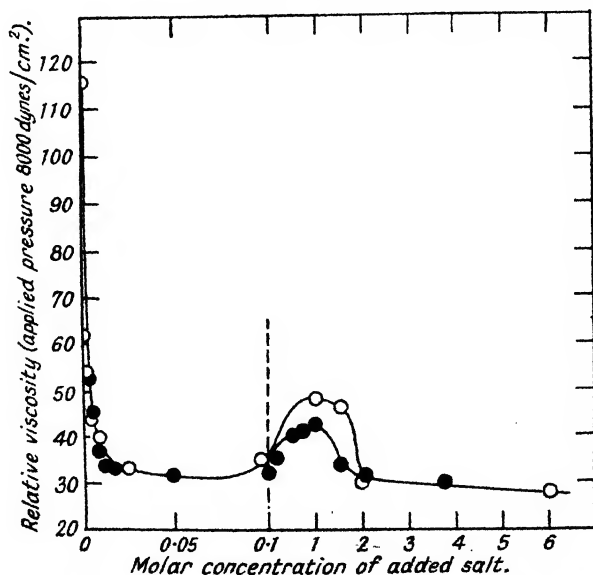

treatment with acid or alkali of solutions of the sodium salt of thymus deoxypentose nucleic acid prepared by Gulland, Jordan, and Threlfall (Part I, this vol., p. 1129) leads to the liberation

of titratable groups, whereas the addition of neutral salts does not, an investigation of the viscosity of solutions of this preparation of this nucleic acid appeared desirable.

Results of this Investigation.—The viscosity of aqueous solutions of this preparation of the sodium salt of thymus deoxypentose nucleic acid increased considerably with rise of concentration (Fig. 1), and the viscosity of a 0.5% solution could not be measured in the capillary viscometers used in this investigation. At all concentrations studied the viscosity varied with the applied pressure, thus being abnormal or structural in character.

The magnitude of the relative viscosity was very much greater than that recorded for other preparations of the sodium salt of this nucleic acid. Thus, the relative viscosity of our material at pH 7.0 in 0.243% solution at 25°, measured in a capillary viscometer at 8000 dynes/cm.², was 116, whereas from measurements with the sodium salt prepared by the method of Bang (Hofmeister's "Beiträge Chem. Physiol. Path.", 1903, 4, 331) and Hammarsten (*loc. cit.*), Vilbrandt and Tennent (*loc. cit.*) record 5.7 for a 0.3% solution at 25° measured in an Ostwald viscometer, and Greenstein and Jenrette (*loc. cit.*) give 5.53, a limiting value at high pressures, for a 0.25% solution at 25° measured in a capillary viscometer.

The addition of sodium chloride or guanidine chloride (the guanidinium ion being specified as most effective by Greenstein and Jenrette) lowered very considerably the relative viscosities of solutions of the sodium salt of thymus deoxypentose nucleic acid (Fig. 2). The viscosity fell rapidly at first as the salt concentration was increased, reaching a critical value at about 0.01M with both sodium chloride and guanidine chloride. On increasing the concentration above the critical value only comparatively small changes in viscosity occurred; a rise to a slight peak and subsequent fall were observed at approximately 1M, a result which may be compared with that observed by Needham, Kleinzeller, Miall, Dainty, Needham, and Lawrence (*Nature*, 1942, 150, 46) for the action of neutral salts on the viscosity of solutions of myosin.

The variation of the viscosity with the pH of the solution is shown in Fig. 3; the ionic strength was maintained at 0.01 throughout. The relative viscosity remained constant as the pH was varied from 5.6 to 10.9, but outside these limits it fell rapidly, and at pH 12.08 and at pH 3.38 the viscosity of the solutions no longer varied with the applied pressure. These results are not in agreement with the data recorded by Vilbrandt and Tennent (*loc. cit.*) who observed a maximum in the relative viscosity at pH 7.0 and a gradual reduction of the relative viscosity as the pH was changed in either direction from neutrality. The results of these authors resemble those obtained by us with samples of the original sodium salt of thymus deoxypentose nucleic acid which had been treated with alkali at pH 12.5 or with acid at pH 3.5 and then precipitated by the addition of ethyl alcohol at pH 7.0 (Fig. 3). Our results with the acid- or alkali-treated material also closely resemble those obtained with a sample of the sodium salt supplied by Professor Caspersson through Professor Astbury in 1939, and prepared by the Hammarsten-Bang procedure.

The data for the streaming birefringence of solutions of the sodium salt of thymus deoxypentose nucleic acid are recorded in the table, and followed closely the changes in viscosity. In agreement with the experimental results of Greenstein and Jenrette (*J. Nat. Cancer Inst.*, 1940, 1, 77, Table 2) and the conclusions of Snellmann and Widström (*Arkiv Kemi, Min. Geol.*, 1945, 19, A, No. 31) solutions of our deoxypentose nucleic acid showed considerable streaming birefringence in the presence of a high concentration (4M) of neutral salt (see table).

Variation with pH (ionic strength maintained at 0.01 throughout) and with concentration of sodium chloride of the streaming birefringence of 0.243% solution of the sodium salt of thymus deoxypentose nucleic acid.

		to	to	to	to	to	
		4.3	5.0	10.0	10.7	11.6	
Streaming birefringence (relative values on arbitrary scale)	0	1	2	3	2	1	0
Original nucleic acid, in water at pH 6.9, 4; in 4M-sodium chloride, 2.							

The action of acid and alkali in reducing the viscosity of solutions of the sodium salt of thymus deoxypentose nucleic acid has been shown by Vilbrandt and Tennent (*loc. cit.*) to be to some extent reversible if the solutions are returned to pH 7.0. We have confirmed this result, but have observed that the regain of high viscosity after acid treatment is different from that which occurs after alkaline treatment. When a 0.243% solution was left at pH 12.5 for 15 minutes and then returned to pH 7.0, the viscosity increased steadily with time (Fig. 4) and

moreover regained its structural character; after 91 hours the relative viscosity had increased to a value of the same order as that of the original acid, but the variation with applied pressure was somewhat different, the viscosity being lower at high pressures and higher at low pressures (Fig. 4). With concentrations of the sodium salt of deoxypentose nucleic acid up to 0.5% there was no appreciable increase in the viscosity at pH 7.0 after treatment at pH 3.5 for 15 minutes, but a 1.0% solution after such treatment gelled on standing for 12 hours.

When the products of alkali- or acid-treatment were precipitated at pH 7.0 by the addition of ethyl alcohol, isolated, dried, and redissolved in water, they showed only a slight increase in viscosity with lapse of time. A marked difference exists, therefore, between the behaviour of precipitated and non-precipitated material after alkali- or acid-treatment.

Discussion.—The results of the viscosity measurements are interpreted qualitatively in view of the fact that the viscosity was not a function of the concentration alone over the range of concentration studied, and for such examples the theoretical treatment of viscosity data is very incomplete (Eirich, *Rep. Prog. Physics*, 1940, 7, 329). Signer, Caspersson, and Hammarsten (*Nature*, 1938, 141, 122) have applied one of the formulæ relating viscosity with the size and shape of the molecule, but we have not felt entitled to adopt such procedure in view of the much greater structural viscosity of solutions of our material as compared with that of the sample supplied by Professor Caspersson.

The evidence obtained by electrometric titration (Gulland, Jordan, and Taylor, *loc. cit.*) suggests that in the original nucleic acid hydrogen bonds exist between the amino- and hydroxyl groups of nucleotides, and that these bonds are broken at reactions more acid than pH 5 and

more alkaline than pH 11. The addition of acid or alkali did not lower the viscosity of solutions of deoxypentose nucleic acid until these critical pH values were reached.

The reduction in viscosity and in streaming birefringence could be explained by the rupture of hydrogen bonds between adjacent chains, producing units of lower molecular weight and greater symmetry. It is also conceivable that a rolling-up of a single polynucleotide chain could occur, following the fission of hydrogen bonds between nucleotides in that chain, thus reducing the molecular asymmetry but not the molecular weight. The present data do not reveal which of these alternatives is correct or whether both processes occur.

It is most improbable that when a solution of the sodium salt of deoxypentose nucleic acid is restored to pH 7 after acid or alkaline treatment, aggregation will produce precisely the same structure as existed in the original nucleic acid micelle, and it is likely that water molecules will play a greater part in the structure of the new micelle. Subsequent precipitation of the material at pH 7.0 by the addition of ethyl alcohol, followed by drying of the product, may thus considerably alter the structure of the micelle, and it is not surprising therefore that in solution the material isolated by precipitation behaved differently from the non-precipitated product.

The decrease in viscosity on the addition of sodium chloride cannot have been caused by a disaggregation of the type described above, since no titratable groups were produced (Gulland, Jordan, and Taylor, *loc. cit.*). At least three explanations of this decrease are possible, a disaggregation of coarse aggregates of micelles, a change in the shape of the micelle, or a change in the structure of the ion atmosphere and the hydrosphere. The data so far obtained do not permit a choice between these alternatives.

EXPERIMENTAL.

The determination of viscosity was made in a viscometer similar to that described by Frampton (*J. Biol. Chem.*, 1939, **129**, 233). Four viscometers were employed, having capillaries 14.6, 13.4, 14.5, and 12.0 cm. long and the following radii: 0.0390, 0.0476, 0.0575, and 0.0965 cm. respectively. The time for the liquid meniscus to fall between two marks etched on the upright tubes at a known distance apart (*ca.* 0.5 cm.) was measured with a stop watch, reading in 1/10 secs., the meniscus being followed by a travelling microscope. In the experimental results recorded in the figures, the geometric means of the initial and final hydrostatic pressures, between which the viscosity was determined, are recorded.

Streaming birefringence was determined by stirring mechanically a solution placed in a small cell on the stage of a polarising microscope.

The preparation of the materials employed has been described in Parts I and II (this vol., pp. 1129, 1131)

It is a pleasure to record our thanks to the British Empire Cancer Campaign for a maintenance grant to one of us (J. M. C.) and for defraying a part of the expenses of this investigation, and to Imperial Chemical Industries Ltd. for the loan of apparatus.

215. *The Crystal and Molecular Structure of Certain Dicarboxylic Acids. Part III. Diacetylenedicarboxylic Acid Dihydrate.*

By J. D. DUNITZ and J. MONTEATH ROBERTSON.

The crystal and molecular structure of diacetylenedicarboxylic acid dihydrate, $\text{HO}_2\text{C}\cdot\text{C}\equiv\text{C}\cdot\text{C}\equiv\text{C}\cdot\text{CO}_2\text{H}\cdot 2\text{H}_2\text{O}$, has been determined from X-ray data, and is shown to be similar in general outline to that of oxalic acid dihydrate and acetylenedicarboxylic acid dihydrate (Parts I and II, this vol., pp. 142, 148). A network of hydrogen bridges extends throughout the crystal and links the water molecules (or oxonium ions) to the adjoining acid molecules.

In the present crystal there is, however, a space-group change, from C_{2h}^2 to C_{2h}^1 , and the molecules possess a two-fold axis of symmetry instead of a centre. The configuration is no longer coplanar, the carboxyl groups at opposite ends of the molecule lying nearly in two planes inclined to one another at about 57° .

The bond distances within the molecule are shown in Fig. 3, and should be accurate to within about ± 0.05 Å., except in the carbon chain [C(2)–C(1) and C(1)–C(1')] where a considerably higher accuracy of about ± 0.02 Å. should apply. The central single bond of 1.33 Å. is the shortest formal single bond so far discovered. This result is discussed, and also the question of whether the carbon-carbon triple bond in acetylene itself is really a suitable standard for the "normal" triple bond type.

In previous papers (*loc. cit.*) we have discussed the structure of oxalic acid dihydrate and acetylenedicarboxylic acid dihydrate and shown that they are of the same type. The two water molecules (or oxonium ions) are situated between the carboxyl groups of adjoining acid molecules, to which they are bound by one very strong and two rather weaker types of hydrogen

bridge. These connections form a spiral network which extends throughout the crystal and confers considerable stability on the whole structure. In these crystals the acid molecules possess a centre of symmetry, the carboxyl groups are nearly symmetrical, and the whole molecule is either planar or very nearly so, as would be expected from general chemical evidence.

We have now completed a similar detailed study of diacetylenedicarboxylic acid dihydrate. In this structure there is a space-group change, from $C_{2h}^5(P2_1/a)$ to $C_{2h}^6(I2/c)$ and a consequent doubling of the c axis. At first sight, and indeed in the principal projection of the structure (Fig. 1), the whole arrangement appears to be entirely analogous to that of the other two structures, apart from the lengthened carbon chain and the c axis doubling. The analysis of the principal zone, ($h0l$), offers no particular difficulty, and proceeds on the same lines as before. In attempting to explain the intensities of other zones of reflections, however, serious difficulties were encountered. These could only be resolved on the assumption that the molecule of diacetylenedicarboxylic acid does not contain a symmetry centre and that the two carboxyl groups are not coplanar but lie in two planes inclined to one another at about 57° . The opposite ends of the molecule are related by a two-fold axis of symmetry which passes through its centre. In Fig. 1 the projection of this two-fold axis gives rise to a centre of symmetry and makes this picture precisely analogous to those already described for the other structures.

This change in configuration is difficult to understand, particularly as the bond-length measurements indicate that resonance effects extend throughout the molecule and these should tend to produce a coplanar form. As discussed more fully below, the configuration adopted in this case appears to be governed by the strongly directed intermolecular hydrogen bridging which exists in the crystal.

Apart from these curious effects, this structure is of special interest in providing fairly reliable measurements on a system of conjugated triple bonds. The linear carbon chain lies in the (010) plane, and two-dimensional Fourier methods provide excellent resolution of the various atoms. Both the triple bonds and their connecting link are found to be somewhat shorter (Fig. 3) than previous measurements on other compounds have indicated. These facts are discussed more fully below after the structure has been described.

Description of the Structure.—*Crystal data.* Diacetylenedicarboxylic acid dihydrate, $C_6H_2O_4 \cdot 2H_2O$; M , 174.1; m. p. (decomp. with charring) $95-100^\circ$; d , calc. 1.43, found 1.43—1.45; monoclinic prismatic, $a = 11.15 \pm 0.03$, $b = 3.75 \pm 0.01$, $c = 20.18 \pm 0.08$ Å., $\beta = 107.0^\circ \pm 0.5^\circ$. Absent spectra, (hkl) when $h + k + l$ is odd; ($h0l$) when either h or l is odd. Space-group, $C_{2h}^4(Ic)$ or $C_{2h}^6(I2/c)$. (C_{2h}^6 assumed in this analysis.) Four molecules per unit cell. Molecular symmetry, centre or two-fold axis. (Two-fold axis assumed in this analysis.) Volume of unit cell, 806.7 Å.³. Absorption coefficient for X-rays, $\lambda = 1.54$, $\mu = 13.4$ cm.⁻¹. Total number of electrons per unit cell = $F(000) = 360$.

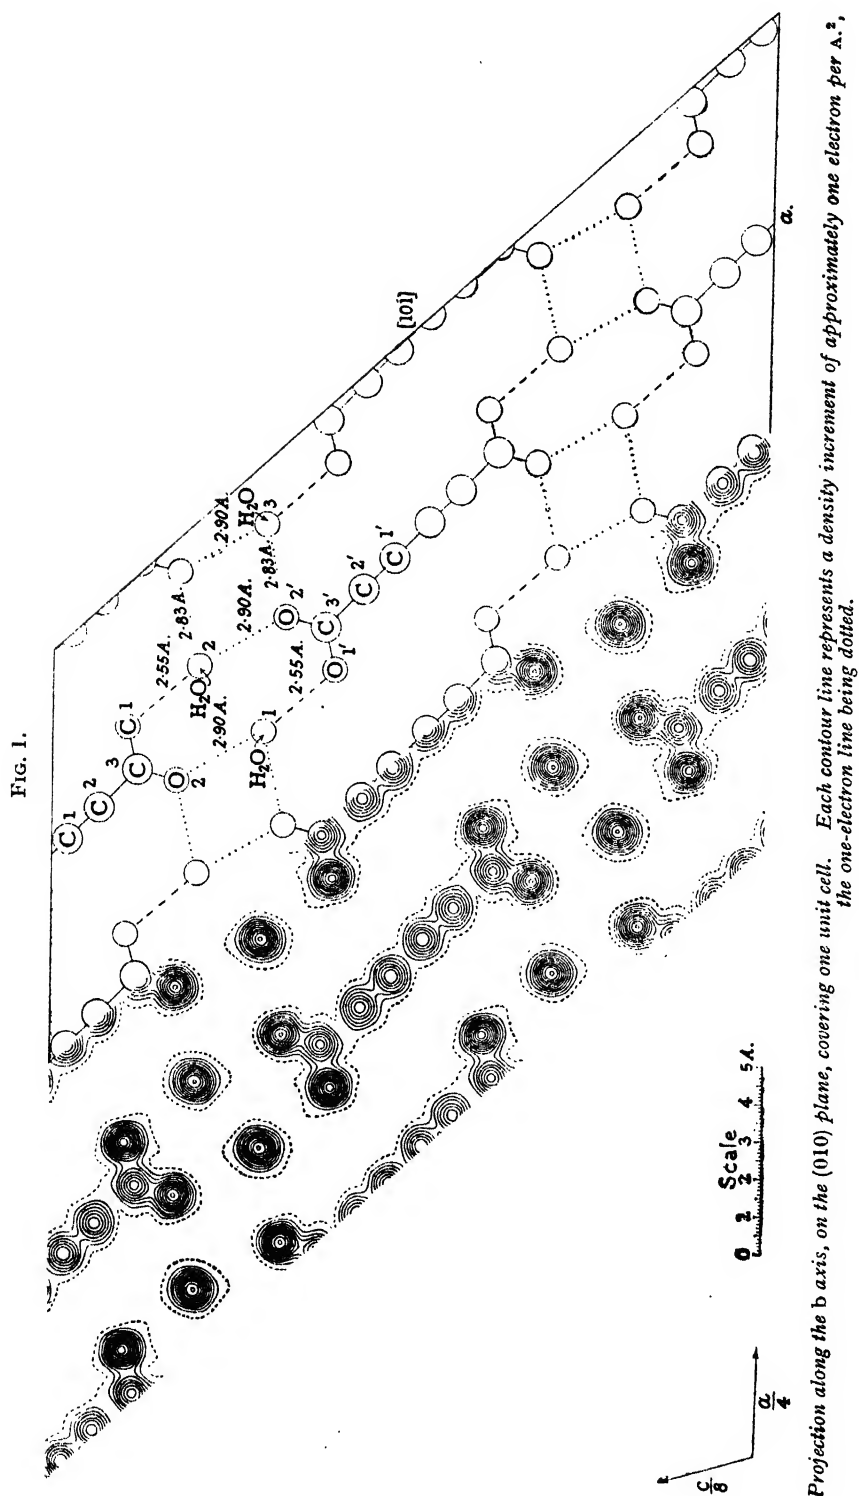

Diacetylenedicarboxylic acid was first prepared by Baeyer (*Ber.*, 1885, 18, 676, 2270) and his method of preparation was followed. Our final product, however, was not identical with that obtained by Baeyer, his being described as the monohydrate while ours was without doubt the *dihydrate*.

Crystals were obtained from water as small, faintly pink or yellow, sword-like needles, elongated in the b -axis direction. The (001) face was always prominently developed and the (101) also appeared, other faces being generally absent. The crystals deepen in colour when exposed to light, becoming purple and eventually black; exposure to X-rays causes them to become quite black almost immediately.

Structure analysis. The dimensions of the unit cell compared with oxalic acid dihydrate and acetylenedicarboxylic acid dihydrate suggested that the main features of the structure were the same as in these two compounds (see Table I, Part I, *loc. cit.*). The inclination of the [101] axis to the a axis is still about 50° and the increase in its half-length (the c axis is doubled) as compared with acetylenedicarboxylic acid dihydrate (2.55 Å.) is again just about the amount required to accommodate an extra pair of carbon atoms.

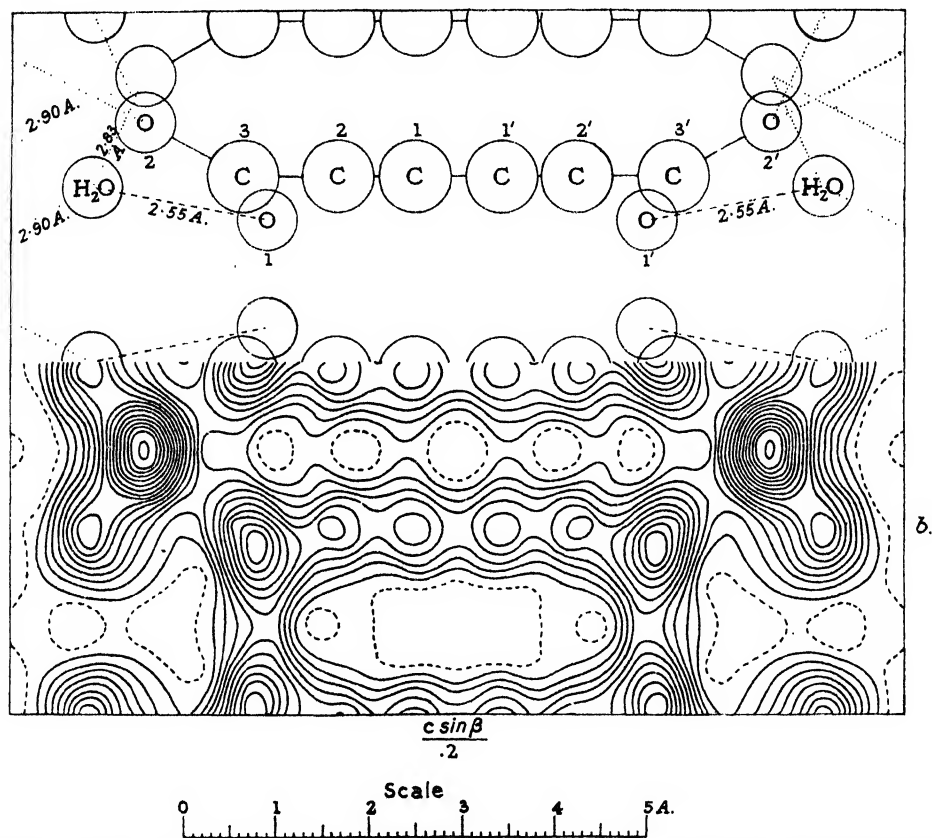

A trial model set up on the assumption that the long axis of the molecule was lying along [101] with the planes of the carboxyl groups inclined at about 30° to the (010) plane gave good agreements for the observed ($h0l$) intensities. The x and z co-ordinates were then refined by two successive Fourier syntheses, giving projections on the (010) plane. The final projection is shown in Fig. 1, from which accurate values of these co-ordinates can be obtained.

To determine the y co-ordinates in the structure, it is necessary to decide between certain alternative arrangements that are possible in the space-group C_{2h}^6 . The centres of the molecules must lie on special positions, but these may be (a) the centres of inversion on the glide plane a , (b) the centres of inversion on the glide plane c , (c) the two-fold rotation axes. This choice of

origins does not affect the projection on (010) described above, but it does affect the general planes and especially the $(0kl)$ structure factors, which were next examined in detail. Alternative (a) was eliminated by trial methods, and as (b) seemed much more likely than (c), by analogy with the previous structures, this possibility was examined in considerable detail. It was not possible to obtain good agreements between the calculated and the observed structure factors, the mean discrepancy always being about 30%. A Fourier projection was made, using terms whose sign seemed reasonably certain, but this projection was unsatisfactory and did not lead to any further refinement of the assumed co-ordinates. The idea of a molecular centre of symmetry was therefore abandoned, and possibility (c) was next explored. A two-fold rotation axis permits new molecular configurations and it was soon found that a

FIG. 2.

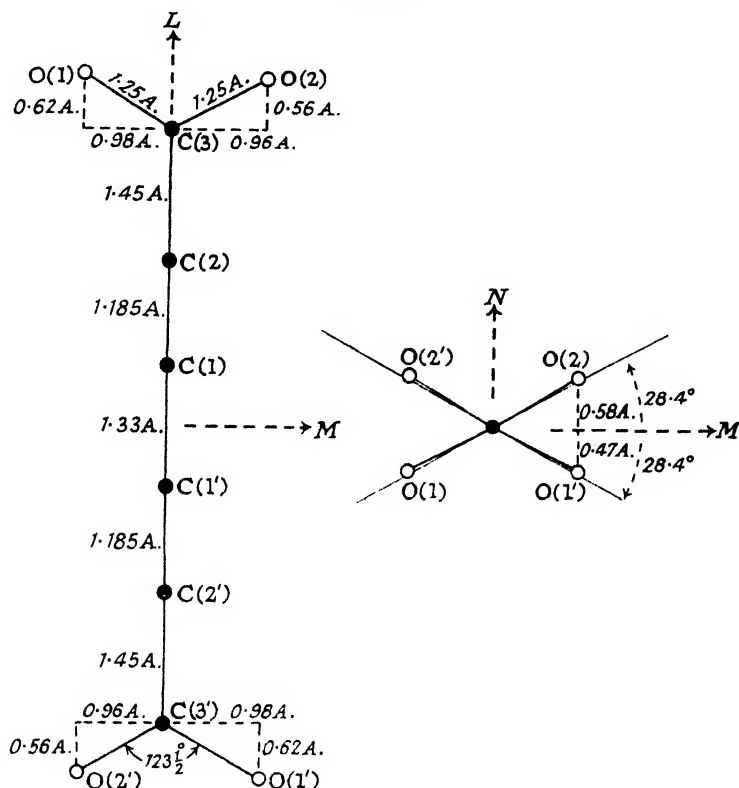

Projection along the a axis, covering half a unit cell. The centres of the molecules are situated on rotation axes, at 0.11 Å. from the glide plane c . Contour scale as in Fig. 1, except that the two-electron line is dotted.

model, consistent with the projection in Fig. 1, but with the planes of the carboxyl groups oppositely inclined, each at about 30° to (010), led to greatly improved agreements for the $(0kl)$ and general structure factors, the mean discrepancy being reduced to less than 20%. The y co-ordinates were then refined by Fourier projections along the a axis, and the final diagram is shown in Fig. 2. The resolution of the atoms in Fig. 2 is not very complete, and it will be seen from the explanatory diagram that considerable overlapping must be expected. It is nevertheless possible to assign y co-ordinates which account fairly well for the shape of the contours. These co-ordinates are rather less certain than the x and z co-ordinates, especially for the atoms C(3), O(1), O(2), and H_2O .

Molecular dimensions and co-ordinates. The x and z crystal co-ordinates obtained from the final Fourier projection on (010) are shown in Fig. 5, and are listed, together with the y co-ordinates, in Table I. These co-ordinates lead to the molecular model given in Fig. 3 and

to the intermolecular distances of Fig. 1. The orientation of the molecule in the crystal is given in Table II, the molecular axis L being the direction of the carbon chain, N the direction of the two-fold rotation axis, and M the normal to the LN plane. Molecular co-ordinates referred to these axes are given in Table III.

Discussion of Results.—Hydrogen bonding and molecular configuration. Comparison of Fig. 1 with the corresponding projections for oxalic acid dihydrate and acetylenedicarboxylic acid dihydrate (Part I, Fig. 1, and Part II, Fig. 1) shows that the same type of structure appears to exist in all three crystals. So far as the intermolecular hydrogen bonding is concerned, the three crystals are almost identical, the relevant distances in diacetylenedicarboxylic acid dihydrate being $O(1)-H_2O = 2.55$ Å., $O(2)-H_2O = 2.90$ Å. and 2.83 Å., almost exactly the same as in acetylenedicarboxylic acid dihydrate. The spiral arrangement described in Parts I and II is exactly reproduced in this compound, the apparently closed circuit $O(1), H_2O, O(2'), C(3'), O(1'), H_2O, O(2), C(3), O(1)$ being actually a spiral which returns to an atom one translation along the b axis from the original atom; the closed four-membered ring formed by the weaker bonds of $2.83, 2.90, 2.83, 2.90$ Å. is again exactly analogous to the previous cases.

The molecule of diacetylenedicarboxylic acid is, however, clearly different in its geometric configuration from those of oxalic acid and acetylenedicarboxylic acid, which possess a centrosymmetric coplanar structure; even in those structures postulated for oxalic acid with a central bond of the normal single-bond distance the essential planarity of the molecule is not doubted (Part I), although in some of its salts the oxalate group has been reported non-coplanar (Hendricks and Jefferson, *J. Chem. Physics*, 1936, 4, 102). The diacetylenedicarboxylic acid molecule is found to possess not a centre of inversion, but a two-fold rotation axis, and the carboxyl groups at opposite ends of the molecule do not lie in the same plane. If two planes are taken, passing through the linear carbon chain and oppositely inclined to the (010) or LM plane at an angle of 28.4° , the carboxyl groups lie one on each of these planes. (The observed co-ordinates show that the oxygen atoms of the carboxyl groups are actually at 0.05 Å. from these planes, but this deviation is probably not significant.)

The normal configuration for this molecule is almost certainly a coplanar one. A conjugated system of the type shown by diacetylenedicarboxylic acid should confer appreciable double-bond character on the single bonds, and the distances observed in the carbon chain, which are further discussed below, show that this is the case. In the absence of any distorting forces such as steric or similar effects, a coplanar structure therefore seems clearly indicated as being the most stable.

It is seen from Fig. 4(c) that a planar centrosymmetric molecule in the space group C_{2h}^2 would lead to a system of hydrogen bonding in the form of a closed circuit, different from that observed in oxalic acid dihydrate and acetylenedicarboxylic acid dihydrate, where infinite spirals of hydrogen bonds occur. Now the structure shown in Fig. 4(c) is a possible structure, and the fact that it does not occur in the crystal shows that it must have a higher total energy than the structure of Fig. 4(b). The non-coplanar configuration for the molecule is, on the other hand, almost certainly of a higher energy than a coplanar configuration, and the energy difference between these two configurations must be more than compensated by the energy difference between the two possible systems of hydrogen bonding. It seems clear that intermolecular hydrogen bonding must be the governing factor in this type of crystal structure, and that it is sufficiently stable and invariant to cause appreciable distortion from the natural coplanar shape of the molecule.

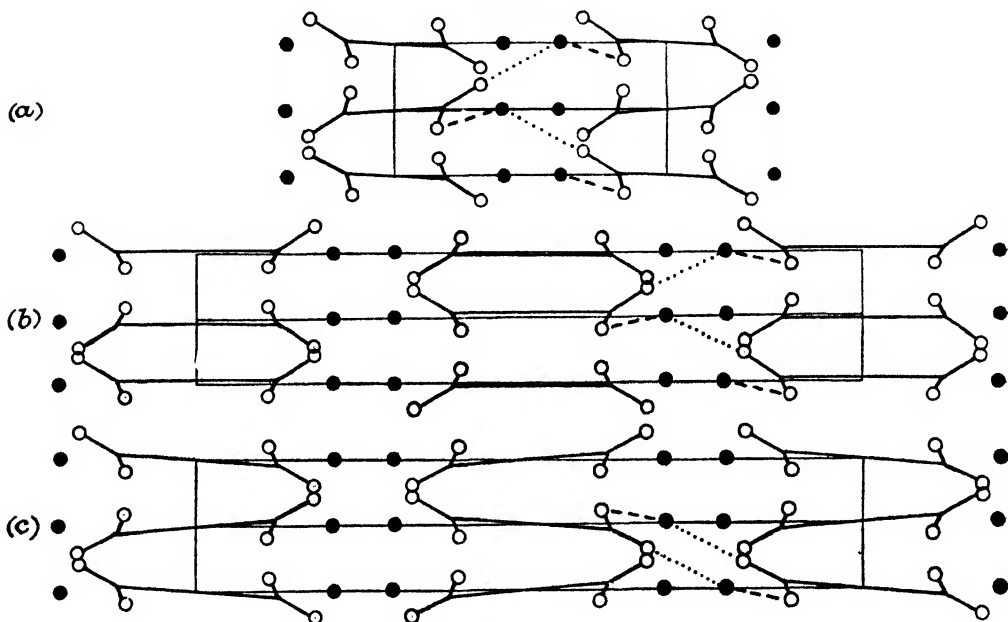

The strong directive power of hydrogen bonds has previously been noted as being able to preserve an open crystal structure which collapses, either partly as in resorcinol (Robertson and Ubbelohde, *Proc. Roy. Soc.*, 1938, A, 167, 122, 136) or completely as in ice, on breaking the bonds by heating. In diacetylenedicarboxylic acid dihydrate the directive power of the hydrogen bonds is sufficient to produce considerable distortion in the molecule itself. Such a directive power seems to indicate a certain amount of covalent character in the hydrogen bond.

The above argument may explain why the expected coplanar configuration for the molecule may not occur in the space-group C_{2h}^2 , but it gives no reason for the change in space-group from C_{2h}^2 in which the other compounds in this series occur. We would expect that the centrosymmetric planar molecule with an infinite spiral arrangement of the hydrogen bonds should exist in the space-group C_{2h}^2 with a lower energy than that of the structure observed.

Bond lengths within the molecule. In the carboxyl group we are again unable to distinguish between the carbon-oxygen bond lengths and find them both 1.25 Å. (In acetylenedicarboxylic acid dihydrate these bonds were 1.26 and 1.27 Å., and in oxalic acid dihydrate, 1.24 and 1.25 Å.; see Parts I and II.) The uncertainty here is of the same order as before, *viz.*, about 0.05 Å., but the three results taken together seem to indicate that the carbon-oxygen distances in the carboxyl group are probably equal, and support the view that the structures are likely to be ionic.

In the carbon chain the distance C(2)–C(3), measured as 1.45 Å., is also rather uncertain, but the fact that it is found to be slightly greater than the corresponding distance in acetylenedicarboxylic acid (1.43 Å.) may be significant. In the diacetylenedicarboxylic acid molecule the atoms no longer lie in one plane. The amount of double-bond character in the bond C(3)–C(2) must therefore be reduced with a consequent increase in the length of the bond.

FIG. 4.

(a) The acetylenedicarboxylic acid dihydrate structure.

(b) The diacetylenedicarboxylic acid dihydrate structure.

(c) A hypothetical diacetylenedicarboxylic acid dihydrate structure with a coplanar molecule in the space-group C_{2h}^2 .

These diagrams show one unit cell of the structures projected along the *a* axis. Oxygen atoms are shown as open circles, water molecules as black circles. For the sake of clarity only one hydrogen bond circuit (dotted lines) is shown in each case.

A considerably higher accuracy, probably to within about 0.02 Å., should apply to the remaining bond length measurements. The results are rather unusual, and for comparison Table IV shows the values which have been reported during the last few years for the various types of bond involved in triple-bonded systems.

We should expect bonds of the type $\equiv C-C\angle$ and $\equiv C-C\equiv$ to be considerably shortened from the normal single-bond distance of 1.54 Å., and the values found in the present investigation and for acetylenedicarboxylic acid are indeed much lower than 1.54 Å. The central bond of 1.33 ± 0.02 Å. is the shortest formal single bond yet reported, and it is, in fact, of just the length usually associated with a pure double bond. Accepting the value of 1.36 ± 0.03 Å. for this bond in diacetylene (Table IV), we might expect some further shortening in the present compound, due to the extra conjugation effects of the carboxyl groups. Wiebenga's value of 1.39 ± 0.03 Å. in diphenyldiacetylene seems rather high.

It should be noted that the general problem of contractions in triple-bonded systems has been given an alternative treatment by Conn, Kistiakowsky, and Smith (*J. Amer. Chem. Soc.*,

TABLE IV.

Bond-length measurements in triple-bonded systems.

1939, **61**, 1868), who suggest an explanation on the grounds of reduced steric hindrance in the acetylene compounds. Some of the contraction may also be due to change in effective single-bond radius (Robertson and Woodward, *Proc. Roy. Soc.*, 1938, *A*, **164**, 436; Penney and Kynch, *ibid.*, p. 409). The results of Crawford and Rice (*J. Chem. Physics*, 1939, **7**, 437) and of Osborne, Garner, and Yost (*ibid.*, 1940, **2**, 131), who show that for dimethylacetylene there is little or no potential barrier to free rotation of the methyl groups, are also significant in this connection and show that double-bond character in the usual sense need not always be present when there is contraction. In view of these results it becomes easier to reconcile the non-coplanar form of the diacetylenedicarboxylic acid molecule with our bond-length measurements.

For the triple bond we obtain a value of 1.185 ± 0.02 Å. in our present investigation, and for acetylenedicarboxylic acid the value was 1.19 ± 0.02 Å. In general, the values recorded for the triple bond in carbon compounds (Table IV) are usually less than, and never greater than, the value in acetylene itself (1.204 ± 0.002 Å.). On the other hand, we might expect that in such conjugated systems the value should be slightly greater than the normal carbon-carbon triple-bond value (see also Penney and Kynch, *loc. cit.*). Although the limits of error are in all cases such that a value of 1.20 Å. is admissible, yet the fact that these values are so consistently low may be significant.

One reason for the discrepancy may be that the acetylene value of 1.204 Å. is obtained spectroscopically and may not be exactly comparable to the X-ray values (see Robertson and Woodward, *Proc. Roy. Soc.*, 1938, *A*, **164**, 436). As far as possible, however, we try to make allowances for displaced electron distributions in the X-ray work.

Another more fundamental reason for the discrepancy may be that acetylene is not a suitable standard on which to base a "normal" triple-bond length. Acetylene shows well-marked

acidic properties and the C-H link must bear considerable ionic character. Structures of the type

must play some part in this molecule and they should have the effect, by resonance energy and by electrostatic attraction, of increasing the C-H bond strength and decreasing the C-H distance. The observed value for this distance in acetylene is 1.057 Å., as against 1.093 Å. in methane, although the contraction may be partly due to an increase in the *s* character of the hybridised carbon orbitals.

In a similar way, if these structures are important, the ionic forces involved should lead to some increase in the distance between the carbon atoms. The triple-bond distance observed in acetylene may therefore represent a "stretched" rather than a "normal" triple bond.

The amount of this stretching is extremely difficult to calculate because so many different types of energy are involved. A very approximate treatment may be effected by considering only the coulombic repulsion between the two negatively charged atoms in the structure $\overset{+}{\text{H}}\text{C}\equiv\overset{+}{\text{C}}\text{H}$. It must, of course, be remembered that this structure is less important than the other two mentioned above, on account of the adjacent charges.

We consider the problem as a two-atom one and make use of the Morse function

$$V(r) = D(-2e^{-a(r-\beta)} + e^{-2a(r-\beta)})$$

For the triple bond the dissociation energy *D* is taken as 190 k.-cals. mol.⁻¹. There is considerable doubt about the value of this constant owing to the uncertain value of the heat of sublimation of diamond. The value adopted is approximately that given by Skinner (*Trans. Faraday Soc.*, 1945, **41**, 645) assuming *L* = 170; *a* is the Morse constant, $\sqrt{K/2D}$, where *K* is the force constant, taken as 15×10^5 dynes cm.⁻¹ or 2180 k.-cals. mol.⁻¹ Å.⁻²; *a* thus has the value 2.4, and β is the correct "ideal" bond length corresponding to maximum stability.

The curve for the triple bond in acetylene has an additional term due to the coulombic repulsion of the two negatively charged carbon atoms, and it may therefore be represented as

$$V = 190(-2e^{-2.4(r-\beta)} + e^{-4.8(r-\beta)}) + \frac{(\delta e)^2}{r}$$

where δ = fraction of ionic character in the bond. This function has $(\partial V/\partial r)_\beta = 0$ at $r = 1.20$ Å.

$$\text{or} \quad \left(\frac{\partial V}{\partial r}\right)_\beta = 4.8 \times 190 \{e^{-2.4(1.20-\beta)} - e^{-4.8(1.20-\beta)}\} - \frac{(\delta e)^2}{r^2} = 0$$

$$\text{or} \quad 912\{e^{-2.4(1.20-\beta)} - e^{-4.8(1.20-\beta)}\} = \frac{(\delta e)^2}{1.20^2}$$

By graphical solution of this equation for various values of δ the results in Table V were obtained. These figures show that the "ideal" triple-bond distance, β , may be somewhat shorter than the acetylene value.

TABLE V.

δ .	$(\delta e)^2/1.20^2$, k.-cal. mol. ⁻¹ .	β , Å.	δ .	$(\delta e)^2/1.20^2$, k.-cal. mol. ⁻¹ .	β , Å.
0.10	2.3	1.199	0.30	19.7	1.191
0.20	9.2	1.196	0.40	36.8	1.182

We consider, therefore, that acetylene may not be a suitable standard for the triple-bond length. One compound which might be considered to possess the "normal" triple bond is di-*tert.*-butylacetylene, the synthesis of which has recently been announced by Hennion and Banigan (*J. Amer. Chem. Soc.*, 1946, **68**, 1202). A detailed X-ray analysis of this compound would be very interesting.

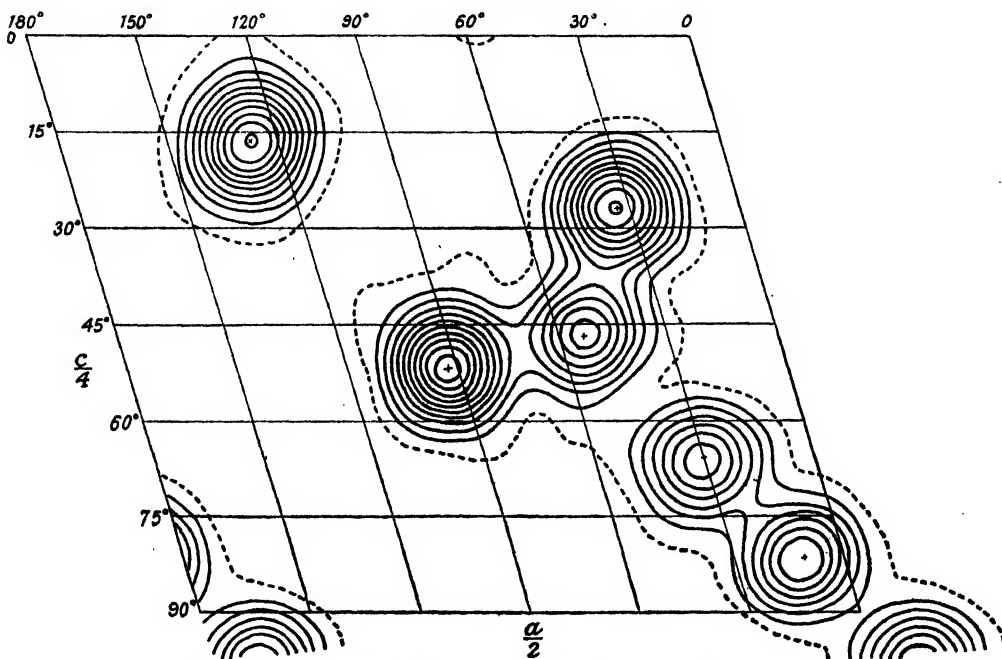

EXPERIMENTAL.

Preparation and Properties.—Diacetylenedicarboxylic acid was prepared by oxidation of the copper compound of propiolic acid with alkaline ferricyanide after Baeyer (*loc. cit.*, p. 2270). The extraction of the acid was difficult and the yields obtained were very poor, being only of the order of a few mg. from about 2 g. of propiolic acid. The compound obtained by us does not correspond to that of Baeyer, which was a monohydrate in the form of rhombic tablets, which darkened at 100°, exploded at 177°, and changed in light to a purple mass. Our product (crystallised from water or aqueous ether-light petroleum) was in the form of pale yellow monoclinic sword-like needles, elongated along the *b* axis. These crystals darkened at 95–100°, decomposed on further heating without explosion, and behaved

similarly to Baeyer's product in light. Microanalysis (Found: C, 41.4; H, 3.8. $C_6H_4O_4 \cdot H_2O$ requires C, 46.2; H, 2.6%. $C_6H_4O_4 \cdot 2H_2O$ requires C, 41.4; H, 3.5%) indicated that our compound is *diacetylenedicarboxylic acid dihydrate*. This was further confirmed by density data; the X-ray density for 4 molecules of monohydrate per unit cell is 1.28 g./c.c., or for 4 molecules of dihydrate per unit cell 1.43 g./c.c., while the observed density, determined by flotation in a mixture of ethylene bromide and benzene, is 1.43–1.45 g./c.c.

The crystals became purple on exposure to light and almost black on exposure to X-rays. With large crystals exposed to X-rays, the blackening was confined to that section of the crystal which was in the actual X-ray beam. The nature of the decomposition product was not determined, but its amount must have been very small, since quite black crystals gave X-ray photographs which showed no trace of powder rings. Prolonged exposure to X-rays did, however, produce photographs complicated by powder rings. The crystals do not lose their water of crystallisation as easily as acetylenedicarboxylic acid dihydrate, but the mosaic character of the crystals is ensured by their decomposition by light and X-rays. Copper-K α radiation was used throughout.

FIG. 5.

Co-ordinates assigned to the atoms in the asymmetric crystal unit.

Space-group Determination.—The following photographs were used to determine the unit cell and space-group. Rotation photographs about the a , b , c axes, and about $[101]$, $[111]$, $[011]$ gave the dimensions of the unit cell and showed that this was body-centred. Oscillation photographs about the b axis and moving-film photographs of the $(0kl)$, $(h0l)$, and (hkl) zones showed that the following halvings occurred: (hkl) appeared only when $(h+k+l)$ was even; $(h0l)$ appeared only when both h and l were even.

These halvings are characteristic of both the space-groups C_{2h}^4 and C_{2h}^6 , and these cannot be distinguished by X-rays since they differ only in the presence or absence of a centre of symmetry. An experiment to distinguish between these space-groups by pyroelectric effect was inconclusive. Finally, the space-group of higher symmetry C_{2h}^6 was assumed, since the calculations are considerably simplified if the structure possesses a centre of symmetry; we consider this assumption to be justified by the subsequent results.

Intensity Measurements.—Intensity estimates were carried out for the $(h0l)$ and $(0kl)$ zones. For the former the specimen employed had cross-section normal to the b axis of 0.13 mm. \times 0.31 mm., while that used for the $(0kl)$ zone had cross-section normal to the a axis of 0.29 mm. \times 0.21 mm. The intensities were estimated, and the F values derived from them, in the same way as for acetylenedicarboxylic acid dihydrate (*loc. cit.*). The range of observed intensities was about 3000 to 1.

Fourier Analysis.—The usual formulae for $\rho(x, z)$ and $\rho(y, z)$ were employed. For $\rho(xz)$ the series was summed at 900 points over the asymmetric unit, an eighth of the unit cell, the axial subdivisions being $a/60 = 0.186$ Å. and $c/120 = 0.168$ Å. Three-figure methods (Robertson, *Phil. Mag.*, 1936, **21**, 176) were used, and the positions of the contour lines were plotted on a scale of 5 cm. to 1 Å. by graphical interpolation from the arrays of summation totals. The final plot of the asymmetric unit for the b projection is shown in Fig. 5, where the final positions assigned to the atoms are indicated by small crosses.

The y co-ordinates together with a check on the z co-ordinates were obtained from the projection along the a axis shown in Fig. 2. $\rho(yz)$ was summed at 225 points over the asymmetric unit, the axial subdivisions being $b/30 = 0.125$ Å. and $(c \sin \beta)/60 = 0.322$ Å. The summations were carried out, and the contour map drawn, as described above for the b projection. Considerable overlapping occurs in the a axis projection and the y co-ordinates are not fixed as rigorously as we should like, but no better resolution can be obtained by two-dimensional methods and any ambiguity can be resolved only by means of three-dimensional Fourier synthesis.

From the final co-ordinates (Table I), all the structure factors were recalculated and the results are given in Table VI. For this calculation the structure factor F has been expressed in the form $fS = F$. For f we have used a composite empirical atomic scattering factor which gives better results than that used in the case of acetylenedicarboxylic acid dihydrate and oxalic acid dihydrate (*q.v.*). The f values used are as follows:

sin θ ($\lambda = 1.54$)	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
f	334	282	224	167	113	80	54	34	19	13

The maximum value of f , at sin $\theta = 0$, may be taken as $F(000) = 360$, the total number of electrons in the unit cell.

S is the geometric structure factor. It is conveniently put into the form

$$60 S = \Sigma 8A \cos 2\pi \left(\frac{hx}{a} + \frac{lz}{c} \right) \cos 2\pi \frac{hy}{b}, \text{ when } l \text{ is even}$$

$$60 S = \Sigma - 8A \sin 2\pi \left(\frac{hx}{a} + \frac{lz}{c} \right) \sin 2\pi \frac{hy}{b}, \text{ when } l \text{ is odd}$$

The carbon and oxygen coefficients are weighted in the ratio of 6 to 9, so that for a carbon atom $A = 1$ and for an oxygen atom $A = 1.5$. Since there are six atoms in the asymmetric unit, three of which have $A = 1$ and three $A = 1.5$, the maximum value of S is conveniently taken as unity.

The percentage discrepancy finally obtained, expressed as

$$\frac{\Sigma (|F \text{ meas.}| - |F \text{ calc.}|)}{\Sigma |F \text{ meas.}|} \times 100$$

is 11.0 for the ($h0l$) reflections, 14.8 for the ($0kl$) reflections, and 11.9 for all reflections.

In the b axis projection (Fig. 1) the F values for the (802) and (10, 0, 8) planes were omitted from the Fourier summation owing to uncertainty of sign.

We thank Dr. E. Warhurst for much helpful discussion during the progress of this work, and one of us (J. D. D.) is indebted to the Carnegie Trustees for a Scholarship.

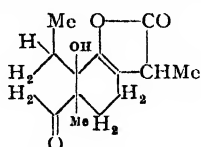

216. The Constitution of ψ -Santonin. Part IV. A Study of the Butenolide System.

By WESLEY COCKER and STANLEY HORNSBY.

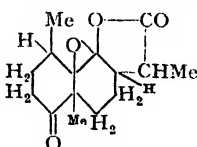

The speeds of bromination and hydrogenation, and the products of the latter, of ψ -santonin and a number of $\alpha\beta$ - and $\beta\gamma$ -butenolides have been compared. Spectroscopic observations have also been made. Possible structures for ψ -santonin are discussed.

Experiments with dihydro- ψ -santonin suggest that this compound can be represented as (III).

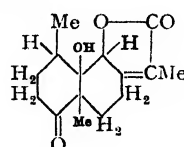

In Part I of this series Clemo and Cocker (*J.*, 1946, 30) discussed the chemistry of ψ -santonin and suggested that one of the structures (Ia) and (II) represented the constitution of this compound, but it was not then possible to decide which was the more likely.

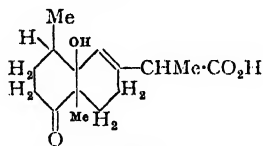

(Ia.)

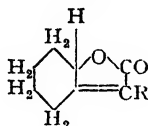

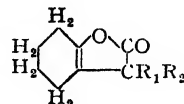

(Ib.)

(II.)

(III.)

(IV; R = H;
V; R = Me.)

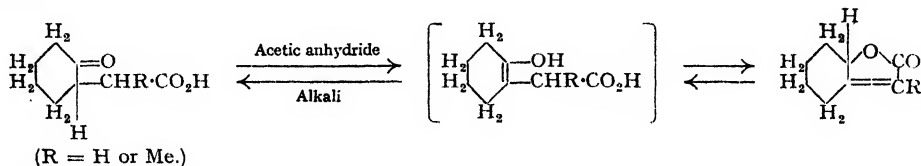

(VI.)

Colour reactions with sodium nitroprusside (cf. Jacobs and Hoffmann, *J. Biol. Chem.*, 1925, 67, 333; Paist, Blout, Uhle, and Elderfield, *J. Org. Chem.*, 1941, 6, 273) strongly suggested the presence of a $\beta\gamma$ -butenolide, whilst the slow reduction of ammoniacal nitrate suggested an $\alpha\beta$ -butenolide (cf. Jacobs, Hoffmann, and Gustus, *J. Biol. Chem.*, 1926, 70, 1).

In view of these opposing reactions it was felt desirable to study the properties of a number of butenolides of both the $\alpha\beta$ - and the $\beta\gamma$ -type in which, as in ψ -santonin, the butenolide is fused in the $\beta\gamma$ -position to a cyclohexane ring.

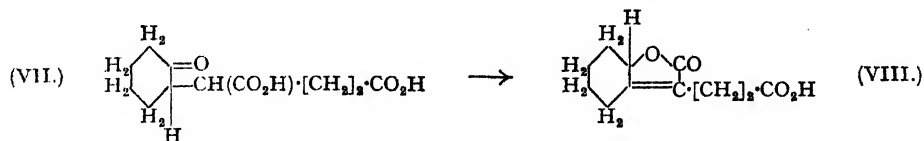

Although various α - and β -substituted butenolides have been studied in which the substituent was cyclohexyl (Elderfield *et al.*, *J. Org. Chem.*, 1941, 6, 289) and a few of the above mentioned fused lactones have been prepared, no systematic study of the properties of the latter compounds seems to have been undertaken. We have therefore prepared and studied the properties of the lactones of the following acids, namely, 2-hydroxycyclohexylideneacetic acid (IV), 2-hydroxycyclohexylidene- α -propionic acid (V), and 2-hydroxycyclohex-1-enyl- α -isobutyric acid (VI; R₁ = R₂ = Me).

The $\alpha\beta$ -butenolides (IV and V) were prepared by the cyclisation of 2-ketocyclohexylmalonic or 2-ketocyclohexyl- α -propionic acid with acetic anhydride; the reactions are apparently as follows:

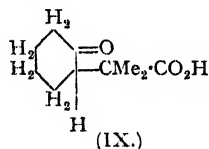

That the product of the cyclisation is an $\alpha\beta$ -butenolide is shown by the fact that when the lactone obtained from 2-ketocyclohexylmalonic acid was submitted to ozonolysis in chloroform, 2-ketocyclohexanol was obtained. Although neither glyoxylic nor oxalic acid was obtained in this reaction, yet when the same lactone was oxidised with neutral permanganate a mixture was obtained from which, in addition to some unchanged lactone, an unidentified carbonyl compound, adipic acid, and oxalic acid were isolated. We do not consider that the isolation of adipic acid and oxalic acid is necessarily of diagnostic value, but together with the evidence from the

ozonolysis experiments there is adequate proof of the $\alpha\beta$ -butenolide structure. The lactone from 2-ketocyclohexyl- α -propionic acid also gave 2-ketocyclohexanol on ozonolysis. Furthermore, Kendal and Osterberg (*J. Amer. Chem. Soc.*, 1927, 49, 2047) showed conclusively by ozonolysis experiments on the product that when 2-ketocyclohexyl- α -glutaric acid (VII) is cyclised it yields the $\alpha\beta$ -butenolide (VIII), a result which is analogous to those we obtained.

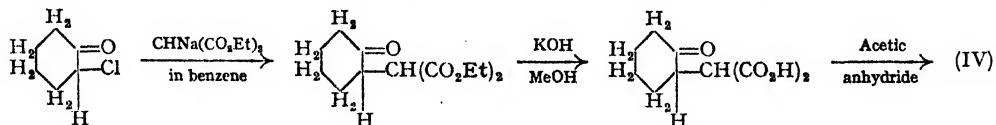

Other workers, e.g., Grewe (*Ber.*, 1939, 72, 426), have concluded that when γ -keto-acids of the type already mentioned are cyclised the result is a $\beta\gamma$ -lactone. This worker assumed that the product of cyclisation of 2-ketocyclohexyl- α -benzylacetic acid was (VI; $R_1 = \text{H}$; $R_2 = \text{CH}_2\text{Ph}$). He found, however, that on catalytic hydrogenation the butenolide system was unaffected, whereas the aromatic nucleus suffered reduction. This resistance to hydrogenation was similar to that shown by lactone (V), and we believe that Grewe's lactone was actually of the $\alpha\beta$ -butenolide type.

The production of an $\alpha\beta$ -butenolide in the manner stated does not appear to be in accordance with the work of Kon and Speight (*J.*, 1926, 2727) who showed that, presumably as a result of the tendency of the six membered ring to acquire a double bond, the equilibrium between cyclohex-1-enylacetic acid and its esters and cyclohexylideneacetic acid and its esters lies on the side of the former compounds. By analogy we should have expected the equilibrium between the $\beta\gamma$ - and $\alpha\beta$ -butenolides under discussion to lie on the side of the former, but it appears that in these lactones the tendency of the double bond to conjugate with the carbonyl group predominates. It was obvious, therefore, that a $\beta\gamma$ -butenolide of type (VI) could only be prepared if the tautomeric system were blocked, i.e., if R_1 and R_2 were groups other than H. We therefore prepared and cyclised 2-ketocyclohexyl- α -isobutyric acid (IX) which yielded the required lactone (VI; $R_1 = R_2 = \text{Me}$).

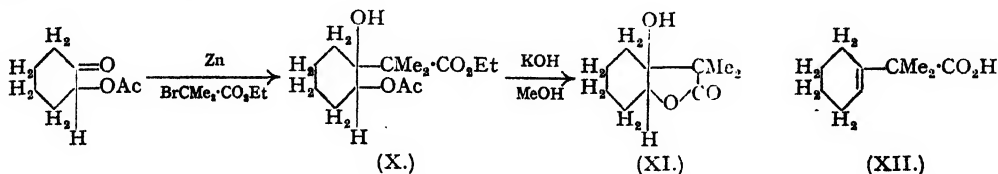

The lactone of 2-hydroxycyclohexylideneacetic acid (IV) was prepared by McCrae, Charlesworth, and Alexander (*Canadian J. Res.*, 1943, 21B, 1) who oxidised the lactone of 2-hydroxycyclohexylacetic acid (Coffey, *Rec. Trav. chim.*, 1923, 42, 382) with bromine and magnesium hydroxide. The keto-acid so obtained was then cyclised by heating at 200° in a vacuum, and the butenolide was obtained as a solid, m. p. 7—8°. We preferred to use a more economical method for the preparation of this lactone. 2-Chlorocyclohexanone was condensed with ethyl sodiomalonate and the ester obtained was saponified with methyl-alcoholic potash to give 2-ketocyclohexylmalonic acid, which was simultaneously lactonised and decarboxylated by refluxing with an excess of acetic anhydride.

By this method we obtained the butenolide as a crystalline solid, m. p. 29—30°. Lactone (V) was prepared in a similar manner, and we found this to be preferable to the method of Clemo and Cocker (*loc. cit.*) who started from 2-carbethoxycyclohexanone and ethyl α -bromopropionate.

The preparation of the lactone of 2-hydroxycyclohex-1-enyl- α -isobutyric acid was troublesome and a number of routes were tried before a satisfactory one was found. The first was by the condensation of 2-carbethoxycyclohexanone in presence of sodium with ethyl α -bromoisobutyrate, and the product, which gave only poor analysis results, was hydrolysed with 8% methyl-alcoholic potash. Unfortunately this gave only pimelic acid and a hygroscopic acid which gave no carbonyl reactions. In the second method 2-acetoxycyclohexanone was condensed in presence of zinc with ethyl α -bromoisobutyrate to give ethyl 1-hydroxy-2-acetoxycyclohexyl- α -isobutyrate (X) in fair yield. All attempts to dehydrate this ester failed. It was boiled with acetic anhydride, with and without anhydrous sodium acetate; it was heated at 160° with potassium hydrogen sulphate; and finally it was heated under reflux with pyridine and phosphoryl chloride: all these treatments left it unchanged. Torrey, Kuck, and Elderfield

(*J. Org. Chem.*, 1941, 6, 289) found similar difficulty in the dehydration of certain tertiary alcohols, but all their compounds yielded to the dehydrating action of a boiling mixture of pyridine and phosphoryl chloride.

When the ester (X) was hydrolysed with alcoholic potash and the mixture acidified, a lactone $\text{C}_{10}\text{H}_{16}\text{O}_3$ was obtained which presumably was (XI). Attempts to dehydrate this lactone were again unsuccessful, but it was found that on heating it with 30% alcoholic sulphuric acid a very small yield of a carbonyl compound was obtained, and this gave a 2 : 4-dinitrophenyl-hydrazone which proved to be identical with that obtained from 2-ketocyclohexyl- α -isobutyric acid. The ketone was probably produced from (XI) by a pinacol-pinacolone rearrangement. The method was, however, of little preparative value.

Finally the required lactone (VI; $\text{R}_1 = \text{R}_2 = \text{Me}$) was obtained by a method similar to that used by McCrae, Charlesworth, and Alexander (*loc. cit.*) for the preparation of (IV). Ethyl 1-hydroxycyclohexyl- α -isobutyrate (Wallach and Mallinson, *Annalen*, 1908, 360, 68) was obtained by the condensation of cyclohexanone with ethyl α -bromoisobutyrate in presence of zinc, and it was dehydrated and then saponified to yield cyclohex-1-enyl- α -isobutyric acid. Von Braun and Münch (*Annalen*, 1928, 465, 55) effected the lactonisation of this acid with hydrogen bromide in acetic acid. We performed the lactonisation with 50% sulphuric acid, and the product was oxidised to 2-ketocyclohexyl- α -isobutyric acid. The lactonisation of cyclohex-1-enyl- α -isobutyric acid mentioned above was, however, accompanied by the production of 1-isopropylcyclohexene. Wallach and Mallinson (*loc. cit.*) showed that this compound could be obtained from isopropylidenecyclohexane by heating with sulphuric acid. Lactone (VI; $\text{R}_1 = \text{R}_2 = \text{Me}$) was finally obtained by the cyclisation of 2-ketocyclohexyl- α -isobutyric acid with acetic anhydride.

Various attempts were made to prepare the lactone of 1-hydroxy-3 : 4-dihydronaphthalene-2-isobutyric acid, but these were unsuccessful.

Hydrogenation Experiments.— ψ -Santonin and the lactones (IV), (V), and (VI; $\text{R}_1 = \text{R}_2 = \text{Me}$) were separately submitted to catalytic hydrogenation at 1 atmosphere pressure of hydrogen, at room temperature using (a) palladised charcoal and (b) Adams's platinum oxide catalyst. The results of these experiments are shown in Fig. 1 and Table I. It can readily be seen that, of all the lactones employed, only ψ -santonin was hydrogenated with any rapidity when palladised charcoal was employed, and here absorption ceased when one molecule of hydrogen had been taken up. The product of the reaction was dihydro- ψ -santonin (III), an unsaturated carboxylic acid. With the same catalyst the $\alpha\beta$ -butenolide (IV) absorbed one molecule of hydrogen in about 16 hours and the product was the saturated lactone of 2-hydroxycyclohexylacetic acid. On the other hand the $\alpha\beta$ -butenolide (V), in which the $\alpha\beta$ -double bond is further protected, absorbed about 0.1 molecule of hydrogen in fifteen minutes in presence of palladised charcoal after which no further absorption took place. The addition of Adams's catalyst at this stage effected no further absorption apart from that expected in the reduction of the catalyst. On working up the reaction mixture only (V) was isolated. The $\beta\gamma$ -butenolide (VI; $\text{R}_1 = \text{R}_2 = \text{Me}$) was unaffected by hydrogen and palladised charcoal, but in presence of Adams's catalyst absorption took place at a very rapid rate and 2 molecules of hydrogen were taken up in 15 minutes with the production of cyclohexyl- α -isobutyric acid, identical with the acid obtained from the hydrogenation of cyclohex-1-enyl- α -isobutyric acid (XII) in presence of Adams's catalyst. In presence of the same catalyst ψ -santonin absorbed one molecule of hydrogen at a speed very similar to that of (VI), but further hydrogenation was slower and was complicated by the reduction of the keto-group. Under similar conditions (IV) was reduced rapidly, but not so rapidly as either ψ -santonin or (VI), and again a saturated lactone was obtained. Finally we found that cyclohex-1-enyl- α -isobutyric acid (XII) was unaffected by hydrogen and palladised charcoal, which falls into line with the absence of reactivity of dihydro- ψ -santonin (III) towards the same reagents, and it is of interest to record that Thakur (*J.*, 1933, 1481) found that cyclohex-1-enyl- α -propionic acid was only slowly reduced with Adams's catalyst.

These results clearly indicate that ψ -santonin and the $\beta\gamma$ -lactone behave alike in the

production of a deoxy-acid on hydrogenation; a result which is similar to that found by Jacobs and Scott (*J. Biol. Chem.*, 1930, **87**, 601) in the investigation of a number of simple $\beta\gamma$ -butenolides. These workers and Paist, Blout, Uhle, and Elderfield (*loc. cit.*) also found that simple $\alpha\beta$ -butenolides are reduced to the corresponding saturated lactones. Both ψ -santonin and (VI; $R_1 = R_2 = \text{Me}$) are more rapidly hydrogenated than the $\alpha\beta$ -butenolides (IV) and (V), but it is well known that $\alpha\beta$ -double bonds, and particularly protected $\alpha\beta$ -double bonds, are very often sluggish or resistant to hydrogenation (Haworth, *Ann. Reports*, 1937, **34**, 328).

Halogenation Experiments. (With C. LIPMAN.)—It is well known that $\alpha\beta$ -unsaturated acids and esters absorb bromine less rapidly than their $\beta\gamma$ -isomerides (Sudborough and Thomas, *J.*, 1910, 97, 715, 2450) and this method was used by Linstead (*J.*, 1927, 355) for determination of the position of equilibrium in mixtures of isomeric unsaturated acids. By a method similar to that advocated by Linstead we have studied the comparative speeds of bromination of ψ -santonin and the three other lactones. For this purpose equivalent quantities (1/1200 g.-mol.) of the lactones in $N/60$ -solution in carbon tetrachloride, containing 30% acetic acid necessary to obtain solution, were treated with 2 mols. of $N/15$ -solution of bromine in carbon tetrachloride, the final concentration of the bromine in the mixture being $N/30$, and the carefully stoppered vessels were placed in a dark container at 16–17°. Aliquot portions of the solutions were withdrawn at intervals and after treatment with potassium iodide the liberated iodine was titrated with $N/40$ -thiosulphate. 2 Mols. of bromine were employed because ψ -santonin brominates first to give a monobromo-compound by substitution and then one molecule of bromine adds to give a tribromo-compound (Clemo and Cocker, *loc. cit.*). Fig. 2 and Table II

FIG. 2.

Bromination of ψ -santonin and the synthetic lactones.

show that ψ -santonin and the $\beta\gamma$ -butenolide (VI; $R_1 = R_2 = \text{Me}$) absorb bromine at approximately the same rate, although it should be remembered that it is the upper part of the graph of ψ -santonin which must be compared with that of (VI), since the lower part of the ψ -santonin graph, which lies upon that of (VI), represents the substitution reaction. When monobromo- ψ -santonin was brominated using one molecule of bromine its rate of bromination was similar to that found for the absorption of the second molecule of bromine in ψ -santonin itself, so that the influence of the hydrogen bromide produced in the substitution reaction in ψ -santonin need not be considered. When (VI) was brominated with 1 mol. of bromine there was no change in the rate of reaction. The absorption of bromine by the $\alpha\beta$ -butenolides (IV and V) is very slow, but the initial rapid absorption is interesting and is paralleled by a similar absorption in the hydrogenation of (V). This is probably due to the presence of some $\beta\gamma$ -butenolide in (IV) and (V).

Cavallito and Haskell (*J. Amer. Chem. Soc.*, 1946, 68, 2332) used Hanus solution (IBr) as a reagent for differentiating between $\alpha\beta$ - and $\beta\gamma$ -lactones. They found that the latter reacted much more rapidly than the former with this reagent.

The bromination and hydrogenation results seem to be evidence in favour of the adoption of structure (Ia) for ψ -santonin.

Spectroscopic Evidence.—Spectroscopic studies do not appear to support the $\beta\gamma$ -structure, and in fact, neglecting the absorption due to the carbonyl group, there is a striking resemblance between the absorptions of ψ -santonin and the $\alpha\beta$ -lactone (V). In each case there is high intensity absorption at the extreme end of the usual ultra-violet range, and in neither is a maximum discernible. This is similar to the experience noted by other workers such as Haynes and Jones (*J.*, 1946, 954) and Ruzicka *et al.* (*Helv. Chim. Acta*, 1942, 25, 435; 1944, 27, 186) with a number of simple $\alpha\beta$ -unsaturated lactones. The $\beta\gamma$ -lactone (VI) absorbs with a much smaller intensity than either ψ -santonin or lactone (V) at comparable wave-lengths.

Colour Reactions and Reactions with Tollens's Reagent.—Lactones (IV) and (V) both instantaneously reduced Tollens's reagent whilst ψ -santonin and (VI; $R_1 = R_2 = \text{Me}$) gave a silver mirror only after twelve hours. These reactions were carried out as follows. A solution of 10 mg. of lactone in 1 c.c. of purified pyridine was treated with 1 c.c. of Tollens's reagent, prepared from equal volumes of 10% sodium hydroxide and 10% silver nitrate to which 10% ammonia was added dropwise until the precipitated silver oxide had disappeared.

The results are interesting since they appear to show that ψ -santonin and lactone (VI; $R_1 = R_2 = \text{Me}$) are alike in the position of the double bond (*i.e.*, they are $\beta\gamma$ -butenolides), but the slowness of reduction of the reagent by these butenolides is contrary to the experience of Jacobs, Hoffmann, and Gustus (*loc. cit.*) who found that the $\beta\gamma$ -butenolides they investigated gave immediate reduction of Tollens's reagent, whereas the $\alpha\beta$ -butenolides were very sluggish. It must be remembered, however, that Jacobs and his co-workers were not investigating lactones fused to a cyclohexane ring, and it is more than likely that this is the explanation of the differing results.

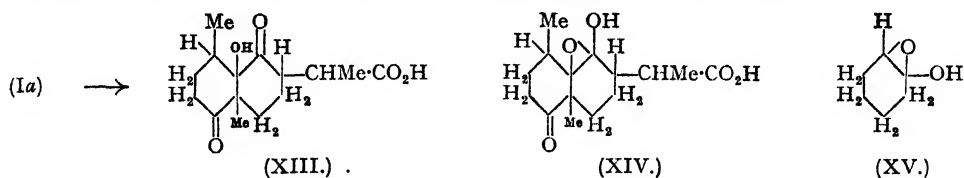

The Legal tests when applied to all the synthetic lactones in the manner recommended by Paist, Blout, Uhle, and Elderfield (*loc. cit.*) were most unsatisfactory. There was little change in colouration with sodium nitroprusside until the solution became distinctly alkaline to phenolphthalein and it is felt that as applied to these particular lactones the Legal test has little diagnostic value.

Cardiac Activity of the Lactones.—The effect on the isolated frog heart of ψ -santonin, the lactones (IV), (V), (VI), and the lactone of 2-hydroxycyclohexylacetic acid was tried through the courtesy of the late Dr. J. Secker of the Department of Physiology of King's College. The concentration of lactone used was 1 mg. per c.c. of 10% aqueous alcohol and it was found that 1 drop of solution of all the butenolides produced cardiac inhibition, whilst the saturated lactone was ineffective. It appears, therefore, that the unsaturated lactone system has some cardiac effect, but it is not specific for either the $\alpha\beta$ - or the $\beta\gamma$ -type. No experiments were performed on cats but it is highly unlikely that any of the lactones would have important effects (*cf.* Swain, Todd, and Waring, *J.*, 1944, 548).

If the $\beta\gamma$ -butenolide structure (I) for ψ -santonin is adopted there are certain experimental results which require an explanation. In the first place when ψ -santonin is saponified with methyl-alcoholic potash a solution is obtained from which the starting material is regenerated even on acidification at 0°. Many experiments were performed but in none of these was there any evidence for the production of a diketo-acid on saponification of ψ -santonin, whereas the diketo-acid (XIII) would be expected from structure (Ia). All the synthetic butenolides give keto-acids on saponification. One possible explanation could be that on hydrolysis the keto-acid undergoes isomeric change with the formation of the cyclic alcohol (XIV), in the same way that Bergmann and Gierth (*Annalen*, 1926, 448, 48) found that 2-ketocyclohexanol can exist in

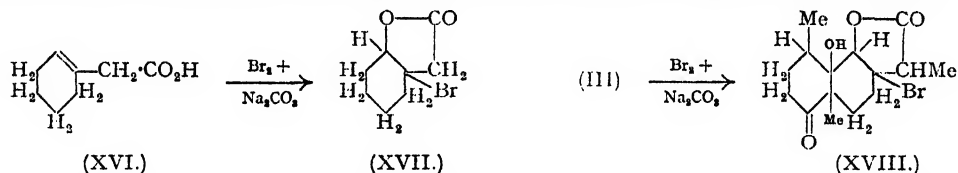

the oxido-form (XV). It is possible that on acidification $^-(XIV)^-$ could lactonise and undergo isomeric change with the formation of (Ia).

A further difficulty in the way of acceptance of structure (Ia) lies in the fact that it has been shown that in the butenolides fused to the cyclohexane ring, unless tautomeric change is

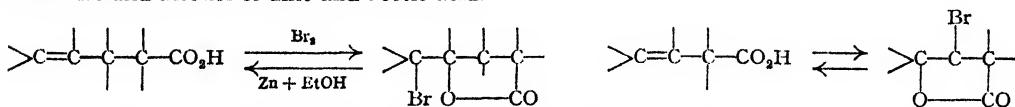

impossible as in (VI), the double bond is found in the $\alpha\beta$ -position. Why then should ψ -santonin be a $\beta\gamma$ -butenolide? We believe that the hydroxyl group is somehow connected with this problem and it may be that structure (Ib) is more acceptable than (Ia), but until we have succeeded in synthesising certain hydroxylated butenolides it would be well to withhold further comment.

Some Experiments with Dihydro- ψ -santonin.—This compound readily decolourises bromine water, and in quantitative experiments performed under identical conditions with those already described it was found that one mol. of bromine was completely absorbed per mol. of acid in less than 5 minutes. This result is strongly suggestive of a $\beta\gamma$ -unsaturated acid. Moreover such $\beta\gamma$ -acids readily form bromo-lactones on treatment, in sodium carbonate, with bromine water. Thus Harding, Haworth, and Perkin (*J.*, 1908, 95, 1963) obtained a bromo-lactone, to which they assigned the structure (XVII), when cyclohex-1-enylacetic acid (XVI) was brominated in sodium carbonate. In a similar manner when dihydro- ψ -santonin was treated in sodium carbonate with bromine water a white crystalline solid was obtained. This was a bromo-lactone, $C_{15}H_{21}O_4Br$, and to this compound by analogy we assign structure (XVIII).

The possibility that the bromo-lactone is a β -lactone may be ruled out, since we have shown already that the $\alpha\beta$ -double bond is resistant to attack of bromine and the mechanism of addition of hypobromous acid is undoubtedly similar to that of bromine itself.

Such bromo-lactones as those mentioned above should be capable of reduction to the corresponding unsaturated acids. Thus Winterstein and his co-workers (*Z. physiol. Chem.*, 1931, 199, 25, 37, 46, 56, 64, 75) have shown that $\beta\gamma$ - and $\gamma\delta$ -unsaturated acids can be converted into crystalline bromo-lactones from which the unsaturated acids are regenerated by reduction with zinc and alcohol or zinc and acetic acid.

When the bromo-lactone (XVIII) was refluxed with zinc dust in alcohol it was smoothly reconverted into dihydro- ψ -santonin. In an analogous manner cyclohex-1-enyl- α -isobutyric acid was converted into a bromo-lactone, $C_{10}H_{15}O_2Br$, from which the unsaturated acid was again obtained by reduction with zinc and alcohol.

We consider that the above evidence strongly supports the structure (III) suggested for dihydro- ψ -santonin.

EXPERIMENTAL.

Lactone of 2-Hydroxycyclohexylideneacetic Acid (IV). 2-Ketocyclohexylmalonic Acid.—Ethyl malonate (63.4 g.) was added dropwise to a stirred and boiling suspension of powdered sodium (9.1 g.) in benzene (300 c.c.) and the reaction was continued until all the sodium had disappeared. The cooled mixture was then slowly treated, with stirring, with 2-chlorocyclohexanone (63 g.). After 1 hour in the cold the mixture was heated on the water-bath and refluxed, with stirring, for 8 hours. It was then cooled and acidified with dilute acetic acid, and the benzene layer was separated, washed with water, and dried. On distillation ethyl 2-ketocyclohexylmalonate (49 g.) was collected as a colourless oil, b. p. 150–151°/3 mm. (Found: C, 61.5; H, 7.9. $C_{15}H_{20}O_5$ requires C, 60.9; H, 7.8%). This ester was

hydrolysed by heating for 2 hours under reflux with a solution of potassium hydroxide (34 g.) in methyl alcohol (500 c.c.) and water (50 c.c.). Methyl alcohol was then removed and the residue was diluted with water, shaken with charcoal, and filtered. The filtrate was acidified, saturated with ammonium sulphate, and extracted several times with ethyl acetate from which the required 2-ketocyclohexylmalonic acid was obtained (19 g.), m. p. 160°. It crystallised from water as colourless needles, m. p. 168–169° (decomp.). McCrae, Charlesworth, and Alexander (*loc. cit.*) give m. p. 163° (Found: C, 54.1; H, 6.0; equiv., 105.1. Calc. for $C_8H_{12}O_5$: C, 54.0; H, 6.0%; equiv., 100). Its 2:4-dinitrophenylhydrazones crystallised from alcohol as yellow needles, m. p. 218–219° (decomp.) (Found: C, 48.0; H, 4.5. $C_{18}H_{18}O_8N_4$ requires C, 47.4; H, 4.2%).

The above acid (19 g.) was gently refluxed for 2 hours with acetic anhydride (80 g.) and the acetic anhydride was then removed under reduced pressure. The residual oil was dissolved in ether, washed several times with sodium hydrogen carbonate solution, dried, and distilled. The product distilled almost completely at 131–133°/3–4 mm. and on cooling it solidified to a mass of colourless needles of (IV), m. p. 29–30° (Found: C, 69.3; H, 7.3. Calc. for $C_8H_{10}O_4$: C, 69.6; H, 7.25%). On hydrolysis with 10% methyl-alcoholic potash the lactone yielded 2-ketocyclohexylacetic acid, m. p. 73°, undepressed by admixture with an authentic specimen prepared by heating 2-ketocyclohexylmalonic acid (cf. McCrae *et al.*, *loc. cit.*) (Found: equiv., 150. Calc. for $C_8H_{12}O_3$: equiv., 156). 2-Ketocyclohexylacetic acid 2:4-dinitrophenylhydrazones crystallised from dilute alcohol as yellow needles, m. p. 193–194° (Found: C, 50.5; H, 4.8. $C_{18}H_{18}O_8N_4$ requires C, 50.0; H, 4.8%).

Oxidation of the Lactone.—(a) *With neutral potassium permanganate.* The lactone (1.0 g.) in water (10 c.c.) containing magnesium sulphate (3 g.) was slowly treated, with shaking, with 1% permanganate (75 c.c.). The mixture was then further shaken for 30 minutes. It was made alkaline to phenolphthalein and filtered. The filtrate was warmed for 30 minutes on the water-bath and extracted with ether from which unoxidised lactone, m. p. 29–30°, was obtained. The alkaline residue was evaporated to a very small bulk, acidified with sulphuric acid, and extracted many times with ether from which adipic acid (crude, m. p. 140°) was isolated. The aqueous residue was freed from sulphate ions, buffered with sodium acetate, and treated with calcium chloride; calcium oxalate was produced, soluble in hydrochloric acid and capable of reducing acid potassium permanganate.

(b) *With ozone.* The lactone (0.5 g.) in purified chloroform (25 c.c.) was subjected to ozonised oxygen (0.009 g.-mol. O_3 /hr.) for 30 minutes. The solvent was then removed in a vacuum at room temperature and the residue was shaken thoroughly with water and left overnight. The solution was treated with sodium carbonate (0.5 g.) and steam distilled. The distillate yielded a 2:4-dinitrophenylhydrazones which on crystallisation from alcohol gave m. p. 231–232° undepressed by an authentic specimen of the 2:4-dinitrophenylhydrazones of 2-ketocyclohexanol. Neither glyoxylic acid nor oxalic acid was, however, identified in the residue from the steam distillation.

Hydrogenation.—The above lactone (1.0002 g.) in glacial acetic acid (20 c.c.) containing palladised charcoal (0.5 g.) absorbed 166.4 c.c. of hydrogen at 15.5°/761 mm. This is equivalent to 0.98 mols. of hydrogen per mol. of lactone. The reaction was complete in 16 hours. The glacial acetic acid was removed under reduced pressure and the residue was distilled to give the lactone of 2-hydroxycyclohexylacetic acid (0.9 g.), b. p. 110–111°/3–4 mm. (Found: C, 68.3; H, 8.6. Calc. for $C_8H_{12}O_3$: C, 68.6; H, 8.6%). Its phenylhydrazide crystallised from dilute acetic acid in colourless plates, m. p. 168° (Found: C, 67.7; H, 8.2. $C_{14}H_{18}O_3N_2$ requires C, 67.7; H, 8.1%). No acid products were isolated from the reduction, and when the reduced lactone was hydrolysed by alkali and the solution acidified it was regenerated unchanged.

When (IV) (0.3070 g.) was hydrogenated in acetic acid (20 c.c.) containing Adams's platinum oxide catalyst (0.05 g.) at 20°/769 mm. hydrogen was rapidly absorbed and absorption was complete (1.17 mols. of hydrogen per mol. lactone) in 30 minutes. When the acetic acid was removed the residue was found to be insoluble in sodium carbonate, and it gave a phenylhydrazide identical with that described above.

Lactone of 2-Hydroxycyclohexylidene- α -propionic Acid (V). 2-Ketocyclohexyl- α -propionic Acid.—The following method was found to be more convenient than that described by Clemons and Cocker (*loc. cit.*). Ethyl methylmalonate (27 g.) in dry benzene (20 c.c.) was added dropwise to powdered sodium (3.55 g.) in dry benzene (50 c.c.), and the reaction was continued until the sodium had disappeared. Then 2-chlorocyclohexanone (20 g.) was slowly added with stirring, and the mixture was stirred and refluxed for 8 hours. It was diluted with water and the benzene layer was separated, dried, and distilled. The ester (18 g.) was collected at 158–162°/3–4 mm., but all attempts to get a good analytical specimen failed. It was therefore hydrolysed under reflux for 2 hours with a mixture of potassium hydroxide (12 g.), methyl alcohol (90 c.c.), and water (30 c.c.). Methyl alcohol was removed under reduced pressure, and the cooled residue was acidified with dilute sulphuric acid and extracted with ether from which 2-ketocyclohexyl- α -propionic acid (5 g.) was obtained, m. p. 133–134°. It crystallised from water (charcoal) as colourless plates, m. p. 134.5–135.5° (Found: equiv., 172. Calc. for $C_9H_{14}O_3$: equiv., 170). Its 2:4-dinitrophenylhydrazones crystallised from alcohol as yellow needles, m. p. 244° (decomp.) (Found: C, 51.3; H, 5.5. Calc. for $C_{19}H_{18}O_8N_4$: C, 51.4; H, 5.1%).

Lactone (V).—The above keto-acid (17.5 g.) was heated under reflux for 2 hours with acetic anhydride (60 c.c.). Acetic anhydride was removed under reduced pressure and the residue was extracted with ether. The extract was washed several times with sodium hydrogen carbonate solution, dried, and distilled, to give the required lactone as a highly refractive liquid, b. p. 133–134°/3 mm. (Found: C, 70.5; H, 7.8. $C_9H_{12}O_3$ requires C, 71.0; H, 7.9%). This lactone was somewhat less soluble in water than its lower homologue, but it was readily and quantitatively saponified with 5–10% methyl-alcoholic potash to 2-ketocyclohexyl- α -propionic acid, m. p. and mixed m. p. 135°.

Attempted hydrogenation. The above lactone (0.9763 g.) in glacial acetic acid (20 c.c.) containing palladised charcoal (0.5 g.) was hydrogenated at 15°/745 mm. 17.5 C.c. of hydrogen were absorbed in about 15 minutes, and then absorption ceased. Adams's catalyst (0.1 g.) just previously reduced was later introduced and a further 30.0 c.c. of hydrogen was absorbed, but even after further shaking overnight no appreciable further absorption took place. On removal of the acetic acid and alkaline hydrolysis of the residue, 2-ketocyclohexyl- α -propionic acid (0.7 g.), m. p. 135°, was recovered.

2-Hydroxycyclohex-1-enyl- α -isobutyrolactone (VI; $R_1 = R_2 = \text{Me}$).—(a) From 2-acetoxycyclohexanone. Clean and bright zinc wool (3.2 g.; 2.1 g.-atoms) was added in portions to 40 c.c. of a mixture of 2-acetoxycyclohexanone (3.5 g.; Bergmann and Gierrth, *Annalen*, 1926, **448**, 48), ethyl α -bromoisobutyrate (4.4 g.), iodine (0.05 g.), and dry benzene (85 c.c.), and the whole was brought to the boil, under reflux, with stirring. Reaction set in, and after 10 minutes the remainder of the benzene solution was added dropwise to the stirred mixture. Stirring and refluxing were then continued for 3 hours. The mixture was cooled and added to 10% sulphuric acid and ice, and, after shaking, the benzene layer was separated, washed with 5% sodium hydrogen carbonate solution, dried, and distilled, the fraction b. p. 139–140°/6 mm. being collected. This was again distilled and the ester collected as a colourless viscous liquid (4.6 g.), b. p. 127–130°/3–4 mm. (Found: C, 62.4; H, 8.9. $\text{C}_{14}\text{H}_{24}\text{O}_5$ requires C, 61.8; H, 8.8%). The ester (3.55 g.) was hydrolysed by heating under reflux for 3 hours with potassium hydroxide (2.5 g.) and methyl alcohol (50 c.c.). Methyl alcohol was removed, and the residue was dissolved in water, clarified with charcoal, and acidified with 20% sulphuric acid. The solution was then saturated with ammonium sulphate and extracted with ether from which a solid, m. p. 69–73°, was obtained. It was crystallised from ligroin (b. p. 40–60°), and the lactone of 1:2-dihydroxycyclohexyl- α -isobutyric acid (XI) was obtained as colourless needles, m. p. 107–108° (Found: C, 65.6; H, 8.3. $\text{C}_{10}\text{H}_{16}\text{O}_5$ requires C, 65.2; H, 8.7%). Attempted dehydration of the ester (3.2 g.) was carried out by boiling for 3 hours with acetic anhydride (6 g.) and fused sodium acetate (3 g.). On hydrolysis of the product only (XI) was obtained. Again dehydration was attempted by heating the ester (2.0 g.) with pyridine (20 c.c.) and phosphoryl chloride (7 c.c.) at 150–160° for 4 hours. The reaction mixture was then cooled and poured into ice and sulphuric acid and the mixture was exhaustively extracted with ether. From the extract a small quantity of oil, b. p. 100–130°/3 mm., was obtained, from which by hydrolysis (XI) was produced. The lactone (XI; 0.5 g.) was heated on the water-bath with 30% sulphuric acid in 50% alcohol (10 c.c.) for 3½ hours. The product was an oil which was immediately saponified with 10% sodium hydroxide and the small amount of acidic product was extracted with ether. It yielded a 2:4-dinitrophenylhydrazone which had m. p. 250°, undepressed by that of authentic 2-ketocyclohexyl- α -isobutyric acid prepared as described below (c).

(b) From 2-carbethoxycyclohexanone. 2-Carbethoxycyclohexanone (13 g.) was added dropwise to sodium ethoxide from sodium (1.76 g.) and alcohol (48 c.c.). The solid sodio-derivative was cooled and with stirring ethyl α -bromoisobutyrate (15 g.) was slowly added and the mixture was refluxed for 24 hours. Alcohol was then removed and the residue was diluted with water and extracted with ether, from which by distillation a fraction, b. p. 155–180°/2–3 mm., was obtained. On redistillation a fraction (5.3 g.) was collected at 170–178°/2–3 mm. This fraction was refluxed for 3 hours with a solution of potassium hydroxide (4 g.) in methyl alcohol (50 c.c.), methyl alcohol was distilled off, and the residue, after acidification was saturated with ammonium sulphate and extracted many times with ether. From this extract pimelic acid, m. p. 103–104° (Found: C, 52.5; H, 7.5; equiv., 73.2. Calc. for $\text{C}_8\text{H}_{12}\text{O}_4$: C, 52.5; H, 7.5%; equiv., 80), and another solid product were isolated. The latter consisted of hygroscopic needles. It was strongly acid but gave no carbonyl reactions. It was not investigated further.

(c) From 1-hydroxycyclohexyl- α -isobutyric acid. This compound was previously prepared by Wallach and Mallinson (*loc. cit.*) but experimental details were scanty. We adopted the following procedure. Clean and bright zinc wool (32 g.) was added in five equal portions to a stirred boiling mixture of cyclohexanone (40 g.), ethyl α -bromoisobutyrate (80 g.), iodine (0.05 g.), and benzene (150 c.c.). The mixture was heated with stirring for 3 hours, then cooled, poured on crushed ice, and shaken with 20% sulphuric acid (300 c.c.). The benzene layer was removed and the aqueous layer was further extracted with benzene and the combined benzene extracts were dried. The extract was distilled and the fraction, b. p. 134–136°/10–12 mm. (32 g.), collected. This consisted of ethyl 1-hydroxycyclohexyl- α -isobutyrate. The above ester (30 g.) was heated for 2½ hours at 150–160° with freshly fused potassium hydrogen sulphate (60 g.). The mixture was cooled and the paste extracted several times with ether. The ether extract was distilled and the fraction (13 g.), b. p. 130–136°/10–12 mm., collected. This was substantially ethyl cyclohex-1-enyl- α -isobutyrate. An earlier fraction (13 g.), b. p. 120–130°/10–12 mm., was the unhydrated ester. A mixture of the unsaturated ester (13 g.), potassium hydroxide (7.2 g.), and methyl alcohol (120 c.c.) was refluxed for 3 hours. The methyl alcohol was distilled off and the residue diluted with water and extracted with ether. The aqueous layer was then clarified with charcoal, acidified, and extracted with ether from which by distillation cyclohex-1-enyl- α -isobutyric acid (4.5 g.) was obtained as a viscous liquid, b. p. 154–160°/10–12 mm. It solidified on being kept, and crystallised from dilute alcohol as long colourless needles, m. p. 71–72° (v. Braun and Münch, *Annalen*, 1928, **465**, 52, give m. p. 69–71°). The acid (0.1 g.) in 10% sodium carbonate (20 c.c.) was treated at room temperature with saturated bromine water in excess. The opalescent liquid was then extracted with ether from which an oil was obtained which slowly solidified. It was purified by sublimation in a vacuum and the bromo-lactone was obtained as long prisms, m. p. 59–60° (Found: C, 49.2; H, 6.3. $\text{C}_{10}\text{H}_{16}\text{O}_5\text{Br}$ requires C, 48.6; H, 6.1%). This lactone had a strong camphoraceous odour; it was insoluble in cold sodium hydroxide but on being warmed with this reagent it rapidly decomposed giving a solution containing sodium bromide.

The above unsaturated acid (13.5 g.) was stirred and gently refluxed with 50% sulphuric acid (135 g.) for 6 hours. The dark gum which was produced on dilution with water was extracted with ether, and the extract was washed with 5% sodium carbonate and dried. On distillation two fractions were obtained: (i) b. p. 50°/10–12 mm. (4 g.), and (ii) b. p. 136–140°/10–12 mm. (4.3 g.). Fraction (i) was distilled at atmospheric pressure and collected at 155–157°. It was undoubtedly 1-isopropylcyclohexene (Found: C, 86.6; H, 12.3. Calc. for C_9H_{16} : C, 87.1; H, 12.9%). It gave a nitrosochloride which crystallised from benzene-ligroin as needles, m. p. 143–144°. Wallach and Mallinson (*loc. cit.*) give m. p. 129–130° (Found: C, 57.3; H, 8.4. Calc. for $\text{C}_9\text{H}_{16}\text{ONCl}$: C, 56.9; H, 8.4%). Fraction (ii) was the lactone of 2-hydroxycyclohexyl- α -isobutyric acid; it solidified on standing and had m. p. 48°. It was considered to be sufficiently pure for the further stages of the synthesis. The lactone (4.3 g.) was hydrolysed by boiling with sodium hydroxide (2 g.) in water (20 c.c.) for 30 minutes. The clear solution

was treated with a boiling solution of magnesium sulphate (6 g. of the heptahydrate) in water (40 c.c.). It was cooled, shaken thoroughly, and treated dropwise at 0° with bromine (5 g.). The mixture was then shaken for 24 hours, further portions of sodium hydroxide being added at intervals to ensure very slight alkalinity to phenolphthalein. The mixture was acidified and exhaustively extracted with ether, from which, after drying, a dark red solid was obtained. This was dissolved in a slight excess of sodium carbonate solution, boiled with charcoal, and filtered, and the hot solution was acidified with concentrated hydrochloric acid. The buff-coloured acid (2.7 g.) had m. p. 149–150° and was considered sufficiently pure for further work. A portion recrystallised from water (charcoal) was deposited as colourless prisms, m. p. 151–152°. This was undoubtedly 2-ketocyclohexyl- α -isobutyric acid (Found: C, 64.6; H, 8.6. $C_{10}H_{16}O_3$ requires C, 65.2; H, 8.6%). Its 2:4-dinitrophenylhydrazone crystallised from alcohol as yellow needles, m. p. 255–256° (decomp.) (Found: C, 52.3; H, 6.0. $C_{18}H_{20}O_8N_4$ requires C, 52.7; H, 5.5%). The above keto-acid (2.7 g.) dissolved in acetic anhydride (15 g.) was heated under reflux for 2 hours. The acetic anhydride was then removed under reduced pressure and the residue was extracted with ether. The extract was washed with sodium carbonate, dried, and distilled, and 2-hydroxycyclohex-1-enyl- α -isobutyrolactone (1.8 g.) was collected at 119–120°/10–11 mm. (Found: C, 71.5; H, 8.3. $C_{10}H_{14}O_3$ requires C, 72.3; H, 8.4%). On alkaline hydrolysis the keto-acid was regenerated.

Hydrogenation of the Lactone (VI; $R_1 = R_2 = Me$).—When the lactone (0.1996 g.) in glacial acetic acid (10 c.c.) mixed with palladised charcoal (0.2 g.) was submitted to hydrogenation at 16°/755 mm. no hydrogen was absorbed, but in a second experiment when lactone (0.1514 g.) in acetic acid (10 c.c.) mixed with Adams's platonic oxide catalyst (50 mg.) was reduced at 18°/758 mm., 7–8 c.c. of hydrogen were absorbed in 3 minutes and two molecules (43 c.c.) in 15 minutes. The acetic acid was then removed in a vacuum and a solid residue was obtained which was completely soluble in sodium carbonate with effervescence. The alkaline solution was shaken with charcoal, filtered, and acidified to give cyclohexyl- α -isobutyric acid as silvery plates, m. p. 77–78°, raised only to 80° on two crystallisations from dilute alcohol. This compound was identical with that obtained when cyclohex-1-enyl- α -isobutyric acid (0.2 g.) was hydrogenated in glacial acetic acid (15 c.c.) mixed with Adams's catalyst (0.06 g.) at 15°/751.5 mm. The total absorption, which took 15 minutes to complete, was 28.4 c.c., equivalent to 1 mol. of hydrogen per mol. of unsaturated acid. No hydrogenation took place with palladised charcoal as catalyst.

Attempts to Prepare 1-Hydroxy-3:4-dihydronaphthalene-2- α -isobutyrolactone.—The method adopted was the attempted condensation of ethyl α -bromoisobutyrate with ethyl 1-keto-1:2:3:4-tetrahydronaphthalene-2-carboxylate. α -Tetralone was prepared by the ring closure of γ -phenylbutyric acid with a mixture of phosphoric acid and phosphoric oxide (cf. Birch and Robinson, *J.*, 1945, 582); this method was more economical than the usual one involving the ring closure of γ -phenylbutyryl chloride (*Org. Synth.*, Coll. Vol. II, 569). α -Tetralone was converted into ethyl 1-keto-1:2:3:4-tetrahydronaphthalene-2-glyoxylate by a method similar to that employed by Hüchel and Goth (*Ber.*, 1924, 57, 1288), but decomposition of this compound to give the carboxylate was improved as follows. A mixture of the glyoxylate (7.5 g.) and finely powdered glass (7 g.) was heated in an oil-bath maintained at 190–195° for 2 hours. On cooling, the paste was extracted several times with ether from which the required ester (6 g.) was obtained as a colourless liquid, b. p. 153–155°/2 mm. (Found: C, 71.9; H, 6.5. Calc. for $C_{18}H_{14}O_3$: C, 71.6; H, 6.4%). The keto-ester (11.3 g.) was slowly added to a suspension of finely powdered potassium (2.1 g.) in xylene (50 c.c.) and the mixture was stirred and refluxed until all the potassium had dissolved. The bromo-ester (10.1 g.) was slowly added and the stirred mixture was heated under reflux for 24 hours. It was then cooled and poured into water, and the xylene layer separated and distilled. Five fractions were obtained, namely: (i) 60–70°/3 mm., (ii) 105–145°/3 mm., (iii) 155–160°/3 mm., (iv) 170–175°/3 mm., and (v) 180–185°/3 mm. Of these (i) was unchanged bromo-ester and (iii) was almost pure keto-ester. Fractions (iv) and (v) were separately hydrolysed for 5 hours with 8% methyl alcoholic potassium hydroxide, and from each a very small quantity of solid was obtained which by several crystallisations from dilute alcohol, was obtained as needles, m. p. 191–192° (Found: C, 69.5; H, 4.0%). It did not give a precipitate with 2:4-dinitrophenylhydrazine and was recovered unchanged after boiling with acetic anhydride for 2 hours. Its investigation was therefore abandoned.

Experiments with Dihydro- ψ -santonin.—All attempts to reduce dihydro- ψ -santonin in presence of palladised charcoal were unsuccessful, but it can be reduced in presence of Adams's catalyst (cf. Clemons and Cocker, *loc. cit.*).

Bromination. Dihydro- ψ -santonin (0.2 g.) in water (10 c.c.) containing sodium carbonate (0.5 g.) was slowly treated, with stirring, with bromine water (0.12 c.c. of bromine in 15 c.c. of water). On the addition of the first drop of bromine water a white precipitate was formed, and this was ultimately collected. It was washed with 10% sodium carbonate, then with water, and dried. On crystallisation from dilute alcohol the bromo-lactone was deposited as colourless prisms, m. p. 180° (decomp.) (Found: C, 52.6; H, 6.15; Br, 22.6. $C_{18}H_{21}O_4Br$ requires C, 52.2; H, 6.1; Br, 23.2%). This compound was readily decomposed on boiling with water yielding a solution containing hydrobromic acid.

Reduction of the bromo-lactone. Bromo-lactone (0.3 g.) in alcohol (5 c.c.) was refluxed with zinc dust (1.0 g.) for 4 hours. The hot mixture was filtered and the filtrate was evaporated to dryness. An oily residue was left and this was rubbed with 10% hydrochloric acid to remove zinc; a solid was thus obtained which, after being washed, was recrystallised from dilute alcohol; it separated as needles (0.2 g.), m. p. 187–188° undepressed with authentic dihydro- ψ -santonin. This compound was again obtained when the bromo-lactone was heated on the water-bath with zinc dust and acetic acid for 3 hours.

One of us (S. H.) desires to thank the Council of King's College for a Post-Graduate Scholarship. We also desire to thank Messrs. T. and H. Smith for a gift of ψ -santonin.

217. *The Kinetics of Aromatic Halogen Substitution. Part III. Iodination by Iodine Chloride.*

By L. J. LAMBOURNE and P. W. ROBERTSON.

Iodination by iodine chloride of, *e.g.*, acetanilide and anisole, like the corresponding brominations by bromine, shows third-order kinetics in acetic acid solution. When there is steric hindrance to the entry of the iodine atom into the benzene ring, as in pentamethylbenzene and *p*-tolyl methyl ether, there is concomitant iodine chloride-catalysed chlorination, and this has an inducing effect on the iodination. In chlorobenzene solution this side reaction becomes more prominent, occurring with a compound like anisole, for which steric hindrance is not to be expected.

THE use of iodine chloride as an iodinating agent has long been known, but its applicability is limited. Chattaway and Constable (*J.*, 1914, 105, 124) showed that in acetic acid solution, a 90% yield of the *p*-iodo-derivative is obtained from acetanilide. In iodination with iodine chloride the liberated hydrogen chloride combines with the reagent to form HICl_2 , with the result that the rate falls off rapidly during the course of the reaction, just as in the corresponding brominations owing to HBr_3 formation. This complicates the kinetic interpretation, necessitating measurements of the initial rates for the evaluation of the reaction order. The general conditions of such measurements have been discussed in Part I of this series (*J.*, 1943, 276). The following results were obtained for acetanilide, times (mins.) being shown for 10% iodine chloride absorption in acetic acid.

Temp.	M/20.		M/40.
24°	160	($n = 3.3$)	780
50	36	($n = 2.6$)	105

The order is approximately 3 at 24° and is less at 50°, an effect similar to that found in the bromination of this compound, for which orders, $n = 3.0$ (24°) and $n = 2.5$ (50°), were obtained at the same concentrations.

The iodination of anisole in acetic acid is accompanied by a certain amount of simultaneous chlorination. Equimolecular amounts of reactants, M/20, at 24°, ceased to react at 78% halogen absorption owing to the formation of HICl_2 . To such a solution a slight excess of anisole was added, and dry nitrogen passed through for 15 minutes. This procedure removed hydrogen chloride, but no chlorine, permitting a further gradual 8% halogen absorption, after which only iodine was left. The ratio of iodination to chlorination is therefore approximately 5 : 1, and on adding water to the solution, *p*-iodoanisole, m. p. 50–52°, was precipitated. The contribution of this concurrent chlorination is not sufficient seriously to affect the order of the iodination reaction, and the times, in acetic acid at 24°, indicate third-order kinetics :

	M/20.		M/40.		M/80.
Time ($x = 20$) at 24°	11.8	($n = 3.0$)	46.5	($n = 3.1$)	216
Time ($x = 20$) at 40°	4.8	($n = 3.0$)	19.0	($n = 3.0$)	77

Experiments with anisole in relative excess revealed that the reaction was unimolecular with reference to anisole and bimolecular with reference to iodine chloride.

Pentamethylbenzene, which was found to undergo bromination in acetic acid at a rapid rate approximately the same as that for anisole, reacts moderately rapidly with iodine chloride. With this compound a steric effect is to be expected, as the approach of the large iodine atom is hindered by the *ortho*-methyl groups. This reveals itself in the sense that the alternative chlorine substitution makes a greater contribution than in the reaction with anisole, where there is no steric hindrance. In M/20-solution in acetic acid at 24° there is 80% halogen absorption, corresponding with the relative contributions, iodination : chlorination = 3 : 1. Rate measurements show predominantly third-order kinetics in the experimental concentration range :

	M/40.		M/80.
Time ($x = 10$)	26	($n = 2.9$)	95

In *p*-tolyl methyl ether steric hindrance to the entry of the large iodine atom into the *o*-substitution is also to be expected, and with M/20-reactants in acetic acid at 24° the iodine chloride substitution stops at ~67% halogen absorption, corresponding with equal contributions of iodination and chlorination; disturbed third-order kinetics are observed :

	M/20.		M/40.		M/80.
Time ($x = 20$)	86	($n = 3.3$)	420	($n = 2.7$)	1390

A summary of these iodine chloride reactions is now given :

	Acetanilide.	Anisole.	Pentamethylbenzene.	<i>p</i> -Tolyl methyl ether.
Concurrent chlorination ...	10%	20%	30%	50%
Relative rates, Br ₂ /ICl	950 : 1	350 : 1	150 : 1	70 : 1

Instead of the total rate of halogenation with iodine chloride becoming less (as compared with bromination) when there is steric hindrance, the reverse effect is observed. The alternative chlorine substitution, which is catalysed by iodine chloride, apparently exerts an inducing effect on the iodination by this reagent, and this becomes more considerable as the relative contribution of the chlorination increases. Other examples of induction in halogenation reactions have been reported (cf. *J.*, 1945, 509). On changing to chlorobenzene as solvent, the tendency for iodine chloride halogenation to proceed by the chlorination route becomes more pronounced, even when there is no steric hindrance; e.g., for anisole the contribution of the chlorination is 50%. Correspondingly, there is an increase in the velocity of the reaction, the relative rates, Br₂ to ICl, for anisole in chlorobenzene being 5 : 1 (in acetic acid solution the ratio is 350 : 1). This concurrent halogenation observed with iodine chloride should be still more pronounced with iodine bromide, as this compound is more dissociated than the chloride. According to Militzer (*J. Amer. Chem. Soc.*, 1938, 60, 256), phenol in carbon tetrachloride solution is exclusively brominated by iodine bromide. It is not, however, necessary to assume that this reaction proceeds according to the scheme $\text{XH} + \text{IBr} \longrightarrow \text{XBr} + \text{HI}$; $\text{HI} + \text{IBr} \longrightarrow \text{I}_2 + \text{HBr}$, for a mechanism involving iodine bromide-catalysed bromination will explain the experimental result.

The iodination of aromatic compounds by iodine chloride is analogous, not only to bromine substitution, but also to iodine chloride and bromine addition to unsaturated compounds. In acetic acid solution in the concentration region *M*/40, all four reactions show third-order kinetics, the order being reduced on rise in temperature owing to the incursion of a bimolecular reaction. It is concluded that the reaction mechanisms are similar (cf. *J.*, 1943, 279), taking place for iodination according to the scheme :

and for third-order kinetics

$$d[\text{XI}]/dt = (k_1 k_3 / k_2) [\text{XH}] [\text{ICl}]^2.$$

EXPERIMENTAL.

The compounds used were: anisole, b. p. 154.5°/760 mm.; *p*-tolyl methyl ether, b. p. 179°/760 mm.; acetanilide, m. p. 113.5°; pentamethylbenzene, m. p. 53.5°. The general technique was as previously described, the reactions being carried out with darkened bottles in a room with dim illumination. At 24° the iodine chloride solutions in acetic acid were found to be stable during the time of a reaction, but at higher temperatures there was a slight decrease in titre, necessitating a small correction. Herewith a typical set of measurements :

10 ml. anisole, *M*/40 + ICl, *M*/40; HOAc, 50°; 1 ml. samples titrated with KI and 0.01*N*-Na₂S₂O₃.

Time (mins.)	0	10	15	20	30	50
Titre (ml.)	4.98	4.62	4.46	4.25	3.98	3.62
Zero titre (ml.)	—	4.98	4.97	4.97	4.96	4.95

From the curve, *x* = 10, *t* = 15; second expt., *x* = 10, *t* = 14.

Experiments to determine relative contributions of anisole and iodine chloride in acetic acid at 24°; times (mins.), *x* = 10: A, *M* + ICl, *M*/20, *t* = 0.60; A, *M*/2 + ICl, *M*/40, *t* = 3.0; A, *M*/4 + ICl, *M*/40, *t* = 3.5; A, *M*/4 + ICl, *M*/80, *t* = 8.0: these gave *n* (anisole) 1.2, *n* (ICl) 2.2. The remaining measurements have been quoted in the text.

VICTORIA UNIVERSITY COLLEGE, WELLINGTON, N.Z.

[Received, November 21st, 1946.]

218. The Kinetics of Halogen Addition to Unsaturated Compounds. Part XII. Iodine Catalysis of Chlorine and Bromine Addition to Ethyl Cinnamate.

By H. D. C. WATERS, A. R. CAVERHILL, and P. W. ROBERTSON.

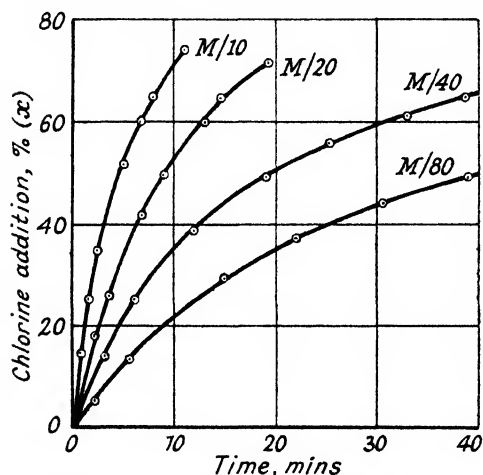

Iodine-catalysed addition of chlorine to ethyl cinnamate in carbon tetrachloride solution proceeds according to the expression $-d[\text{Cl}_2]/dt = k[\text{A}][\text{Cl}_2][\text{ICl}]$, and in the corresponding bromine reaction, $-d[\text{Br}_2]/dt = k[\text{A}][\text{Br}_2][\text{IBr}]$. At higher concentrations of added iodine,

the order for the chloride and the bromide becomes greater than unity. In the polar solvents chloroform and *o*-dichlorobenzene, the overall rate is one order less than in carbon tetrachloride, as for uncatalysed bromine addition. A general theory is proposed to explain the phenomenon of *trans*-halogen addition with inversion.

THE influence of iodine as a catalyst for bromine addition has long been recognised (Hertz and Mylius, *Ber.*, 1906, **39**, 3816; Bruner and Fischler, *A.*, 1914, ii, 260), but such rate measurements as have been made are insufficient to establish the kinetics of the reaction. Although iodine is known to catalyse chlorine addition to unsaturated compounds, there appears to be no record of any kinetic investigation of such reactions. However, Slator (*J.*, 1903, **83**, 729) has studied the kinetics of the reaction, $C_6H_6 + Cl_2$, in benzene as a solvent or diluted with carbon tetrachloride, with added iodine. The reaction proceeds with 70% substitution and 30% chlorine addition at a rate given by the expression, $-d[Cl_2]/dt = k[A][Cl_2][ICl]^2$, but the reaction was examined over only a limited iodine chloride concentration range.

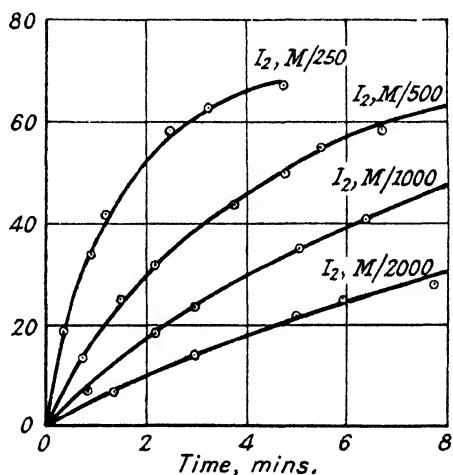

Just as the chlorination of benzene does not proceed in the absence of iodine, chlorine adds to ethyl cinnamate in dry carbon tetrachloride at a rate too slow to be measured, but with a small amount of added iodine the change goes rapidly to completion. At the end of the reaction the original amount of iodine is left, as is indicated by tintometric observation or titration of the

FIG. 1.

Ethyl cinnamate-chlorine, with I_2 , $M/1000$.

FIG. 2.

Ethyl cinnamate-chlorine, both $M/20$, with I_2 .

residual iodine. The kinetics of the reaction can be conveniently studied by rate determinations (a) with reactants, $A + Cl_2$, constant, and different amounts of iodine, or (b) with iodine constant and varying initial concentrations of $A + Cl_2$. The results of these experiments are shown in Figs. 1 and 2, the measurements being made in dry carbon tetrachloride under nitrogen at 24° .

The average orders, $\alpha = 10$ to $\alpha = 50$, for $A + Cl_2$ (Fig. 1) are: $M/10$ — $M/20$, $n = 2.0$; $M/20$ — $M/40$, $n = 2.0$; $M/40$ — $M/80$, $n = 2.0$. The reaction is thus bimolecular with respect to $A + Cl_2$, and the constancy of the bimolecular coefficients during the separate runs indicates the absence of autocatalytic disturbances. This is shown by a typical measurement, in carbon tetrachloride at 24° :

α	10	20	30	40	50
k_2 (reactants $M/20$, I_2 $M/1000$)	2.1	2.1	2.1	2.2	2.2

The average values of t_1/t_2 with different amounts of added iodine (Fig. 2) are: $M/2000$ — $M/1000$, 2.0; $M/1000$ — $M/500$, 2.0; $M/500$ — $M/250$, 2.4. On further addition of iodine the initial rates become too rapid for accurate measurements, but reach a maximum when the iodine chloride concentration is approximately equal to that of the chlorine, and then diminish.

The iodine is present almost entirely as chloride, and when its amount is small it does not appreciably alter the chlorine concentration, so these measurements are in accord with the rate expression

$$-d[Cl_2]/dt = k[A][Cl_2][ICl]$$

The increase in order with respect to iodine, when its amount becomes more considerable, will be discussed later.

The reaction between ethyl cinnamate and bromine in carbon tetrachloride (in nitrogen at 24°) was found to be not accurately reproducible under the conditions of the experiments, a result possibly due to the sensitiveness of this reaction to oxygen (cf. Bauer and Daniels, *J. Amer. Chem. Soc.*, 1934, 56, 378). Added iodine caused a very considerable acceleration of the rate, and the measurements, now found to be reproducible, were made by varying separately $A + Br_2$, and I_2 (Figs. 3 and 4).

The difference in appearance between Figs. 1 and 3 is due to the fact that bromination is a higher-order reaction than chlorination. The average orders, $x = 20$ to $x = 50$, for $A + Br_2$, are: $M/5-M/10$, $n = 2.9$; $M/10-M/20$, $n = 2.9$; $M/20-M/40$, $n = 3.0$. Special experiments,

FIG. 3.

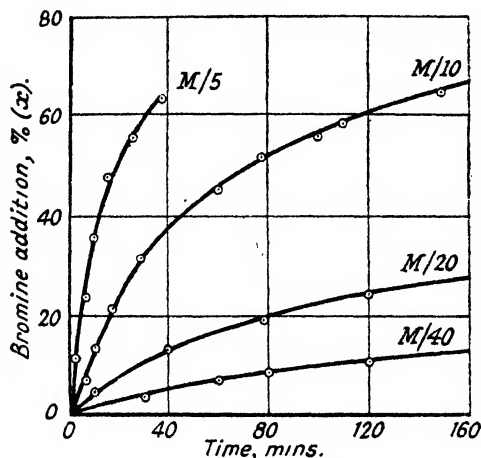

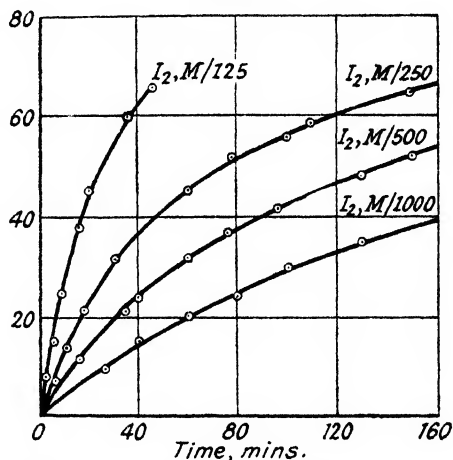

Ethyl cinnamate-bromine, with I_2 , $M/250$.

FIG. 4.

Ethyl cinnamate-bromine, both $M/10$, with I_2 .

A being varied and Br_2 kept constant, showed that the reaction was first order for A and second order for Br_2 . Correspondingly, the bimolecular coefficients fall as the reaction proceeds:

x	10	20	30	40	50	60
k_2 (reactants $M/10$, I_2 $M/500$)	0.16	0.155	0.15	0.145	0.135	0.125

The effect of varying the amount of added iodine is shown in Fig. 4, the average t_1/t_2 ratios being: $M/1000-M/500$, 1.9; $M/500-M/250$, 1.95; $M/250-M/125$, 2.7. As for the iodine-catalysed additions of chlorine, the order with respect to iodine is constant for low concentrations of added iodine, and subsequently increases. Iodine with bromine in carbon tetrachloride solution is almost entirely present as IBr , so these results correspond, for small amounts of iodine bromide, with the rate expression

$$-d[Br_2]/dt = k[A][Br_2]^2[IBr]$$

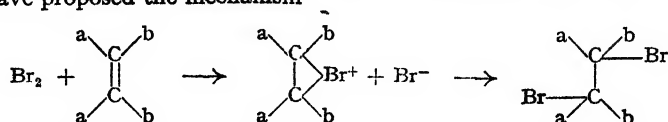

In polar aprotic solvents such as chloroform and *o*-dichlorobenzene, addition of bromine shows third-order kinetics (*J.*, 1945, 509). Added iodine in these solvents causes a relatively smaller catalysis than in carbon tetrachloride, and for small amounts of iodine the rate is given by the expression

$$-d[Br_2]/dt = k[A][Br_2][IBr]$$

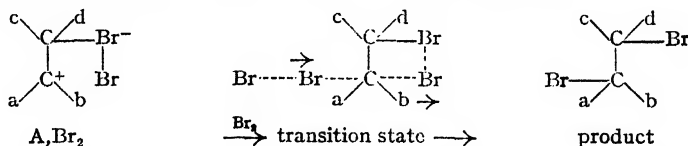

The iodine-catalysed addition of bromine to allyl benzoate in carbon tetrachloride has also been examined, with reactants $M/10$ and $M/20$, and iodine $M/500$ and $M/1000$. The average orders obtained were $A + Br_2$, $n = 2.8$; IBr , $n = 1.3$, so for this compound also the catalysed reaction can be regarded as a fourth-order reaction with one or more molecules of bromine replaced by iodine bromide. With greater amounts of added catalyst, the order for iodine bromide increases, but the reaction becomes too rapid for accurate measurement.

The addition of halogen to ethylenic compounds is a two-stage process, and to explain the

trans-addition with inversion that takes place, Roberts and Kimball (*J. Amer. Chem. Soc.*, 1937, 59, 947) have proposed the mechanism

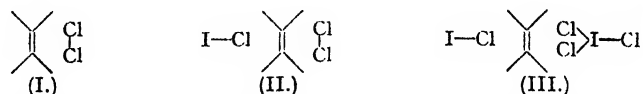

The discovery that addition of bromine may take place by a termolecular mechanism (*J.*, 1937, 335) was not inconsistent with this mode of formulation, as the result could be explained by the reaction proceeding: $A + Br_2 \longrightarrow A, Br_2 \xrightarrow{Br_2} ABr^+ + Br_3^- \longrightarrow ABrBr + Br_2$ (*J.*, 1943, 276). There are, however, certain formalistic difficulties in connection with Roberts and Kimball's theory. The Br^- released in the first stage must move to the reverse side of the positive ion to complete the process, and the model of the transition state reveals a condition of considerable strain. An alternative mechanism is now proposed, according to which the initial addition compound forms a four-atom ring (in which the strain is less than in a three-atom ring) and the change is completed by a second molecule of bromine:

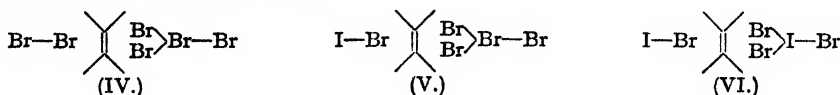

The formation of A, Br_2 is due to the electrophilic attack by Br_2 on A , and A, Br_2 is represented by one of its possible resonance structures. The dotted lines in the diagram of the transition state indicate bond lengths intermediate between covalent and ionic bonds, as suggested by Dostrovsky, Hughes, and Ingold (*J.*, 1946, 173), and the arrows show the direction of the movement of the bromine atoms. The model thus constructed fulfils the requisite conditions for minimum strain, the bonds $C-C$, $C-a$, and $C-b$ all being in one plane, and the direction $Br-C-Br$ at right angles to this plane. The criticism may be made, however, that with such a mechanism there should be a possibility of *cis*-addition also, and in fact this is actually found, more extensively indeed than suggested in general in writings on this subject. For instance, Liebermann and Finkenbeiner (*Ber.*, 1895, 27, 2235) have shown that addition of chlorine to cinnamic acid in the dark in carbon tetrachloride takes place almost entirely by the *cis*-mechanism, whereas in the light the high m. p. isomer formed by *trans*-addition is obtained. No reference was made to the drying of the solvent, so the reaction appears to have been catalysed by water. In the corresponding addition of bromine to cinnamic acid in the same solvent, in the dark there is 37% *cis*-addition, which becomes reduced to 13% when the reaction takes place in light (Michael, *Ber.*, 1901, 34, 3663). When steric hindrance to addition becomes considerable, e.g., in *o*-nitrostilbene, addition of bromine may take place preferentially by the *cis*-mechanism (Peiffer, *Ber.*, 1915, 48, 1051).

With a small amount of added iodine we find that addition of chlorine to cinnamic acid, in the dark, takes place with the formation chiefly of the *trans*-addition product. These observations suggest the following modes of reaction mechanism for addition of chlorine to ethyl cinnamate: (I), no iodine, *cis*; (II), a small amount of iodine, *trans*; (III), a larger amount of iodine, *trans*, the iodine trichloride being represented by one of its possible resonance structures.

With the higher-order addition of bromine to ethyl cinnamate the process becomes more complicated, one or two molecules of bromine being replaced in the catalysed reactions by iodine bromide. This is illustrated by the following representations: (IV), fourth-order addition of bromine; (V), the same reaction catalysed by a small amount of iodine; and (VI), catalysed by a larger amount of iodine.

It was proposed (de la Mare, Scott, and Robertson, *J.*, 1945, 509) that the high-order bromine additions in the non-polar solvent carbon tetrachloride might be explained by a chain mechanism involving activated molecules, and it was considered that the iodine-catalysed reactions might have diagnostic value. Actually, it is difficult to devise a suitable chain mechanism involving iodine bromide molecules, and the kind of formulation suggested in the present communication appears on the whole a more likely mode of representation than a chain reaction for catalysed as well as uncatalysed bromine addition.

EXPERIMENTAL.

The materials and method were as previously described (*J.*, 1945, 511) except that chloramine-r was used instead of iodine in the back titration. Herewith the details of one of the measurements:

Ethyl cinnamate, $m/20 + Cl_2$, $m/20 + I_2$, $m/500$ in CCl_4 , at 24° .

Time (mins.)	0.88	1.80	2.73	4.80	9.80	12.20

219. Potassium Fluoaluminates.

By F. A. PAINE and J. PEARSON.

The chemical composition of potassium cryolite, the synthetic analogue of the naturally-occurring (sodium) cryolite, does not correspond to the theoretical K_3AlF_6 , and certain manufactured batches have been found to be abnormally acid. Preliminary experiments had indicated that the salt was not stable in water; it was therefore desirable that the chemistry of the double fluorides of potassium and aluminium should be studied more fully, and the effect of water on potassium cryolite elucidated. Under normal conditions of manufacture, from aluminium and potassium fluorides or potassium hydroxide and "hexafluoaluminic acid" in aqueous solution, it is impossible to prepare a stable material corresponding to the true potassium hexafluoaluminate. A well-defined pentafluoaluminate, K_5AlF_6 , has been shown to exist, and evidence has been obtained for the existence also of a tetrafluoaluminate, $KAlF_4$. When it is expected that the hexafluoaluminate would be formed, there usually results a material in which the molecular ratio of potassium fluoride to aluminium fluoride is slightly less than 3 : 1. This is in agreement with some recently published work. The effect of water upon potassium cryolite has been shown to be, first, dissociation of the double salt into potassium fluoride and potassium pentafluoaluminate, followed by solution of the latter if the concentration of potassium fluoride in the aqueous phase is less than 0.15%. The concentration of potassium fluoride necessary to inhibit dissociation of potassium cryolite is of the order of 0.55%. The high acidities associated with some batches are to be attributed to the presence of an acid salt and not to hydrolytic effects.

DURING the examination of commercially prepared samples of potassium cryolite, nominally K_3AlF_6 , it was found that the potassium contents were much lower, and the aluminium contents much higher, than those calculated. In view of this discrepancy, a review was made of the possible methods of analysing such a substance, and many of them were tried with a view to ascertain whether the unexpected values were the result of unsuitable procedures. Since considerable significance has been attached to the results finally obtained, this review is given in an appendix. Table I gives the results of the examination of typical batches, in which allowance has been made for moisture and traces of sodium present, in comparison with the

TABLE I.

Sample	1.	2.	3.	4.	5.	6.	Calc., %.
Potassium	43.5	43.6	44.0	44.2	44.5	44.3	45.4
Aluminium	11.1	11.3	11.3	11.3	11.4	11.1	10.5
Fluorine	45.4	45.1	44.7	44.5	44.1	44.6	44.1

expected proportions. From the figures it will be seen that the molecular ratio of potassium fluoride to aluminium fluoride is less than the 3 : 1 expected.

A review of the literature (Mellor, "Inorganic and Theoretical Chemistry", Vol. V, pp. 306, 307; Gmelin, "Handbuch der Anorganische Chemie", Vol. 35, p. 450) shows that until recently potassium penta- and hexa-fluoaluminates have been regarded as stable compounds,

slightly soluble in water, containing potassium and aluminium fluorides in the molecular ratios 2 : 1 and 3 : 1, respectively. Apart from the relative proportions of water of crystallisation present in the salts, there had been no suggestion that any differences existed between the fluoaluminates prepared by melting together the components and those obtained by precipitation from aqueous solutions. During the course of the present investigation, a paper appeared (Brosset, *Chem. Abs.*, 1943, 37, 13), demonstrating from crystallographic studies that while potassium penta-fluoaluminate is first formed on adding potassium fluoride to solutions containing aluminium and fluoride ions, the compound produced in the presence of excess of potassium fluoride is not K_3AlF_6 but $K_{3-x}AlF_{6-x} \cdot xH_2O$, *i.e.*, potassium cryolite in which part of the potassium fluoride in the crystal lattice has been replaced by water. Brosset (*loc. cit.*) states that the only stable compounds obtainable by mixing aqueous solutions are K_3AlF_6 and $K_{2.8}AlF_{5.8}$.

EXPERIMENTAL.

In order to test the truth of Brosset's statement, potassium aluminium fluorides were prepared under carefully controlled conditions, and the resulting materials analysed by the methods detailed in the appendix. As a confirmation, conductometric titrations of aluminium fluoride with potassium fluoride in aqueous solution were conducted in the hope that these would reveal the existence of definite compound formation. These experiments are described below. Although the majority of samples of commercial potassium cryolite examined were essentially neutral in reaction, some were found to be abnormally acid, in that their suspensions in water required considerable additions (up to 60 mg. of potassium hydroxide per g. of solid) to render them neutral. The cause of this acidity has also been investigated. It had been anticipated, by analogy with sodium cryolite, that the solubility of potassium cryolite would be very low; reference may be found (Mellor, *op. cit.*) to figures quoted as solubilities of potassium cryolite, and as nothing is said to the contrary, it must be assumed that these refer to what were believed to be true solutions of the cryolite. It was found, however, that in certain circumstances, up to 22% by weight of potassium cryolite could be extracted by water, and qualitative and quantitative tests have indicated that this extractable material is potassium fluoride. In fact, an instance was brought to the authors' notice, in which the high solubility of potassium cryolite was explained on the assumption that the material consisted, not of the double salt, but of a mechanical mixture of the two components, from which water dissolved the more soluble potassium fluoride. In view of the fact that potassium cryolite is normally prepared from aqueous solution, it was decided to investigate fully the action of water on the compound. The results are reported later.

Except in the analytical procedures, it was found necessary to use paraffin-waxed glass or platinum vessels, since many of the reagents employed dissolved glass, etc., to an inconvenient extent.

Preparation of Potassium Fluoaluminates.—(i) *From potassium aluminate and hydrofluoric acid.* Solutions were prepared of potassium aluminate in potassium hydroxide in which the molar ratios of potassium to aluminium were 3 : 1 and 2 : 1. To avoid the presence of other anions, the solutions were made by dissolving weighed amounts of pure aluminium foil in standardised potassium hydroxide. These solutions were titrated with hydrofluoric acid, and the end-points determined potentiometrically with a calomel-antimony electrode combination. As would be expected, the end-points corresponded with the production of K_3AlF_6 and K_2AlF_6 , since the potential of the antimony-antimony oxide electrode was influenced only by the hydrogen-ion concentration of the systems. The precipitated solid phases were filtered off, washed with the minimum of cold water, dried, and analysed. The constitutions corresponded to the empirical formulae $K_{2.9}AlF_{5.9}$ and $K_{1.9}AlF_{4.9}$, respectively. This indicates that although K_3AlF_6 and K_2AlF_6 may have been formed initially, the hexafluoaluminate after brief washing had lost potassium fluoride, whilst the pentafluoaluminate had absorbed, from the finally acid solution, some hydrofluoric acid which had not been removed by washing and drying.

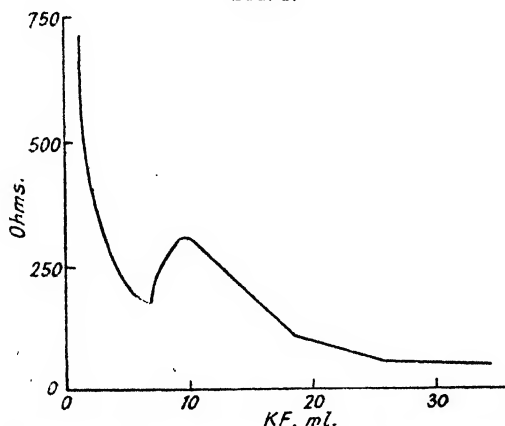

A solution of potassium aluminate (K : Al = 3 : 1) was neutralised with hydrofluoric acid, the potential of the antimony electrode then having a value corresponding to the middle of the potential-volume curve found in the first titration. This potential corresponded very closely with the change-point of methyl-red indicator. Similarly, hydrofluoric acid was neutralised with potassium aluminate. Finally, the aluminate was slightly over-neutralised with the acid. The solid phases produced in each case were filtered off, washed briefly, and dried. 1 G. of each was stirred with 100 ml. of cold water and titrated with N/20-potassium hydroxide solution, the end-points being determined potentiometrically. The acidities of the samples were found to correspond to 0.8, 2.7, and 56.8 mg. of potassium hydroxide per g., respectively. This indicates that in the presence of excess of hydrofluoric acid, potassium cryolite absorbs acid and does not readily part with it. This is probably due to the formation of a small proportion of an acid salt. This acid salt may be considered to be formed by the replacement of part of the potassium fluoride in the crystal lattice by hydrofluoric acid, in the same manner as Brosset (*loc. cit.*) has suggested for the replacement of potassium fluoride by water. The acidities observed in some commercial batches of potassium cryolite are thus to be ascribed to the presence of an acid salt, produced by the addition of slight excess of hydrofluoric acid, and not to hydrolysis. It has been found that a solution of aluminium fluoride in water is not acid.

(ii) *From potassium hydroxide and "hexafluoaluminic acid".* Addition of potassium hydroxide to "hexafluoaluminic acid" (a solution of aluminium fluoride or hydroxide in hydrofluoric acid in the correct proportions) and *vice versa* produced solids having properties, chemical and physical, identical with those of the products obtained above.

Conductometric Titrations of Potassium Fluoride and Aluminium Fluoride.—A saturated solution of aluminium fluoride in water was titrated with aqueous potassium fluoride and the conductivity of the aqueous phase determined when equilibrium had been established after each addition of titrant. Cell-resistance (*i.e.*, reciprocal of conductivity) was actually measured and plotted against volume of

potassium fluoride. The concentration of potassium fluoride was chosen so that the amount added made no significant change in the total volume. A typical curve obtained in this way is shown in Fig. 1. At the stage corresponding to 7.0 ml., precipitation of solid phase commenced, and the sudden rise in resistance at that point is to be attributed to the deposition of salt and not to the formation of a compound. The breaks at 9.3, 18.65, and 26.05 ml. correspond to the formation of KAlF_4 , K_2AlF_6 , and $\text{K}_{2.8}\text{AlF}_{5.8}$, respectively. This is in agreement with Brosset's work. It is noteworthy that Russian workers have examined synthetic and natural cryolite. Tananaev and Lechak (*Compt. rend. Acad. Sci. U.R.S.S.*, 1943, XLI, 3, 144) report that the ratio $\text{NaF} : \text{AlF}_3$ for Greenland cryolite is in the range 2.7—2.8. They

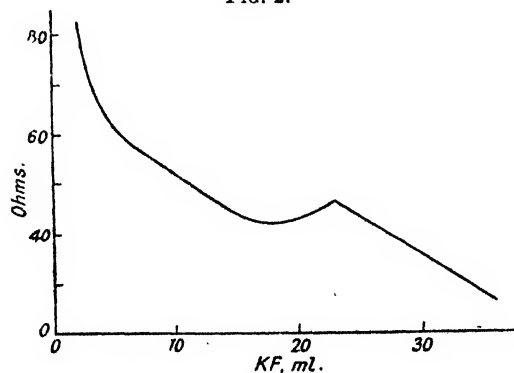

FIG. 1.

Conductometric titration of aluminium fluoride solution with potassium fluoride.

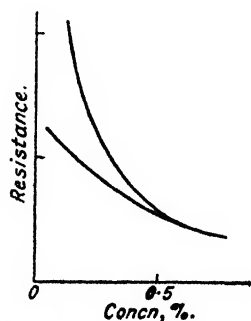

suggest a formula, for the natural and synthetic material, of $11\text{NaF} \cdot 4\text{AlF}_3$, which corresponds to $\text{Na}_{2.75}\text{AlF}_{5.75}$. Yatlow (*J. Gen. Chem. Russia*, 1937, 7, 2439) states that sodium cryolite is formed as a result of a reaction between the tetrafluoroaluminate, yielded initially by solutions of sodium fluoride and aluminium fluoride, and sodium fluoride. As the proportion of sodium fluoride is increased, the ratio of NaF to AlF_3 in the composition of the precipitate increases from 1 to 2.8. Yatlow has demonstrated the existence of sodium tetra- and penta-fluoroaluminates, but states that attempts to synthesise cryolite from aqueous solutions yielded a material of the composition $2.7\text{--}2.8\text{NaF} \cdot \text{AlF}_3$. The analogy with potassium fluoroaluminates is thus complete.

FIG. 2.

Conductometric titration of potash alum solution with potassium fluoride.

FIG. 3.

Conductivity of potassium fluoride solutions as influenced by addition of potassium cryolite.

No evidence was found for the formation of the hexafluoroaluminate when an aqueous solution of potash alum was titrated with potassium fluoride (see Fig. 2), the only significant break in the curve, at 23.2 ml., corresponding to formation of potassium pentafluoroaluminate. After the addition of 18 ml. of potassium fluoride solution, solid commenced to separate; the subsequent rise in resistance is to be attributed to this fact. This observation is not in accord with that of Berzelius (*Pogg. Ann.*, 1824, 1, 43) that potassium cryolite is formed from potash alum in the presence of excess of potassium fluoride. This point requires further examination, but it is of interest that a commercially prepared material, reputed to be potassium cryolite and made from potash alum and potassium fluoride, was found to consist of the hydrated pentafluoroaluminate, $\text{K}_2\text{AlF}_5 \cdot \text{H}_2\text{O}$.

The Effect of Water on Potassium Fluoaluminates.—A suspension of potassium cryolite (5 g. in 87.5 ml. of distilled water) was kept at 35° and stirred continuously, with precautions against loss by evaporation. At hourly intervals portions of the suspension were withdrawn, the solid phase removed, and the solution analysed. In every instance the only compound in solution was potassium fluoride. Its concentration increased gradually with time, until after about 6 hours it had become constant. At this stage there was present in every 10 ml. of solution 0.063 g. of potassium fluoride, *i.e.*, a 0.63% solution of potassium fluoride inhibited further dissociation of the hexafluoroaluminate to pentafluoroaluminate and fluoride.

The conductivities of solutions of potassium fluoride of various concentrations were determined. To fixed volumes of these solutions was added a standard weight of potassium cryolite (two typical commercial materials, $K_{2.7-2.8}AlF_{5.7-5.8}$ were used). The liquid was stirred until no further change in conductivity occurred. The initial and final conductivities (as resistance of a nominal volume of solution) were plotted against the concentration of the original solutions. The curves for the two samples were identical and are shown in Fig. 3. It will be seen that the two branches of the graph merge at a concentration of 0.55 to 0.60%. Since at concentrations below 0.55% the conductivity of a potassium fluoride solution was increased by the addition of potassium cryolite, it follows that dissociation of the cryolite had occurred. At concentrations of 0.60% and above, no alteration in conductivity was observed; no dissociation of the cryolite had taken place. This value for the inhibiting concentration is in good agreement with that found by analysing aqueous extracts; the conductivity measurements were carried out at 20° as against 35° used in the extraction method.

The above-mentioned samples of potassium cryolite and a sample of anhydrous potassium pentafluoroaluminate were used to study further the effect of water. 5 G. of each were suspended in 500 ml. of distilled water and shaken at room temperature until equilibrium was reached. The solid residues were removed and dried. The clear solutions and portions of the solids were analysed. 3 G. of the remaining solids were each suspended in 300 ml. of water and treated as above. The first extraction with water removed from each of the cryolites approximately 22% of potassium fluoride and left a residue with a composition approximating to K_2AlF_6 . The first aqueous extraction of the potassium pentafluoroaluminate removed only 13.3%, and this was found to be of a composition identical with that of the starting material and of the solid residue. The second extraction removed from each sample 13.2% of pentafluoroaluminate, leaving a solid of the same composition. It will thus be seen that the action of water on potassium cryolite is to dissociate and dissolve away potassium fluoride and then to take into solution the pentafluoroaluminate. Experiments conducted with solutions of various concentrations of potassium fluoride showed that the concentration required to prevent the solution of the pentafluoroaluminate is about 0.15%, *i.e.*, slightly less than the 0.22% resulting from the first water-extraction of the cryolite samples.

Appendix.

Analysis of Potassium Fluoaluminates.—(i) *Potassium.* Any method which involves preliminary separation of aluminium with ammonia or ammonium salts, etc., is liable to give low results owing to losses by adsorption on the precipitated alumina, by spitting during evaporation of solutions to dryness, and by decrepitation during heating to expel ammonium salts. Estimation as perchlorate, without separation of aluminium, avoids these losses, and has been found to give results in general higher than those obtained when potassium is estimated as sulphate, a method subject to the above-mentioned disadvantages. Some comparative figures are:

Sample	(a)	(b)	(c)	(d)	(e)	(f)
K, % (determined as K_2SO_4)	42.9	42.5	43.2	43.5	43.5	43.9
K, % (" " $KClO_4$)	43.4	43.8	43.9	43.8	43.5	44.1

(ii) *Aluminium.* Time is saved if aluminium is determined in the solution as used for the potassium estimation. This can be accomplished by precipitation with 8-hydroxyquinoline. Results are identical with those obtained when the aluminium is estimated as alumina; the use of oxine is to be preferred since the aluminium content of the "oxinate" is much smaller than that of alumina, and accidental impurities in the precipitate are of less importance.

(iii) *Fluorine.* Various modifications of the method involving titration with thorium nitrate have been examined. All suffer from the drawback that the end-point of the titration, using sodium alizarinsulphonate as indicator, may be uncertain and difficult to assess, though in the hands of an experienced operator accurate results are obtainable. The estimation as lead chlorofluoride is simpler; the distillation is easy to control, the weight of the sample taken is fairly large, and the estimation may be finished gravimetrically or volumetrically as desired, identical results being obtained by either method. Volumetric estimation was not employed in view of the consumption of silver nitrate. It should be noted that preliminary melting of the material with fusion mixture, as recommended by certain authorities, is not only unnecessary, but leads, in fact, to low results, as shown by the following figures:

F, % with fusion	44.6	44.0	44.3
F, % without fusion	45.2	44.5	44.3

It was found that fusion of potassium cryolite alone at temperatures above 900° leads to loss in weight, and also that sodium fluoride is volatile on heating.

(iv) *Sodium.* When it is desired to determine sodium content, it is necessary to decompose the cryolite with sulphuric acid, remove the aluminium, and use zinc uranyl acetate as precipitant.

The authors wish to thank the Chief Scientific Officer, Ministry of Supply, for permission to publish this paper.

220. Unsaturated Lactones. Some Esters of Aconic and Coumalic Acids.

By N. R. CAMPBELL and J. H. HUNT.

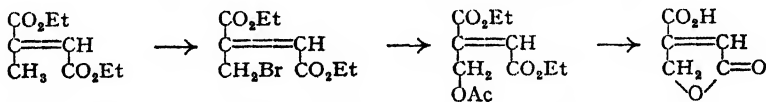

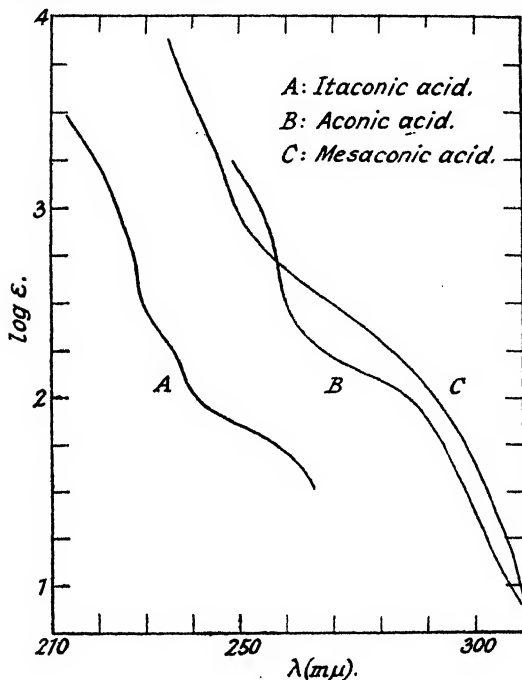

Aconic acid has been synthesised by a new method, which affords positive evidence for its acceptance as a β -substituted $\alpha\beta$ -butenolide. The older method of preparation has been developed, and a series of esters of aconic and coumalic acids prepared. The results of simple toxicity tests on the acids and their esters are given.

AMONG the simpler unsaturated lactones examined by Chen, Elderfield, Steldt, and Fried (*J. Pharmacol.*, 1942, **74**, 381) for cardioactivity, the methyl and ethyl esters of coumalic acid were

noteworthy for some positive result. It was considered desirable to extend this series of esters and to compare them biologically with a similar, related, series of esters of aconic acid.

The structure of coumalic acid is well established and probably beyond doubt, but there has been no positive evidence in support of the normally accepted $\beta\gamma$ -position of the double bond in aconic acid. The structure of this acid was given by Fittig and Beer (*Annalen*, 1883, **216**, 92) as β -carboxybutenolide, but they were unable to allocate an exact position to the double bond. We have now prepared the $\alpha\beta$ -acid by a method which does not involve conditions likely to cause migration, and have identified it with aconic acid prepared by the usual method from itaconic acid.

This new method of preparation involved bromination of the methyl group of diethyl mesaconate (diethyl methylfumarate) by means of *N*-bromosuccinimide, replacement of the bromine by an acetoxy-group under mild conditions, hydrolysis with barium hydroxide, and cyclisation by warming with water.

This evidence of structure brings aconic acid into line with the series of substituted butenolides which includes the aglycones of the digitalis and strophanthus groups of heart-poisons. The latter were also considered to be $\beta\gamma$ -butenolides before the work of Elderfield, Paist, Blout, and Uhle (*J. Org. Chem.*, 1941, **6**, 273) who produced evidence suggesting the present accepted $\alpha\beta$ -structure.

We have examined the ultra-violet absorption of aconic acid and compared the results with those obtained by Bielecki and Henri (*Ber.*, 1913, **46**, 2602) on mesaconic and itaconic acids, which are open-chain analogues of the two possible structures for aconic acid; we find that the absorption of aconic acid corresponds more closely to that of the fully conjugated isomer, thereby supplying further evidence for the $\alpha\beta$ -disposition of the double bond in aconic acid (see Fig.).

The preparation of aconic acid from itaconic acid was also studied. Itaconic acid was prepared by pyrolysis of citric acid (*Org. Synth.*, 1943, Coll. Vol. 2, 3 68); the isolation of acetone as a by-product together with approximately the theoretical volume of carbon monoxide indicated that acetonedicarboxylic acid was among the primary products of pyrolysis. Itaconic acid was brominated and the resulting "itadibromopyro-tartaric acid" (not isolated) converted into sodium aconate by a modification of the method used by Meilly (*Annalen*, 1874, **171**, 153), giving a greatly improved yield.

Esters of coumalic acid have been prepared by von Pechmann (*Annalen*, 1891, **264**, 279), Ruzicka (*Helv. Chim. Acta*, 1921, **4**, 504), and Caldwell, Tyson, and Lauer (*J. Amer. Chem. Soc.*, 1944, **66**, 1483). The method employed has generally involved treatment of a sulphuric acid solution of coumalic acid with the required alcohol, the coumalic acid being frequently prepared *in situ* from malic acid. We have employed both versions of this method and have also used much smaller (catalytic) quantities of sulphuric acid with azeotropic removal of water. Replacement of sulphuric acid by hydrogen chloride was not successful. We have compared the yields of one ester by the four methods; the first gave a considerably higher yield than the others.

The methyl and ethyl esters of aconic acid have been described by Meilly (*loc. cit.*), Reiter and Bender (*Annalen*, 1905, **339**, 316), and Wislicenus, Böklen, and Reuthe (*ibid.*, 1908, **363**, 353). The most suitable method for preparation of aconic esters is by reaction of silver aconate with the appropriate alkyl halide, usually at elevated temperature. With the exception of the *n*-butyl ester, the aconates prepared have all been obtained as crystalline solids; the isopropyl ester has been obtained in liquid and solid forms, both with satisfactory analyses. Ethyl aconate was described by Wislicenus (*loc. cit.*) as a liquid; under identical conditions we obtained a crystalline product.

While Rast's method gave satisfactory results for the molecular weights of all coumalates prepared, the aconates showed values ranging from theoretical to three times theoretical. We have been unable to explain this, or to correlate these anomalous results with the existence of solid and liquid forms.

Biological Investigation.—As a result of solubility difficulties in testing of these and other compounds by the usual assay method for digitalis, we adopted a simple toxicity test, the assumption being made that high cardioactivity might be accompanied by high toxicity. The substances were dissolved or suspended in arachis oil and administered subcutaneously to mice; median lethal doses (L.D./50) were calculated from the number of deaths after four days.

Toxicities in the coumalate series appear to decrease with increasing length of the alkyl chain, rather than with increasing molecular weight; the level of toxicity in the aconate series was so low that massive doses would be required for any variations to become apparent. It seems improbable that notable toxicity or cardioactivity will be found among simple esters of either of these acids.

	L.D./50.		L.D./50.
Coumalic acid	0.8 mg./g.	<i>n</i> -Butyl coumalate	>1 mg./g.
Methyl coumalate	0.3 mg./g.	isoButyl coumalate	0.6 mg./g.
Ethyl coumalate	0.33 mg./g.	Benzyl coumalate	>1 mg./g.
<i>n</i> -Propyl coumalate	0.55 mg./g.	cycloHexyl coumalate	0.55 mg./g.
isoPropyl coumalate	0.4 mg./g.		

Aconic acid, methyl aconate, ethyl aconate, *n*-propyl aconate, isopropyl aconate, *n*-butyl aconate, isobutyl aconate, benzyl aconate, and cyclohexyl aconate, all showed L.D./50 > 1 mg./g.

EXPERIMENTAL.

Sodium Aconate.—Itaconic acid (260 g.) was stirred to a paste with water (340 c.c.), and bromine (320 g.) slowly added, the temperature not being allowed to rise above 50°. When all but a trace of bromine had disappeared, the solution was neutralised with sodium hydrogen carbonate (336 g.). The mixture was then heated to 50° on the water-bath and treated with a suspension of sodium carbonate (106 g., anhydrous) in water (158 c.c.) at 50°, added in small portions until the solution remained neutral to bromothymol-blue. The mixture was cooled and allowed to remain at 0° for 1 hour. The crystalline sodium salt was filtered off, washed with iced water and with 95% alcohol, and dried in a vacuum at 110°. Yield of anhydrous sodium aconate, 179 g. (59%).

Silver Aconate.—Sodium aconate (100 g.) was stirred with water (80 c.c.) and heated to 40°. Silver nitrate (112.5 g.) dissolved in warm water (40 c.c.) was added, the mixture cooled to 0°, and the crystalline precipitate filtered off, washed with iced water and methanol, and dried in a vacuum desiccator. Yield, 147 g. (94%).

Aconic Acid.—Anhydrous sodium aconate (10 g.) was suspended in dry ether (30 c.c.). Dry hydrogen chloride was then passed in with stirring, until a gain in weight of 3.0 g. was obtained. The mixture was left overnight, the solid (11.5 g.) filtered off and extracted with ether in a continuous extractor. Removal of solvent left 7.6 g. of aconic acid, m.p. 162°. A further 0.7 g. of impure aconic acid, m.p. 156°, was obtained by evaporation of the original mother liquor. Total yield, 97%.

Ethyl Aconate (cf. Wislicenus, *loc. cit.*).—Silver aconate (30 g.) and ethyl iodide (15 c.c.) were heated in a sealed tube at 100° for 4 hours. The contents of the tube were extracted with ether, the extract washed with sodium hydrogen carbonate solution and water and dried (MgSO₄), and the solvent removed. The residue (15.5 g.) was distilled at reduced pressure, 8.95 g. of partly crystalline material (b. p. 132°/15 mm.) being collected. The crystals were separated and recrystallised from methanol at -10°. Yield, 3.3 g.; m. p. 64° (Found: C, 53.87; H, 5.31; M, 478. Calc. for C₇H₈O₄: C, 53.51; H, 5.13%; M, 157).

n-Propyl Aconate.—Silver aconate (20 g.) was refluxed for 1½ hours with *n*-propyl bromide (20 c.c.), excess of bromide then distilled off, and the residue diluted with ether and filtered. The brown oil (10.1 g.) remaining after removal of the ether was distilled, yielding 4.4 g. of partly crystalline material (b. p. 80–88°/0.1 mm.) which was dried on a porous tile. The ester, recrystallised from benzene–cyclohexane, had m. p. 34° (Found: C, 56.2; H, 6.04; M, 286. $C_9H_{10}O_4$ requires C, 56.5; H, 5.92%; M, 170).

isoPropyl Aconate.—(a) Silver aconate (14 g.) and isopropyl bromide (10 c.c.) were heated in a sealed tube at 100° for 3 hours. The contents of the tube were extracted with ether and the ether and excess of isopropyl bromide removed by distillation, leaving a brown oil (5 g.). Distillation of this yielded the ester as a colourless oil (1.7 g.), b. p. 70–71°/0.1 mm., n_D^{20} 1.460 (Found: C, 56.4; H, 5.58; M, 213. $C_8H_{10}O_4$ requires C, 56.5; H, 5.92%; M, 170).

(b) isoPropyl iodide (14 c.c.) was added slowly to silver aconate (28 g.) and benzene (30 c.c.). On gently heating the mixture a violent reaction commenced, necessitating cooling. The mixture was then refluxed for 1½ hours and cooled. The insoluble material was filtered off, washed with benzene, and extracted with ether in a continuous extractor. The ethereal extract yielded acetic acid (4.0 g.). The benzene solution was washed with sodium hydrogen carbonate solution, then with water, and dried ($MgSO_4$). Removal of the benzene gave a brown oil (9.48 g.), which on distillation gave two fractions: (i) b. p. 88–92°/0.2 mm., (ii) b. p. 100–120°/0.1 mm. Fraction (ii) which was partly crystalline was dried on a porous tile and recrystallised from light petroleum (b. p. 40–60°); m. p. 80° (Found: C, 56.3; H, 5.81%; M, 172).

n-Butyl Aconate.—Silver aconate (12.7 g.) was heated with *n*-butyl iodide (8 c.c.) and benzene (20 c.c.) in a sealed tube at 100° for 1 hour. The product, treated as for *n*-propyl aconate, yielded the ester as a colourless oil (2.5 g.), b. p. 91°/0.1 mm., n_D^{20} 1.471 (Found: C, 58.8; H, 6.66; M, 491. $C_9H_{12}O_4$ requires C, 58.7; H, 6.57%; M, 184).

isoButyl Aconate.—Silver aconate (25.4 g.) was refluxed for 1½ hours with isobutyl bromide (14 c.c.) and benzene (30 c.c.). The mixture was diluted with ether, filtered, and the filtrate washed with sodium hydrogen carbonate solution, then with water, and dried ($MgSO_4$). After removal of the ether the crude oily product (9.8 g.) was distilled under reduced pressure. The fraction, b. p. 86–88°/0.1 mm., partly crystallised and was dried on a porous plate. The solid ester was recrystallised from light petroleum (b. p. 60–80°); m. p. 114° (Found: C, 58.7; H, 6.58; M, 200. $C_9H_{12}O_4$ requires C, 58.7; H, 6.57%; M, 184).

Benzyl Aconate.—Silver aconate (11.5 g.) was refluxed for 1 hour with benzene (20 c.c.) and benzyl chloride (8.4 c.c.). The filtered benzene solution was washed with sodium hydrogen carbonate solution, then with water, and dried ($MgSO_4$). After removal of the benzene the ester was distilled under reduced pressure, b. p. 140°/0.04 mm., and recrystallised from cyclohexane. Yield, 1.1 g.; m. p. 59–60° (Found: C, 66.03; H, 4.55; M, 384. $C_{10}H_{10}O_4$ requires C, 66.04; H, 4.62%; M, 218).

cycloHexyl Aconate.—Acetic acid (6.25 g.) was dissolved in cold concentrated sulphuric acid (10 c.c.), the solution cooled to 0°, and cyclohexanol (15.8 c.c.) added. The mixture was allowed to warm to 18°, left for 20 hours, then poured on crushed ice and extracted with ether. After being washed, dried, and freed from solvent, the ester was crystallised from pentane (3.4 g.) and recrystallised from light petroleum (b. p. 60–80°); m. p. 68° (Found: C, 62.88; H, 6.72; M, 295. $C_{11}H_{14}O_4$ requires C, 62.84; H, 6.71%; M, 210).

isoPropyl Coumalate.—Malic acid (50 g.) was added slowly with stirring to fuming sulphuric acid (150 g.) containing 10% of sulphur trioxide, and the mixture heated on the water-bath until evolution of gas ceased. The mixture was then cooled and isopropyl alcohol (165 c.c.) added. After being heated on the water-bath for 1 hour under reflux, the mixture was cooled, poured on ice (200 g.), partly neutralised with sodium carbonate, left overnight, and filtered. The filtrate was extracted with ether, and the extract washed, dried and freed from solvent. The residual oil was distilled under reduced pressure. The fraction, b. p. 102–110°/0.1 mm., deposited crystals of the ester which were twice crystallised from light petroleum (b. p. 40–60°). Yield, 6 g.; m. p. 44° (Found: C, 59.4; H, 5.35; M, 171. $C_9H_{10}O_4$ requires C, 59.3; H, 5.41%; M, 182).

n-Butyl Coumalate.—Malic acid (100 g.), fuming sulphuric acid (300 g.), and *n*-butyl alcohol (200 c.c.) were brought into reaction by the method employed for isopropyl coumalate. After distillation of the crude reaction mixture, the fraction, b. p. 120–124°/0.1 mm., solidified on standing. The ester was twice recrystallised from light petroleum (b. p. 40–60°). Yield, 10 g.; m. p. 41° (Found: C, 61.4; H, 6.14; M, 191. $C_{10}H_{12}O_4$ requires C, 61.2; H, 6.16%; M, 196).

n-Propyl Coumalate.—(a) Malic acid (100 g.), fuming sulphuric acid (300 g.), and *n*-propyl alcohol (176 g.) were brought into reaction by the method employed for isopropyl coumalate. Yield of pure ester, 14 g. (20%).

(b) Coumalic acid (6.8 g.) was dissolved in concentrated sulphuric acid (13 g.) and cooled to room temperature. *n*-Propyl alcohol (13 g.) was added, and the mixture heated with occasional shaking, on the water-bath, under reflux for 1 hour and poured into iced water (50 c.c.). The solid was filtered off, washed, and dried (6 g.). The filtrate was extracted with ether and a further quantity of solid obtained, which was added to that previously obtained and distilled under reduced pressure. The fraction, b. p. 96–100°/0.1 mm., was crystallised from light petroleum (b. p. 60–80°). Yield of ester, 5 g. (57%); m. p. 59–60° (Found: C, 59.8; H, 5.74; M, 188. $C_9H_{10}O_4$ requires C, 59.3; H, 5.41%; M, 182).

(c) Coumalic acid (6.8 g.) was covered with *n*-propyl alcohol (13 g.) and saturated with dry hydrogen chloride at 0°. The mixture was allowed to warm to room temperature, and next day was poured into water. No ester could be isolated; unchanged coumalic acid (5 g.) was recovered.

(d) A mixture of coumalic acid (6.8 g.), *n*-propyl alcohol (10.6 c.c.), toluene (10 c.c.), and concentrated sulphuric acid (2 drops) was distilled slowly, the distillate being dried (K_2CO_3) and returned. After 3 hours toluene and excess of propyl alcohol were distilled off. Yield of ester, 3 g. (34%).

isoButyl Coumalate.—Coumalic acid (7.1 g.), concentrated sulphuric acid (15 g.), and isobutyl alcohol (17.5 c.c.) were brought into reaction by the method employed for *n*-propyl coumalate. The crude ester

was distilled and the fraction, b. p. 120—126°/0.1 mm., twice crystallised from light petroleum (b. p. 40—60°). Yield, 6 g.; m. p. 62° (Found: C, 61.1; H, 6.21; M, 199. $C_{10}H_{13}O_4$ requires C, 61.2; H, 6.12%; M, 196).

Benzyl Coumalate.—Silver coumalate (4.5 g.) (von Pechmann, *loc. cit.*) was refluxed for 1 hour with benzyl chloride (5 c.c.) and benzene (15 c.c.). The filtered benzene solution was washed and dried. Removal of the benzene left an oil (2.7 g.), which was distilled under reduced pressure, b. p. 140—150°/0.05 mm., and crystallised twice from ether. Yield of *ester*, 0.52 g.; m. p. 92° (Found: C, 67.9; H, 4.19; M, 238. $C_{13}H_{11}O_4$ requires C, 67.8; H, 4.35%; M, 230).

cycloHexyl Coumalate.—Coumalic acid (12.6 g.) was dissolved in concentrated sulphuric acid (25 c.c.) and the mixture cooled to 0°. cycloHexanol (45 c.c.) was added and the mixture allowed to warm to room temperature and left for 3 days. The mixture was worked up as under cyclohexyl aconate, yielding 6.5 g. of crude crystalline *ester* which after further crystallisation (charcoal) from light petroleum (b. p. 60—80°) had m. p. 70° (Found: C, 65.09; H, 6.46; M, 224. $C_{12}H_{14}O_4$ requires C, 64.8; H, 6.35%; M, 222).

Diethyl γ -Bromomesaconate.—(a) Diethyl mesaconate (71 g.) was refluxed with *N*-bromosuccinimide (71 g.) and carbon tetrachloride (213 c.c.) for 30 hours. The mixture was cooled, filtered, freed from solvent, and diluted with light petroleum (b. p. 40—60°) (200 c.c.) which precipitated traces of succinimide. After filtration and removal of solvent the *ester* was distilled, b. p. 91°/0.1 mm. Yield, 52 g. (Found: C, 39.8; H, 5.07; Br, 33.6. $C_8H_{13}O_4Br$ requires C, 40.77; H, 4.94; Br, 30.14%).

(b) Diethyl mesaconate (48.5 g.) was heated under reflux with *N*-bromosuccinimide (31 g.), carbon tetrachloride (50 c.c.), and benzoyl peroxide (2.4 g.) for 1 hour. The mixture was filtered and the filtrate washed and dried. After removal of solvent the residue (60.0 g.) was distilled; unchanged diethyl mesaconate (18.2 g., b. p. 60—65°/0.15 mm.) was followed by the main fraction, b. p. 94—98°/0.15 mm. (31.3 g.), which was redistilled; b. p. 72°/0.10 mm., n_D^{20} 1.485 (Found: C, 40.71; H, 5.04; Br, 31.3%). Repeated distillation of the *ester* failed to give a product with a correct bromine analysis.

Aconic Acid.—Diethyl γ -bromomesaconate (10 g.) was heated for 1 hour on the water-bath, under reflux, with potassium acetate (5 g. fused) in absolute alcohol (50 c.c.). The mixture was cooled and filtered, most of the alcohol distilled off, and the residue taken up in benzene. The resulting oil was distilled, 7.23 g. being collected, b. p. 96°/0.1 mm.

The crude acetoxy-derivative (4.2 g.) was stirred for 1½ hours at room temperature with water (50 c.c.), and barium hydroxide (8.15 g.) was gradually added. The slightly cloudy solution was filtered and treated with 5*N*-sulphuric acid (10.5 c.c.). After removal of the barium sulphate, the solution was heated at 70° for ½ hour and then gave a deep purple colour in the Legal test whereas no colour was produced before heating. Extraction with ether in a continuous extractor gave a mass of sticky crystals which were washed with a little dry ether. Yield, 0.6 g. of crystals, m. p. 164°, which did not depress the m. p. of aconic acid (Found: C, 46.84; H, 3.31. Calc. for $C_6H_4O_4$: C, 46.89; H, 3.14%). The methyl ester (from the silver salt and methyl iodide) had m. p. 82° and did not depress the m. p. of methyl aconate.

Our thanks are due to Prof. Buttle and to Dr. M. Vogt, both of the Pharmacology Dept., the College of the Pharmaceutical Society, for their co-operation in working out details of the toxicity test employed and for preliminary tests (not quoted here). All the biological results were determined by Dr. H. O. J. Collier of the Pharmacology Dept. of this Company, to whom our thanks are also due. Ultra-violet absorption determinations were kindly carried out by Mr. H. F. W. Kirkpatrick. We desire also to thank the Directors of Messrs. Allen & Hanburys Ltd. for permission to publish.

ALLEN & HANBURYS LTD., WARE.

[Received, November 27th, 1946.]

221. Pyrazine Derivatives. Part III. Conversion of Diketopiperazines into Pyrazine Derivatives. Synthesis of 2-Hydroxy-3:6-di-*sec*-butylpyrazine from isoLeucine.

By R. A. BAXTER and F. S. SPRING.

A method for the conversion of diketopiperazines (α -amino-acid anhydrides) into pyrazine derivatives is described. isoLeucine anhydride (IX) has been converted into 2-chloro-3:6-di-*sec*-butylpyrazine (XI) and thence into 2-hydroxy-3:6-di-*sec*-butylpyrazine (II), and similarly alanine anhydride (III) has been converted into 2-chloro- (IV) and 2-hydroxy-3:6-dimethylpyrazine (VII).

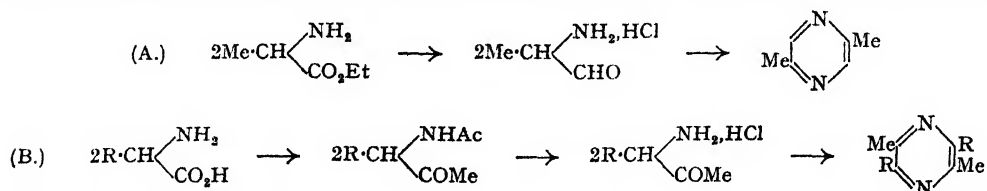

THE antibacterial substance aspergillic acid, for which the structure (I) has been suggested, is obtained from culture filtrates of the mould *Aspergillus flavus* using a medium containing an

amino-acid source such as tryptone. The present paper describes some preliminary experiments undertaken with the object of developing a synthetic route, starting from isoleucine, to

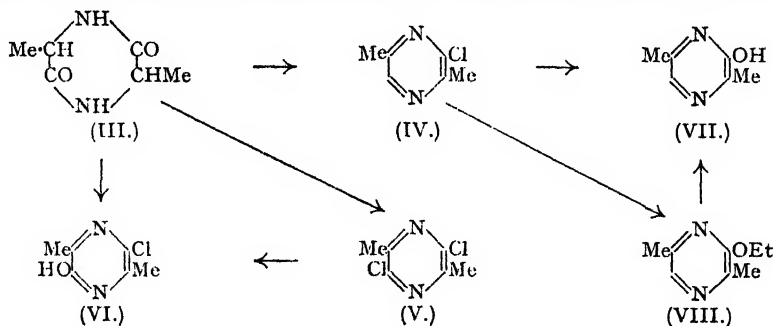

aspergillic acid or to the related deoxyaspergillic acid for which structure (II) has been suggested (for literature see Newbold and Spring, this vol., p. 373).

Two syntheses of pyrazine bases from α -amino-acids have been described. Reduction of the ethyl ester of alanine with sodium amalgam in the presence of hydrochloric acid gave the hydrochloride of α -aminopropaldehyde which when treated with alkali and mercuric chloride yielded 2 : 5-dimethylpyrazine in poor yield (A) (Neuberg, *Ber.*, 1908, **41**, 956; Fischer, *ibid.*, p.

1019). The second synthesis (B) consists in treatment of an α -amino-acid with acetic anhydride and pyridine to yield an α -acetamido-ketone which, when hydrolysed with hydrochloric acid, gave the corresponding α -amino-ketone hydrochloride. The latter when condensed with alkali in the presence of an oxidising agent gave a fully substituted pyrazine base (Dakin and West, *J. Biol. Chem.*, 1928, **78**, 745, 757).

Our method of approach to the problem consisted in a study of methods for converting a diketopiperazine (α -amino-acid anhydride) into an aromatic pyrazine derivative. The simplest reaction of this type would involve oxidation of a diketopiperazine to a dihydroxypyrazine, but so far as we are aware no transformation of this type has been reported. Abderhalden (*Z. physiol. Chem.*, 1924, **140**, 52; 1925, **143**, 128; 1925, **144**, 234) has shown that oxidation of glycine anhydride with potassium permanganate or with hydrogen peroxide and ferrous sulphate yields oxamide (cf. Ludtke, *Biochem. Z.*, 1925, **143**, 158), and according to Arai (*ibid.*, 1930, **226**, 233) glycine anhydride and phenylalanine anhydride on prolonged shaking with oxygen both yield urea. Goldschmidt and Steigenwald (*Ber.*, 1925, **58**, 1346) have shown that treatment of alanine anhydride with hypobromite yields an imidazolone derivative (cf. Goldschmidt, Wiberg, Nagel, and Martin, *Annalen*, 1927, **456**, 1). The present paper describes a method for the conversion of α -amino-acid anhydrides into halogen substituted pyrazine derivatives and the characterisation and conversion of these into hydroxypyrazine derivatives.

Treatment of *dl*-alanine anhydride (III) with phosphoryl chloride gives a mixture of 2-chloro-3 : 6-dimethylpyrazine (IV) and 2 : 5-dichloro-3 : 6-dimethylpyrazine (V). Separation of the two reaction products is relatively simple since the dichloro-derivative is not basic, whereas 2-chloro-3 : 6-dimethylpyrazine is soluble in 3*N*-hydrochloric acid. The formation of the monochloro-derivative (IV) from alanine anhydride does not involve an oxidation step, whereas the formation of 2 : 5-dichloro-3 : 6-dimethylpyrazine involves the oxidation of an intermediate dihydropyrazine derivative, a common step in many pyrazine syntheses. Treatment of *dl*-alanine anhydride with phosphoryl chloride in the presence of a tertiary base (dimethylaniline) gives only the monochloro-derivative, the intermediate dichlorodihydropyrazine presumably losing hydrogen chloride and thereby yielding the stable aromatic 2-chloro-3 : 6-dimethylpyrazine. 2-Chloro-3 : 6-dimethylpyrazine was not isolated from the reaction product obtained by treatment of *dl*-alanine anhydride with a mixture of phosphoryl chloride and phosphorus pentachloride (as oxidising agent), the reaction giving 2 : 5-dichloro-3 : 6-dimethylpyrazine in poor yield, together with a small quantity of 2-chloro-5-hydroxy-3 : 6-dimethylpyrazine

(VI); the latter was the only isolated product of the reaction between *dl*-alanine anhydride and phosphorus pentachloride.

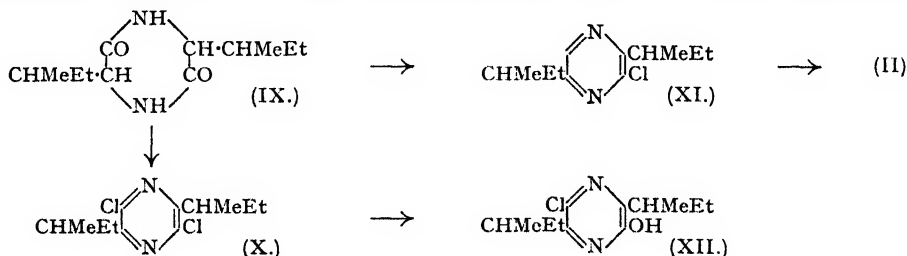

Prolonged treatment of 2-chloro-3:6-dimethylpyrazine with concentrated potassium hydroxide solution gives 2-hydroxy-3:6-dimethylpyrazine (VII) identical with that previously obtained by different synthetic methods (Baxter, Newbold, and Spring, this vol., p. 370). Less drastic methods for the replacement of the halogen atom by hydroxyl were sought, but so far we have not succeeded in replacing the halogen by an amino-group. Treatment of 2-chloro-3:6-dimethylpyrazine with alcoholic sodium ethoxide yields 2-ethoxy-3:6-dimethylpyrazine (VIII), hydrolysis of which with hydrochloric acid gives 2-hydroxy-3:6-dimethylpyrazine (VII).

Treatment of 2:5-dichloro-3:6-dimethylpyrazine with concentrated aqueous alkali yields 2-chloro-5-hydroxy-3:6-dimethylpyrazine (VI). This compound is soluble in alkali and reprecipitated from alkaline solution on acidification: its ultra-violet absorption spectrum is very similar to those of the simple hydroxypyrazine derivatives examined by Newbold and Spring (this vol., p. 373). 2-Chloro-5-hydroxy-3:6-dimethylpyrazine was recovered unchanged after treatment under drastic conditions with alcoholic ammonia. Although attempts to convert it into 2-hydroxy-3:6-dimethylpyrazine by reduction in alkaline solution with Raney alloy [Schwenk and Papa, *J. Org. Chem.*, 1944, 9, 1; *Ind. Eng. Chem. (Anal.)*, 1943, 15, 576] were unsuccessful, this transformation was effected by heating 2-chloro-5-hydroxy-3:6-dimethylpyrazine with solid potassium hydroxide. Treatment of 2-chloro-5-hydroxy-3:6-dimethylpyrazine with phosphoryl chloride using conditions which successfully convert *dl*-alanine anhydride into a mixture of 2-chloro- and 2:5-dichloro-3:6-dimethylpyrazine gives a very small yield of 2:5-dichloro-3:6-dimethylpyrazine, the starting material being largely recovered unchanged.

The reaction stages described above constitute a conversion of *dl*-alanine into 2-hydroxy-3:6-dimethylpyrazine. It was of great interest, therefore, to attempt to convert *dl*-isoleucine into 2-hydroxy-3:6-di-*sec*-butylpyrazine in order to compare the product with the racemate previously obtained by Newbold and Spring (*loc. cit.*) by a different synthetic route.

Ehrlich (*Ber.*, 1907, 40, 2550) obtained an *isoleucine* anhydride by heating *d*-isoleucine and commented that the compound was probably a mixture of isomers. Dutcher and Wintersteiner (*J. Biol. Chem.*, 1944, 155, 359) describe a racemic *isoleucine* anhydride prepared from *dl*-isoleucine. Using a modification of the method developed by Sannié (*Bull. Soc. chim.*, 1942, 9, 487) for the preparation of amino-acid anhydrides in which the α -amino-acid is heated with ethylene glycol, *dl*-isoleucine gave a *dl*-isoleucine anhydride in 49% yield. In a second method, α -bromo- β -methylvaleryl chloride was reacted with *dl*-isoleucine methyl ester hydrochloride and the product heated with alcoholic ammonia to yield a *dl*-isoleucine anhydride. Although the specimens of anhydride obtained by the two methods appear to be identical, it is clear that they may comprise different mixtures of isomers.

Treatment of *dl*-isoleucine anhydride (IX) with phosphoryl chloride gives a mixture of 2:5-dichloro-3:6-di-*sec*-butylpyrazine (X) and 2-chloro-3:6-di-*sec*-butylpyrazine (XI). The halogen substituents in these pyrazine derivatives are even less reactive than those in the corresponding dimethyl homologues. Thus 2-chloro-3:6-di-*sec*-butylpyrazine was recovered unchanged after prolonged refluxing with 20% potassium hydroxide solution, conditions which

converted 2-chloro-3:6-dimethylpyrazine into 2-hydroxy-3:6-dimethylpyrazine. When heated to 180° with powdered potassium hydroxide, however, 2-chloro-3:6-di-*sec*-butylpyrazine yielded 2-hydroxy-3:6-di-*sec*-butylpyrazine (II) identical with the racemate obtained previously from di-*sec*-butylpyrazine. 2:5-Dichloro-3:6-di-*sec*-butylpyrazine was also unchanged after treatment with concentrated aqueous alkali, but when heated with powdered potassium hydroxide it gave 2-chloro-5-hydroxy-3:6-di-*sec*-butylpyrazine (XII).

EXPERIMENTAL.

2:5-Dichloro-3:6-dimethylpyrazine.—A mixture of 2:5-diketo-3:6-dimethylpiperazine prepared from *dl*-alanine by the method described by Sannié (*loc. cit.*) (5 g.) and phosphoryl chloride (50 c.c.) was heated at 120° (bath temp.) for 20 minutes. Excess of phosphoryl chloride was removed under reduced pressure and the residue triturated with ice-water. The solid was collected (filtrate *A*), washed with water, and dried over phosphoric oxide (yield, 1.3 g.). Sublimation of this material at 60–80°/2 mm. gave 2:5-dichloro-3:6-dimethylpyrazine as prisms, m. p. 73° (Found: C, 41.1; H, 3.7; N, 15.4. $C_8H_8N_2Cl_2$ requires C, 40.7; H, 3.4; N, 15.8%). Light absorption in alcohol: Maximum at 2975 Å., $\epsilon = 810$.

2-Chloro-3:6-dimethylpyrazine.—The filtrate *A* was treated with sodium carbonate solution until just alkaline and the mixture extracted with ether. The extract was dried, the ether removed, and the residue distilled to yield 2-chloro-3:6-dimethylpyrazine as an oil, b. p. 78°/15 mm. (1.4 g.), n_D^{20} 1.5284 (Found: C, 50.2; H, 4.8. $C_8H_8N_2Cl$ requires C, 50.5; H, 4.9%). 2-Chloro-3:6-dimethylpyrazine is soluble in 3*N*-hydrochloric acid. It forms a picrate, m. p. approx. 100°, and a chloroplatinate, m. p. > 360°, which are extremely soluble in the common solvents; this extreme solubility precluded their satisfactory purification.

Treatment of alanine anhydride (5 g.) with phosphoryl chloride (30 c.c.) and dimethylaniline (10 c.c.) for 20 minutes at 120° gave 2-chloro-3:6-dimethylpyrazine (1 g.). Difficulty was experienced in separating the product from the dimethylaniline; this may account for the low yield.

2-Chloro-5-hydroxy-3:6-dimethylpyrazine.—(a) A mixture of *dl*-alanine anhydride (5 g.), phosphorus pentachloride (5 g.), and phosphoryl chloride (15 c.c.) was refluxed for 30 minutes. Excess of phosphoryl chloride was removed by distillation and the residue triturated with water to give 2:5-dichloro-3:6-dimethylpyrazine (0.5 g.), m. p. and mixed m. p. 72–73°. The mother liquor was neutralised with sodium carbonate and extracted with chloroform. Evaporation of the dried (Na_2SO_4) extract gave a solid (0.8 g.) which, after crystallisation from benzene (needles) followed by sublimation, gave 2-chloro-5-hydroxy-3:6-dimethylpyrazine as needles, m. p. 224°. Although sparingly soluble in water, it is soluble in dilute sodium hydroxide and precipitated from this solution on acidification (Found: C, 45.6; H, 4.7. $C_8H_7ON_2Cl$ requires C, 45.4; H, 4.4%).

(b) A solution of 2:5-dichloro-3:6-dimethylpyrazine (0.5 g.) in dioxan (4 c.c.) and aqueous potassium hydroxide (10 c.c.; 20%) was refluxed for 20 hours. The solution was acidified with hydrochloric acid, the crystalline solid collected and purified by sublimation at 140°/1 mm. to give 2-chloro-5-hydroxy-3:6-dimethylpyrazine (0.35 g.) as needles, m. p. 224°, either alone or when mixed with the specimen described above (Found: N, 17.5. $C_8H_7ON_2Cl$ requires N, 17.7%). Light absorption in alcohol: Maxima at 2285 Å., $\epsilon = 10,000$ and 3330 Å., $\epsilon = 6,800$.

***dl*-isoLeucine Anhydride.**—(a) *dl*-isoLeucine (9 g.) was refluxed with ethylene glycol (54 c.c.) for 4 hours. The crude anhydride (2 g.) which separated on standing was purified by extraction with chloroform and evaporation of the chloroform filtrate. On crystallisation of the residue from alcohol, *dl*-isoleucine anhydride formed felted needles, m. p. 270° (sintering at 259°) (yield 49%) (Found: C, 63.5; H, 9.6. Calc. for $C_{11}H_{22}O_2N_2$: C, 63.7; H, 9.7%).

(b) An ice-cooled suspension of *dl*-isoleucine methyl ester hydrochloride (6.2 g.) in chloroform (80 c.c.) and α -bromo- β -methylvaleryl chloride (8 g.) was stirred and treated during 1 hour with a solution of *n*-butylpiperidine (22 g.) in chloroform (20 c.c.). The ice-bath was removed and the mixture stirred for a further hour. The chloroform solution was washed successively with water, dilute hydrochloric acid, sodium carbonate solution, and water. Evaporation of the dried chloroform solution under reduced pressure gave a semi-solid mass which did not crystallise completely. It was dissolved in ethanol (150 c.c.), the solution saturated with ammonia at 0° and heated at 180° for 8 hours. The reaction mixture was evaporated to dryness and the residue extracted with chloroform. The chloroform extract was evaporated and the product (1.4 g.) crystallised from alcohol to yield *dl*-isoleucine anhydride as needles, m. p. 270°, sintering at 280°. A mixture of this anhydride with a specimen prepared by method (a) softened at 260° and melted at 270° (Found: C, 64.2; H, 9.6; N, 12.6. Calc. for $C_{11}H_{22}O_2N_2$: C, 63.7; H, 9.7; N, 12.4%).

2:5-Dichloro-3:6-di-sec-butylpyrazine.—*dl*-isoLeucine anhydride (2.0 g.) was refluxed with phosphoryl chloride (20 c.c.) for one hour. The phosphoryl chloride was removed under reduced pressure and the product triturated with ice-water. The mixture was extracted with ether, the extract dried (Na_2SO_4), and the solvent removed. Distillation of the residue gave an oil (1.2 g.), b. p. 118°/12 mm. The oil was shaken with concentrated hydrochloric acid (15 c.c.) and the crystalline mass collected (0.15 g.) (filtrate *B*) and sublimed at 50°/1 mm. to yield 2:5-dichloro-3:6-di-sec-butylpyrazine as plates, m. p. 58–60° (Found: C, 55.3; H, 6.9; N, 10.9. $C_{12}H_{18}N_2Cl_2$ requires C, 55.2; H, 6.9; N, 10.7%).

2-Chloro-3:6-di-sec-butylpyrazine.—The filtrate *B* was diluted with water and neutralised with sodium carbonate solution. The mixture was extracted with ether and the extract dried and distilled; 2-chloro-3:6-di-sec-butylpyrazine (0.8 g.) was thus obtained as a colourless oil; b. p. 116°/12 mm., n_D^{20} 1.5030 (Found: C, 64.2; H, 8.5; N, 12.0. $C_{12}H_{18}N_2Cl$ requires C, 63.6; H, 8.4; N, 12.4%).

2-Ethoxy-3:6-dimethylpyrazine.—2-Chloro-3:6-dimethylpyrazine (1 g.) was treated with an alcoholic solution of sodium ethoxide (from 0.4 g. of sodium and 10 c.c. of ethanol) and the mixture heated under reflux for 4 hours. The solution was concentrated, diluted with water, and extracted with ether. The dried extract was distilled to give 2-ethoxy-3:6-dimethylpyrazine (0.7 g.) as a colourless oil, b. p. 81°/15 mm., n_D^{20} 1.4993 (Found: C, 62.8; H, 7.7; N, 18.5. $C_8H_{12}ON_2$ requires C, 63.2; H, 7.9; N, 18.4%). The picrate separated as prismatic needles from methanol, m. p. 108–109° (Found: C, 44.4; H, 4.2; N, 18.8. $C_{14}H_{16}O_7N_4$ requires C, 44.1; H, 3.9; N, 18.4%).

2-Hydroxy-3:6-dimethylpyrazine.—(a) 2-Chloro-3:6-dimethylpyrazine (1 g.) was heated under reflux with aqueous potassium hydroxide (20%; 10 c.c.) for 18 hours. The solution was neutralised (litmus) with hydrochloric acid and evaporated to dryness under reduced pressure. The residue was extracted with benzene and the extract concentrated; 2-hydroxy-3:6-dimethylpyrazine (0.6 g.) then

separated as needles. After recrystallisation from the same solvent it had m. p. 208—210° either alone or when mixed with an authentic specimen.

(b) A solution of 2-ethoxy-3:6-dimethylpyrazine (0.6 g.) in hydrochloric acid (5*N*, 20 c.c.) was heated under reflux for 18 hours. The solution was evaporated to dryness, the residue dissolved in water, and the solution neutralised by the addition of sodium carbonate solution and evaporated to dryness. The residue was extracted with benzene and the extract concentrated; 2-hydroxy-3:6-dimethylpyrazine (0.4 g.), m. p. and mixed m. p. 208—210°, then separated as needles.

(c) 2-Chloro-5-hydroxy-3:6-dimethylpyrazine (0.5 g.) was heated at 180—200° for 5 hours with powdered potassium hydroxide (2 g.). The cold reaction product was dissolved in water, and the solution neutralised with dilute hydrochloric acid and then evaporated to dryness (reduced pressure). Extraction with benzene in the usual manner gave 2-hydroxy-3:6-dimethylpyrazine (0.2 g.) as needles, m. p. and mixed m. p. 208—210°. The picrate separated as blades from methanol, m. p. 180—182°, undepressed when mixed with the specimen described by Baxter, Newbold, and Spring (*loc. cit.*).

2-Hydroxy-3:6-di-*sec*-butylpyrazine.—2-Chloro-3:6-di-*sec*-butylpyrazine (0.5 g.) was heated with powdered potassium hydroxide (2 g.) for 4 hours at 180°. The reaction mass was dissolved in water and the solution extracted with ether. The alkaline solution was acidified; 2-hydroxy-3:6-di-*sec*-butylpyrazine (0.3 g.) then separated. It was collected and purified by sublimation at 110°/1 mm., and so obtained as small needles, m. p. 122—124°, not depressed when mixed with a specimen, m. p. 122—124°, prepared as described by Newbold and Spring (*loc. cit.*). Light absorption in alcohol: Maxima at 3250 Å., $\epsilon = 10,000$ and 2290 Å., $\epsilon = 9,100$.

2-Chloro-5-hydroxy-3:6-di-*sec*-butylpyrazine.—2:5-Dichloro-3:6-di-*sec*-butylpyrazine (0.3 g.) was heated with powdered potassium hydroxide (2 g.) for 4 hours at 160—180°. The mass was dissolved in water and unchanged dichloro-compound (0.2 g.) isolated by extraction with ether. Acidification of the solution with hydrochloric acid gave a solid which after sublimation at 90°/1 mm. gave 2-chloro-5-hydroxy-3:6-di-*sec*-butylpyrazine, m. p. 105—106°. It is freely soluble in the common organic solvents, but insoluble in water (Found: C, 59.4; H, 8.0. $C_{12}H_{13}ON_2Cl$ requires C, 59.4; H, 7.8%).

We thank Mr. J. J. Gallagher for assistance in some of the experiments described. Grateful acknowledgment is made to the Department of Scientific and Industrial Research for a Grant.

222. Pyrazine Derivatives. Part IV. Pyrazine N-Oxides and their Conversion into Chloropyrazines.

By G. T. NEWBOLD and F. S. SPRING.

2:5-Dialkylpyrazines are readily oxidised to a mixture of the corresponding mono- and di-*N*-oxides. The mono- and di-*N*-oxides are smoothly converted into 2-chloro- and 2:5-dichloro-3:6-dialkylpyrazines respectively. Hydrolysis of the 2-chloro-3:6-dialkylpyrazine gives the corresponding 2-hydroxy-3:6-dialkylpyrazine. By this route, 3:6-di-*sec*-butylpyrazine yields a 2-hydroxy-3:6-di-*sec*-butylpyrazine identical with the racemate described by us in Parts II and III (this vol., p. 373, and preceding paper).

TREATMENT of 2:5-dimethylpyrazine (I, R = Me) with hydrogen peroxide in aqueous acetic acid gives 2:5-dimethylpyrazine *N*-oxide (II, R = Me) in 62% yield and 2:5-dimethylpyrazine di-*N*-oxide (III, R = Me) in 24% yield. Treatment of 2:5-dimethylpyrazine *N*-oxide with phosphoryl chloride gives 2-chloro-3:6-dimethylpyrazine (IV, R = Me) in 85% yield. Alkaline hydrolysis of the latter as described in the preceding paper yields 2-hydroxy-3:6-dimethylpyrazine (V, R = Me). This route to 2-hydroxy-3:6-dimethylpyrazine starting from 2:5-dimethylpyrazine is superior to that described by Baxter, Newbold, and Spring (this vol., p. 370).

2 : 5-Dimethylpyrazine di-*N*-oxide is converted by the action of phosphoryl chloride into 2 : 5-dichloro-3 : 6-dimethylpyrazine (VI, R = Me), identical with that described in the preceding paper. The yield, however, is low and is not increased by the use of sulphuryl chloride instead of phosphoryl chloride.

Treatment of 2 : 5-di-*sec*.-butylpyrazine (I, R = *sec*.-C₄H₉) with hydrogen peroxide gives a mixture of the corresponding mono- and di-*N*-oxides. 2 : 5-Di-*sec*.-butylpyrazine di-*N*-oxide (III, R = *sec*.-C₄H₉) is obtained in 64% yield, and on treatment with phosphoryl chloride it is converted into 2 : 5-dichloro-3 : 6-di-*sec*.-butylpyrazine (VI, R = *sec*.-C₄H₉), identical with that obtained from isoleucine anhydride. The mono-*N*-oxide (II, R = *sec*.-C₄H₉) was not isolated in a pure state; when treated with phosphoryl chloride it is converted into 2-chloro-3 : 6-di-*sec*.-butylpyrazine (IV, R = *sec*.-C₄H₉). The latter was characterised by hydrolysis to 2-hydroxy-3 : 6-di-*sec*.-butylpyrazine (V, R = *sec*.-C₄H₉), identical with the preparation described in the preceding paper and with that described in Part II (*loc. cit.*).

EXPERIMENTAL.

2 : 5-Dimethylpyrazine Di-*N*-oxide.—A solution of 2 : 5-dimethylpyrazine (5.5 g.) in glacial acetic acid (20 c.c.) was treated with hydrogen peroxide solution (40 c.c.; 100-vol.) and maintained at 56° for 16 hours. The solution was evaporated to small bulk under reduced pressure, and the residue was cooled in ice-water and made alkaline with sodium hydroxide solution. The mixture was extracted with chloroform (10 × 25 c.c.), the extract dried (Na₂SO₄), and the solvent evaporated under reduced pressure. The solid residue was digested with boiling chloroform (25 c.c.), the mixture cooled, and the solid collected (filtrate A). Crystallisation from a large volume of chloroform gave 2 : 5-dimethylpyrazine di-*N*-oxide as needles (1.7 g.); it has no definite m. p., darkening profoundly at approximately 280°, and is not molten at 360°. The di-*N*-oxide is readily soluble in cold water but sparingly soluble in cold organic solvents. It is less soluble in 3*N*-sodium hydroxide solution than in water. It sublimes readily at 200°/0.5 mm. (Found: C, 51.3; H, 5.8. C₈H₈O₂N₂ requires C, 51.4; H, 5.7%).

2 : 5-Dimethylpyrazine *N*-Oxide.—The filtrate A and the mother liquors from the crystallisation of the di-*N*-oxide were combined, concentrated, and cooled, and some di-*N*-oxide was removed by filtration. The filtrate was evaporated to dryness and the solid residue (3.9 g.; m. p. 100°) was crystallised from benzene to give 2 : 5-dimethylpyrazine *N*-oxide as small colourless needles, m. p. 105–108°; it rapidly sublimes at 100°/0.001 mm. (Found: C, 58.0; H, 6.3. C₈H₈ON₂ requires C, 58.1; H, 6.45%). 2 : 5-Dimethylpyrazine *N*-oxide (0.6 g.) was heated with hydrogen peroxide solution (5 c.c.; 100-vol.) and glacial acetic acid (5 c.c.) for 18 hours at 56°. The reaction mixture was treated as described above to give 2 : 5-dimethylpyrazine di-*N*-oxide (0.5 g.), darkening at approximately 280° and not molten at 360° (Found: C, 51.5; H, 5.9%).

2-Chloro-3 : 6-dimethylpyrazine.—2 : 5-Dimethylpyrazine *N*-oxide (2.75 g.) was added in small portions to phosphoryl chloride (15 c.c.) with cooling and shaking. The mixture was cautiously warmed until solution was complete and the solution heated under reflux for 10 minutes. Excess of phosphoryl chloride was removed under reduced pressure and the residue poured on crushed ice. The mixture was neutralised with sodium carbonate and extracted with chloroform (6 × 25 c.c.), and the combined extracts were dried (Na₂SO₄). The chloroform was evaporated and the residual oil distilled under reduced pressure to give a main fraction, b. p. 75–80°/12 mm. (2.7 g.; 85%), which on redistillation yielded 2-chloro-3 : 6-dimethylpyrazine as a colourless oil, b. p. 77°/12 mm.; *n*_D²⁰ 1.5275 (Found: C, 50.8; H, 4.8; N, 19.4. Calc. for C₈H₈N₂Cl: C, 50.5; H, 4.9; N, 19.6%).

Hydrolysis of 2-chloro-3 : 6-dimethylpyrazine as described in the preceding paper gave a 50% yield of 2-hydroxy-3 : 6-dimethylpyrazine which after sublimation had m. p. 210–211°, undepressed on admixture with a specimen prepared *via* 2-amino-3 : 6-dimethylpyrazine (Baxter, Newbold, and Spring, *loc. cit.*).

2 : 5-Dichloro-3 : 6-dimethylpyrazine.—(a) 2 : 5-Dimethylpyrazine di-*N*-oxide (0.5 g.) was treated with phosphoryl chloride (2.5 c.c.) and heated under reflux for 30 minutes. Excess of phosphoryl chloride was removed under reduced pressure and the residue triturated with ice-water. The solid was collected and purified by sublimation to yield 2 : 5-dichloro-3 : 6-dimethylpyrazine (100 mg.), m. p. 70–72°, not depressed by the preparation described in the preceding paper (Found: C, 41.0; H, 3.5. Calc. for C₈H₆N₂Cl₂: C, 40.7; H, 3.4%).

(b) The di-*N*-oxide (0.5 g.) was refluxed for 1 hour with sulphuryl chloride (10 c.c.). The excess of reagent was removed by distillation to give 2 : 5-dichloro-3 : 6-dimethylpyrazine (90 mg.), m. p. 71–73°.

2 : 5-Di-*sec*.-butylpyrazine Di-*N*-oxide.—2 : 5-Di-*sec*.-butylpyrazine (4.2 g.) in glacial acetic acid (30 c.c.) and hydrogen peroxide solution (30 c.c.; 100-vol.) was heated at 56° for 17 hours. The solution

was evaporated to small bulk under reduced pressure, and the residue made alkaline with sodium hydroxide solution and extracted with chloroform (6 × 20 c.c.). The combined extracts were dried (K₂CO₃) and evaporated to dryness under reduced pressure. The residue was recrystallised from benzene-light petroleum (b. p. 40–60°) to give 2 : 5-di-*sec*.-butylpyrazine di-*N*-oxide as needles, m. p. 159–161° (yield 64%). 2 : 5-Di-*sec*.-butylpyrazine di-*N*-oxide is insoluble in water; it dissolves in 5*N*-hydrochloric acid and is precipitated on basification of the solution (Found: C, 64.2; H, 9.0. C₁₂H₂₀O₂N₂ requires C, 64.3; H, 8.9%).

2 : 5-Dichloro-3 : 6-di-*sec*.-butylpyrazine.—A mixture of the di-*N*-oxide (1.6 g.) and phosphoryl chloride (20 c.c.) was gently warmed and then heated under reflux for 30 minutes. Excess of phosphoryl chloride was removed under reduced pressure and the residue poured into ice-water. After neutralisation with sodium carbonate the solid was extracted with chloroform, and the dried (Na₂SO₄) extract

evaporated to yield an oil which solidified on cooling. The solid was purified by sublimation at 50°/0.5 mm., and the sublimate crystallised from aqueous ethanol to yield 2 : 5-dichloro-3 : 6-di-*sec.*-butylpyrazine (46% yield) as laminae, m. p. 59–61°, undepressed when mixed with the specimen described in the preceding paper (Found : C, 54.8; H, 6.9; N, 10.9. Calc. for $C_{12}H_{18}N_2Cl_2$: C, 55.2; H, 6.9; N, 10.7%).

2-Chloro-3 : 6-di-*sec.*-butylpyrazine.—The mother liquors from the crystallisation of 2 : 5-di-*sec.*-butylpyrazine di-*N*-oxide were evaporated. The viscous liquid (1.0 g.), which would not solidify, was heated under reflux with phosphoryl chloride (10 c.c.) for 30 minutes and the reaction mixture worked up in the usual manner to give 2-chloro-3 : 6-di-*sec.*-butylpyrazine (0.6 g.) as a colourless oil, b. p. 118–120°/14 mm.; n_D^{20} 1.5037 (Found : N, 12.1. Calc. for $C_{12}H_{18}N_2Cl$: N, 12.4%). Treatment of the chloro-compound (0.4 g.) with potassium hydroxide using the conditions described in the preceding paper gave 2-hydroxy-3 : 6-di-*sec.*-butylpyrazine (0.15 g.) as small needles which after sublimation had m. p. and mixed m. p. 121–123°.

[Received, November 27th, 1946.]

223. Nitration in Sulphuric Acid. Part V. Nitration of 2 : 4-Dinitrotoluene in a Two-phase System.

By G. M. BENNETT, J. C. D. BRAND, D. M. JAMES, T. G. SAUNDERS, and GWYN WILLIAMS.

The results of a series of experiments on the rate of nitration of dinitrotoluene in a two-phase system under various conditions are discussed in the light of the study of nitration in homogeneous sulphuric acid solution (Part IV, this vol. p. 474), but a complete analysis of the results is not possible owing to the lack of data concerning the concentrations in the two phases.

The rate of nitration for any one concentration of nitric acid is approximately proportional to the molar excess of sulphuric acid over water present.

Owing to the higher proportion of nitric acid and lower proportion of sulphuric acid present in comparison with the experiments in homogeneous solution, and also to solubility effects, there is no optimum composition of the acid mixture giving a maximum rate of nitration such as occurs with 92% sulphuric acid in homogeneous nitration. Consistently with this the influence of added bisulphates and nitrous acid is in all cases to depress the rate of reaction.

PART IV (*loc. cit.*) of this series described a study of the kinetics of nitration of 2 : 4-dinitrotoluene in homogeneous solution in sulphuric acid, with small concentrations of nitric acid and nitro-compound. The influence of water upon the rate of nitration was shown to be due to the production of bisulphate ion (equation 1), which exerts a dual influence, assisting nitration by increasing the proton-accepting quality of the medium and hindering nitration by its effect upon the extent to which nitric acid is converted into the nitronium ion NO_2^+ (equation 2). This ion is the effective nitrating agent (Part I, *J.*, 1946, 869).

In actual practice, however, the conversion of dinitrotoluene (DNT) into trinitrotoluene (TNT), whether on the laboratory or on the industrial scale, is carried out with larger proportions of nitric acid and with sufficient organic material to produce a two-phase system. In this paper we present the results of laboratory experiments on the two-phase nitration of DNT, designed to show whether the influence of water upon the rate of nitration in a two-phase system is consistent with the conclusions derived from the experiments with homogeneous systems, and, in particular, to ascertain whether added bisulphate ion influences the rate of the two-phase nitration in a predictable manner. The results here described will be confined to those of importance for these two purposes: a more extensive account of the two-phase experiments, with full experimental details, will be published elsewhere.

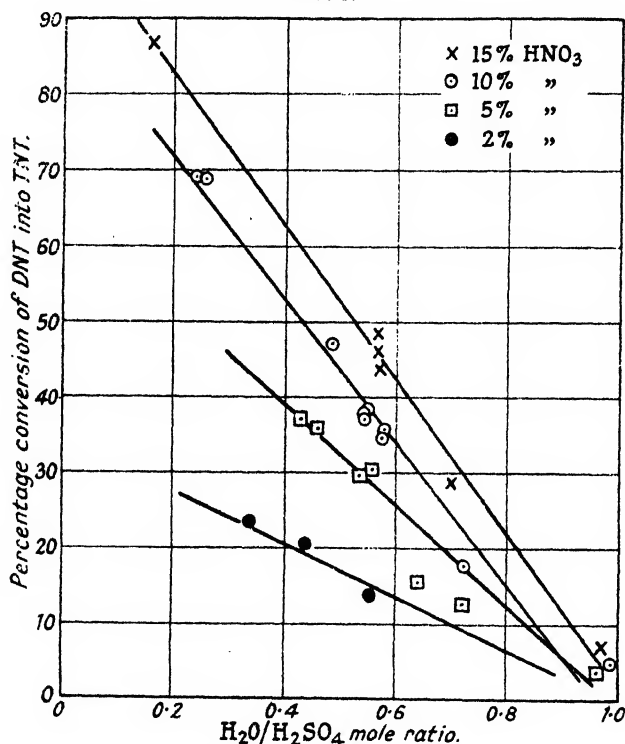

Method of Experiment.—In each nitration chosen quantities of reagents were vigorously stirred together at a specified temperature (usually 100°) for a certain time (usually 60 mins.), the reaction was stopped by pouring into water, and the composition of the organic products found, after washing and drying, by measurement of density with a pyknometer and by reference to a density-composition curve. The material subjected to nitration was usually a 50% dinitrotoluene-trinitrotoluene mixture in order to make the experiment similar in conditions to those found in one of the vessels of a nitrating plant where nitration is proceeding vigorously.

To determine strictly comparable rates of reaction would require the measurement of instantaneous initial velocities of the process, but the experimental errors would be large for

short times of reaction so that a compromise was necessary and the nitrations were continued for times sufficient to give changes large enough for accurate determination. A consideration of the various experimental errors shows that an observed change of 1% in the proportion of TNT present may be regarded as significant, but the corresponding calculated percentage conversion will be of the order of 2%.

Sulphuric Acid-Water Ratio.—The criteria we have used in examining the process are the $\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ and the HNO_3/DNT molar ratios. Fig. 1 summarises the results obtained at 100° with widely varying $\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ ratios for four different values of the HNO_3/DNT ratio, and shows clearly that nitration becomes negligible when the water/sulphuric acid ratio approaches unity. This is reminiscent of the nitration threshold found by Hetherington and Masson (*J.*, 1933, 105) for the nitration of nitrobenzene at 35° , but the latter substance has a much higher speed of nitration and, in presence of large amounts of nitric acid, its nitration continued to

FIG. 1.

Extent of nitration in 1 hour at 100° of 50% DNT in TNT mixture with 2.43 wts. of mixed acids of various compositions.

points somewhat beyond the 1 : 1 ratio of water to sulphuric acid. The results of our velocity measurements for the nitration of dinitrotoluene in homogeneous solution show values falling towards zero in the region of a $\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ mole ratio of 0.87, and although this agrees approximately with the indications of Fig. 1 there appears to be a small but real discrepancy since appreciable nitration was found in two-phase experiments for acids of ratio 1.0. The explanation of this may lie in the slight change of composition of the acid mixture in consequence of the partition of water and acids between the two phases. Complete data on this point are not available, but some unpublished experiments by Mr. S. E. Napier, made to study the compositions of the two phases in such nitrations, showed that the aqueous acid present in the organic phase, amounting to 5–10% of that phase, always showed a $\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ ratio much higher than that of the acid phase in equilibrium with it. This must result in the effective $\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ molar ratio in two-phase nitrations being somewhat lower than that of the acid mixture as prepared and analysed before the experiment, and may well account for the discrepancy observed.

Fig. 1 shows that rates of nitration for each concentration of nitric acid fall in an approximately linear manner towards the point when $\text{H}_2\text{O}/\text{H}_2\text{SO}_4 = 1$, and this means that the rates are nearly proportional to $1 - \text{H}_2\text{O}/\text{H}_2\text{SO}_4$ or $(\text{H}_2\text{SO}_4 - \text{H}_2\text{O})/\text{H}_2\text{SO}_4$, i.e., nearly proportional to the fraction of sulphuric acid which is in molar excess of the water present. This is consistent with our view that nitration must depend on there being a molecular excess of sulphuric acid over the water present in the nitrating mixture, because the reaction (1) is complete, and it is only the excess of sulphuric acid which converts nitric acid into the active nitrating species NO_2^+ on which the reaction depends.

A detailed analysis of the results of these two-phase experiments in terms of the velocities of reaction determined in homogeneous sulphuric acid solution is, however, not at present possible because the available data as to the exact compositions of the two phases are far too fragmentary.

A remarkable regularity was observed in the course of some experiments carried out by Messrs. J. C. Dine and D. Fysh directed to answering the practical question "what is the necessary composition of mixed acid to give a specified extent of nitration?" It was found that for various concentrations of nitric acid (of 5% and upward when working at 100°) the required rate of nitration was obtained when the water mole-fraction had a certain value. Moreover, this was found to hold at three different temperatures, a necessary minimum concentration of nitric acid and a prescribed water mole-fraction being specified for each temperature.

A partial explanation of this result is again suggested by our theory when the concentrations of nitronium ion present in these acid mixtures are considered. Calculation from the ionic equilibria, using the constants determined in our study of kinetics in homogeneous sulphuric acid solution (Part IV, *loc. cit.*), shows that the acids giving the required rate of nitration have approximately constant concentrations of NO_2^+ ion. The data for six such acids found to give a prescribed rate of 16.5% conversion of DNT in 30 minutes at 100° are shown in the table

Composition of nitrating acids giving a specified rate of nitration at 100°.

Acid No.	Wt., %.			Mole-fractions.			Calculated moles of NO_2^+ /l.
	H_2SO_4 .	HNO_3 .	H_2O .	H_2SO_4 .	HNO_3 .	H_2O .	
1	75.0	15.0	10.0	0.489	0.152	0.359	0.60
2	80.6	9.85	9.6	0.543	0.103	0.354	0.72
3	85.4	5.06	9.5	0.590	0.054	0.356	0.62
4	87.3	3.94	8.8	0.618	0.043	0.338	0.64
5	87.5	3.71	8.75	0.621	0.041	0.338	0.61
6	93.6	2.0	4.4	0.776	0.026	0.198	0.58

above. The experimental measurements of Chédin (*Mem. des Services chimiques de l'Etat*, 1944, 31, 113), interpreted according to our views, give results of the same order and equally consistent except for acid No. 6. Such acids might be expected to have equal nitrating powers. This leaves out of account, however, the two-phase nature of the system, and the fact that the concentrations in the acid phase, where nitration takes place, must differ slightly from those in the nitrating acid selected.

When a wide range of nitration data are re-examined in relation to the water mole-fraction in the acid used it appears from Fig. 2, in which the extent of nitration is plotted against the water mole-fraction, that with acids of 5% nitric acid and upwards the rate of nitration varies in a linear manner with varying water mole-fraction, independently of wide variations in the concentration of nitric acid present.

It may be pointed out that acids of the same water mole-fraction are acids of nearly equal water/sulphuric acid ratios since the mole-fraction of sulphuric acid in them does not vary much. In fact, if the nitric acid present is increased while the water mole-fraction is kept constant, a slightly lower $\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ ratio must result and the relationship shown in Fig. 2 may arise from a compensation in the ionisation equilibrium between a somewhat diminished proportion of free sulphuric acid and the increased amount of nitric acid present.

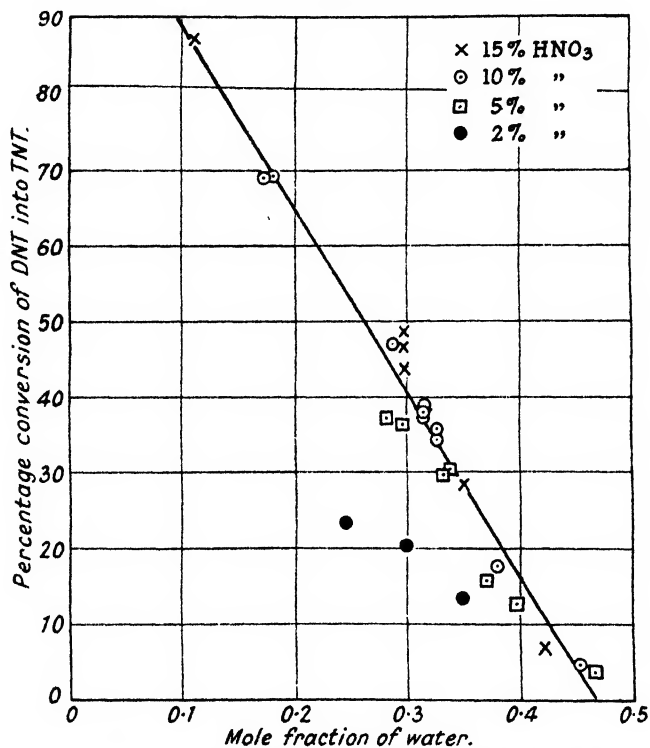

If, on the other hand, we consider the trend of the results of two-phase nitrations in acids of diminishing water content, we find that the nitration rates (using nitrating acids containing 5 or 10% HNO_3) increase steadily as the mole-fraction of water is reduced to zero and show no sign of a maximum for a nitrating acid composed of nitric acid and any aqueous sulphuric acid, comparable with the sharp maximum in homogeneous solutions at 92% H_2SO_4 ($\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ molar ratio = 0.48). There are two reasons which may account for this difference:

(a) In two-phase experiments with dinitrotoluene the nitration takes place in the acid

phase. Nitration in the organic phase is negligible, as shown by Mr. W. W. Jones and Mr. A. E. Flood (unpublished observations; compare Hetherington and Masson, *loc. cit.*, who state that no nitration occurs in the nitrobenzene phase, and Lewis and Suen, *Ind. Eng. Chem.*, 1940, **32**, 1095, who found the rate of nitration of benzene to be 5–10 times as fast in the acid phase as in the organic phase). The solubility of dinitrotoluene in the acid phase increases with diminishing water content, and this must at least tend to move the optimum composition for nitration in the direction of acids of lower water content (compare D. I. James, *J.*, 1935, 785).

(b) The occurrence of a medium giving a maximum rate for homogeneous nitration depends on the existence of a range of nitrating acids in which an increase in water content accelerates nitration, and this is due to the nearly complete conversion of water and nitric acid into ionic forms by the sulphuric acid in this range. The rising proportion of water therefore increases the concentration of HSO_4^- ion in this region much faster than it diminishes that of the NO_2^+

FIG. 2.

Extent of nitration in 1 hour at 100° of 50% DNT in TNT mixture with 2.43 wts. of mixed acids of various compositions.

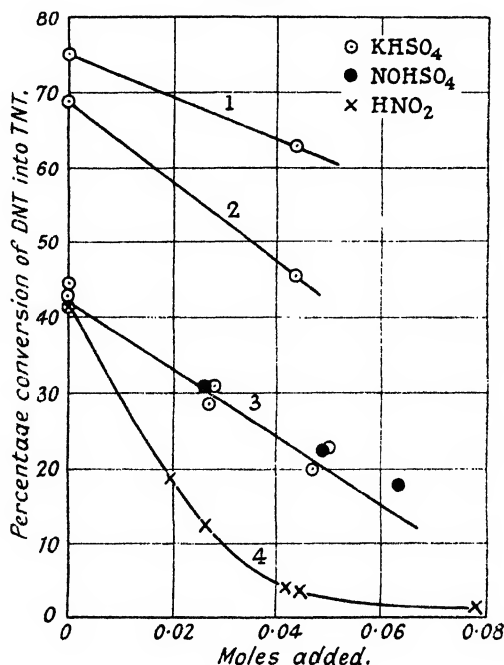

ion. This can only occur, however, when sulphuric acid is present in sufficient molecular excess over both water and nitric acid. In a typical two-phase experiment the nitrating acid was of composition 84.4% H_2SO_4 , 9.9% HNO_3 , 5.7% H_2O (nitric acid in 93.7% sulphuric acid) and the actual quantities in reaction were: dinitrotoluene 0.0384, sulphuric acid 0.293, nitric acid 0.0538, water 0.108 mole. In this mixture sulphuric acid is in 1.8-fold excess over the nitric acid plus water, as compared with a 4-fold excess in our homogeneous nitration in 96% sulphuric acid. It is readily shown by calculation of the ionic equilibria in these mixtures (discussed in Parts I and IV of this series) that with 5 or 10% of nitric acid present the conversion of the nitric acid into the cationic form NO_2^+ does not approach completeness with any sulphuric acid–water mixture. An examination of the curves from the observations of Chédin (*loc. cit.*) also leads to the same conclusion.

This view is supported by the effect produced on the rate of nitration by the addition of bisulphates.

Effect of Bisulphates and Nitrous Acid.—In Part IV it was shown that the effect of bisulphate

ions in homogeneous nitrations was to accelerate the reaction in the region between the optimum concentration and 100% sulphuric acid but to retard it in acid-water mixtures of less than 92% sulphuric acid. According to our view, the two-phase nitrating mixtures are all effectively analogous to the latter range of media for homogenous nitration, and this requires that bisulphates should always retard the two-phase process. This question has been examined experimentally, for two-phase nitrations with a mixed acid containing 10% of nitric acid, by observing the effect of adding (a) potassium bisulphate, (b) nitrosyl bisulphate, and (c) nitrous acid. The last of these reacts reversibly according to the equation $\text{HNO}_2 + 2\text{H}_2\text{SO}_4 \rightleftharpoons \text{NO}^+ + \text{H}_3\text{O}^+ + 2\text{HSO}_4^-$, so that one mole of nitrous acid produces two moles of bisulphate ion and one mole of oxonium ion all capable of affecting the nitric acid ionisation equilibrium.

FIG. 3.

Effects of added substances on extent of nitration at 100°.

- | | | | |
|----------|--|------------------------|----------------------------|
| Curve 1. | 89.1% H_2SO_4 : $\text{H}_2\text{O}/\text{H}_2\text{SO}_4 = 0.072$. | Nitration for 30 mins. | } $\text{HNO}_3 = 9.8\%$. |
| 2. | 86.2% H_2SO_4 : $\text{H}_2\text{O}/\text{H}_2\text{SO}_4 = 0.245$. | Nitration for 60 mins. | |
| 3 and 4. | 81.8% H_2SO_4 : $\text{H}_2\text{O}/\text{H}_2\text{SO}_4 = 0.563$. | Nitration for 60 mins. | |

The results of these experiments are shown in Fig. 3. A retardation of the reaction is apparent in all cases. The large retarding effect of bisulphate, shown in the upper two curves, is specially noteworthy since the $\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ ratios for these acids were 0.072 and 0.245, corresponding to points well on the acid side of the optimum velocity point in homogeneous nitrations ($\text{H}_2\text{O}/\text{H}_2\text{SO}_4 = 0.48$). This confirms the supposition made above [p. 1188, (b)] that, in two-phase nitration, the proportion of nitric acid present is usually too high for its conversion into nitronium ion to be nearly complete.

In this connection it is noteworthy that the nitration of benzoic acid and other substances by means of potassium nitrate and concentrated sulphuric acid (Houben, "Methoden der Organischen Chemie", 3rd edn., 1941, iv, 195) involves essentially homogeneous conditions and that here the reaction is facilitated by the potassium bisulphate formed in solution.

The effects of potassium and nitrosyl bisulphate are not quite equivalent, but the discrepancy is accounted for when allowance is made for the incompleteness of the ionisation reaction of nitrous acid: the substance is 90% ionised in such solutions according to the estimate of Hantzsch and Berger (*Z. anorg. Chem.*, 1930, 190, 321).

The effect of nitrous acid in depressing the speed of nitration is seen to be more than twice

that of potassium bisulphate, as was to be expected, but here again the result is modified by the reversal of the ionisation equilibrium.

The influence of nitrous acid upon two-phase nitration has made itself felt in another way. If the initial nitrating agent contains too high a proportion of water, nitration stops before the whole of the available reacting material has been consumed. Such an effect, which is similar to the nitration threshold of Hetherington and Masson for nitrobenzene (compare p. 1186), is a natural consequence of the accumulation of water liberated during nitration with a consequent increase of the $\text{H}_2\text{O}/\text{H}_2\text{SO}_4$ ratio to a point where the speed of nitration becomes negligible. But the arrest in the nitration of DNT actually occurs at an earlier stage, because the oxidation processes accompanying the nitration (see Part IV, *loc. cit.*) produce nitrous acid, the retarding action of which is added to that of the water in bringing the reaction to a standstill.

The authors express their thanks to Professor W. E. Garner, F.R.S., in whose laboratory this work was carried out, and to the Director-General of Scientific Research (Defence) for permission to publish.

224. β -Cycloylpropionitriles. Part I. A General Synthesis and Conversion into Pyrrole Dyes.

By EDWARD B. KNOTT.

Cyclyl β -dialkylaminoethyl ketone hydrochlorides, readily obtained by the Mannich reaction, are converted to β -cycloylpropionitriles by refluxing with aqueous potassium cyanide. The nitriles on hydrolysis yield β -cycloylpropionic acids some of which are not otherwise readily available. β -Benzoylpropionitrile readily absorbs hydrogen chloride to give a crystalline chloroimide salt which on treatment with alcohol gives an alkyl β -benzoylpropimino-ether hydrochloride. The latter, also formed by the conventional method, gives with hot alcoholic ethyl orthoformate, red 3:3'-pyrromethin and with β -ethoxyacetaldehyde acetal, a blue 3:3'-pyrrotrimethin dye.

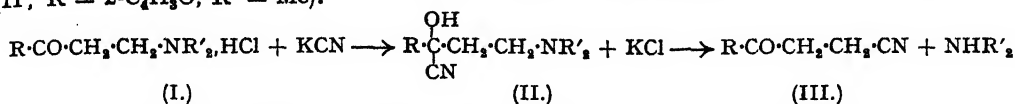

THE preparation of β -cycloylpropionic acids is normally achieved by a Friedel-Crafts condensation of an unsaturated carbocycle or heterocycle with succinic anhydride. This method gives positive results with most suitable carbocyclic and stable heterocyclic compounds. The same acids can also be prepared from the cyclyl bromomethyl ketone by condensation with ethyl sodiomalonate followed by hydrolysis and decarboxylation. Both of these methods fail, however, when the cyclic component is relatively unstable. Thus furan or 2-bromoacetylfuran gave only tars when submitted to either of the above processes. Since β -2-furoylpropionic acid was required, an alternative method of preparation was sought.

One method would be by the hydrolysis of β -2-furoylpropionitrile if such a compound were readily available. No general method for the preparation of β -cycloylpropionitriles has been developed, although one such nitrile, β -benzoylpropionitrile (β -cyanopropiophenone) was prepared by Allen, Gilbert, and Young (*J. Org. Chem.*, 1937, 2, 227) by the addition of hydrogen cyanide to phenyl vinyl ketone.

It is well known (Mannich and Hönig, *Arch. Pharm.*, 1927, 265, 598) that cyclyl β -dialkylaminoethyl ketones vary in their stability and that many of them, on steam distillation, lose dialkylamine to give cyclyl vinyl ketones. It is also known (Reichert and Posemann, *ibid.*, 1937, 275, 67) that Mannich salts react with sodionitromethane to give γ -nitrobutyrophenones. It appeared fruitful, therefore, to investigate the action of alkali cyanides on Mannich salts, since such alkalis should release the Mannich bases, and under certain conditions the latter, by loss of dialkylamine followed by hydrogen cyanide addition, might be converted into the desired nitriles.

It has been reported (Mannich and Braun, *Ber.*, 1920, 53, 1874) that the Mannich salt obtained from cyclohexanone on treatment with aqueous potassium cyanide yields a cyanohydrin of the Mannich base. The β -dialkylaminopropiophenone hydrochlorides (I; R = Ph) which were chosen for model experiments also gave oils on the addition of aqueous potassium cyanide. These are believed to be the cyanohydrins (II; R = Ph) but they readily decomposed on attempted distillation and were not analysed. The product from 2-furyl β -dimethylamino ethyl ketone hydrochloride (I; R = 2-C₄H₃O) and cold aqueous potassium cyanide, however,

was obtained crystalline and found to be 2-furyl β -dimethylaminoethyl ketone cyanohydrin (II; R = 2-C₄H₃O, R' = Me).

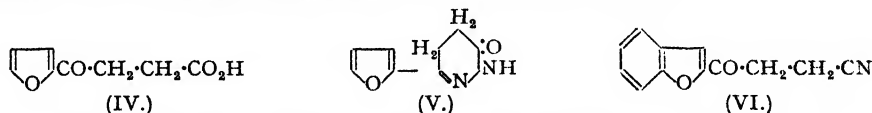

The decomposition of (II; R = Ph), with or without its isolation, was readily brought about by short heating under reflux in water, preferably in the presence of excess alkali cyanide. Dialkylamine was evolved, and β -benzoylpropionitrile formed in reasonably good yield. The yield and the state of purity of the crude product, as well as the optimal reaction time, depended primarily on the concentration of the aqueous cyanide. The greater the dilution the purer was the product, and up to a point the higher the yield. Too great a dilution lowered the yield, owing to the solubility of the nitrile in water. Replacement of water as solvent by aqueous alcohol, and other combinations, always gave lower yields.

The application of this method to other salts (I; R = aryl, or 2-thienyl) gave similar yields of nitrile. β -2-Furoylpropionitrile is much more soluble than the other nitriles and must be extracted from the reaction mixture. 2-Benzfuryl β -cyanoethyl ketone (VI) was also obtained by this method. The reaction appears to be fairly general and the only exception amongst the salts used involved 3-nitro- β -dimethylaminopropiophenone hydrochloride. This salt, the base of which is known to be very unstable, readily releasing amine and formaldehyde (Mannich and Dannehl, *Arch. Pharm.*, 1938, 276, 206), gave only resins with potassium cyanide. 1-Naphthyl β -dimethylaminoethyl ketone hydrochloride, which decomposed rapidly on heating in aqueous solution, gave the expected nitrile only when a large excess of cyanide was present.

The reaction applied to *p*-chloro- β -dimethylaminopropiophenone hydrochloride gave only a 16.5% yield of the required nitrile and a second solid, analysis of which indicated the empirical formula C₁₈H₁₅O₂NCl₂. It formed a monophenylhydrazone and was decomposed to an oil by boiling 18% hydrochloric acid. The simplest substance of this composition, *viz.*, Cl·C₆H₄·CO·CH₂·CH₂·C(NH)·CH₂·CH·CO·C₆H₄Cl, would be formed by addition of the intermediate *p*-chlorophenyl vinyl ketone to the *p*-chlorobenzoylpropionitrile, giving 4-imino-1 : 7-diketo-1 : 7-di-*p*-chlorophenylhept-2-ene.

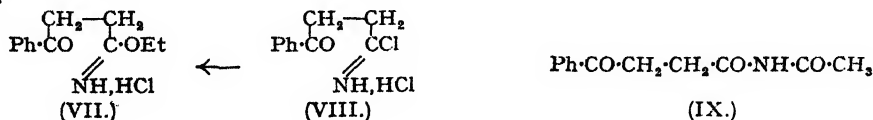

This method of preparation of the nitriles appears to apply only where R' is alkyl. Such Mannich salts obtained by the substitution of dialkylamines by piperidine or morpholine do not decompose under the conditions employed here. Similarly, Mannich salts from cyclic ketones or propiophenone gave only oils or resins on similar treatment.

In all cases the nitrile was readily hydrolysed to the β -cycloylpropionic acid (cf. Allen *et al.*, *loc. cit.*). β -2-Furoylpropionic acid (IV) resembles β -benzoylpropionic acid in its melting point and physical appearance. It was characterised by its ethyl ester and its conversion into 3-keto-6-(2'-furyl)-2 : 3 : 4 : 5-tetrahydropyridazine (V) by hydrazine hydrate.

On treating an alcoholic solution of β -benzoylpropionitrile with hydrogen chloride, ethyl β -benzoylpropimino-ether hydrochloride (VII) was obtained, the base of which is crystalline but not very stable; (VII) was also obtained by treating the nitrile with hydrogen chloride in dry benzene and dissolving the resulting, crystalline chloroimide salt (VIII) in ethyl alcohol. The chloroimide fumed strongly in air, slowly releasing hydrogen chloride to give the original nitrile. It was decomposed by water to give chiefly the original nitrile together with some β -benzoylpropionamide.

On warming (VII) with 18% hydrochloric acid, ethyl β -benzoylpropionate was formed in quantitative yield, whilst its base, on heating with acetic anhydride, gave the expected N- β -benzoylpropionylacetamide (IX). The corresponding imino-ether salts from β -4-methoxybenzoylpropionitrile and β -4-hydroxybenzoylpropionitrile are very sensitive to moisture, and on dissolving in 99% alcohol were converted into β -4-methoxy- and β -4-hydroxybenzoylpropionamides.

ethyl alcohol. A sample was obtained as glistening plates, m. p. 192°, from ethyl alcohol, in which it is sparingly soluble (Found: N, 6.2; Cl, 15.2. $C_{11}H_{11}O_2NCl$ requires N, 6.1; Cl, 15.45%).

4-Bromo- β -dimethylaminopropiophenone Hydrochloride (I; R = 4-BrC₆H₄).—*p*-Bromoacetophenone (25 g.), dimethylamine hydrochloride (12 g.), paraformaldehyde (4.5 g.), concentrated hydrochloric acid (0.5 c.c.), and ethyl alcohol (30 c.c.) were refluxed together for 2 hours, then chilled, and acetone (50 c.c.) added; the salt (17.9 g.; 49%) crystallised, and formed jagged needles, m. p. 196°, from ethyl alcohol (Found: N, 4.7. $C_{11}H_{11}ONClBr$ requires N, 4.8%).

2-Benzfuryl β -Dimethylaminoethyl Ketone Hydrochloride (I; R = 2-benzfuryl).—2-Acetylbenzofuran (34 g.) (Stoermer and Schäfer, *Ber.*, 1903, **36**, 2863), dimethylamine hydrochloride (17.3 g.), paraformaldehyde (7.2 g.), and ethyl alcohol (100 c.c.) were refluxed together for 2 hours. The clear solution was concentrated to half its volume, acetone (200 c.c.) added, and the mixture chilled. The crystals (21 g.; 39%) were washed with acetone and obtained as tiny needle rosettes (Found: N, 5.15; Cl, 13.5. $C_{15}H_{15}O_2NCl$ requires N, 5.5; Cl, 14.0%), m. p. 188°, from ethyl alcohol. The filtrates gave unchanged acetylbenzofuran (16.5 g.) on dilution with water.

α -Dimethylaminomethylpropiofenone Hydrochloride.—Propiophenone (134 g.), dimethylamine hydrochloride (106 g.), paraformaldehyde (40 g.), concentrated hydrochloric acid (2 c.c.) and ethyl alcohol (160 c.c.) were heated under reflux for 2 hours. After cooling, ether was added to precipitate an oil, which solidified on shaking (184 g.; 81%). It formed tiny needles, m. p. 142.5°, from ethyl alcohol-ether (Found: N, 6.35. $C_{11}H_{11}ONCl$ requires N, 6.15%).

β -Benzoylpropionitrile (III; R = Ph).—(a) β -Dimethylaminopropiophenone hydrochloride (213.5 g.; 1 mol.) (*Org. Synth.*, **23**, 30) and potassium cyanide (130 g.; 2 mols.) were placed in a flask and boiling water (2600 c.c.) added rapidly. The whole, consisting of an aqueous and an oily layer, was refluxed for 30 minutes. Part of the dimethylamine distilled and was collected in dilute hydrochloric acid. On chilling, the oil crystallised, and crystals formed from the aqueous layer. The nitrile (67% yield) formed almost colourless blades, m. p. 76°, from benzene-light petroleum (Found: C, 75.2; H, 5.85; N, 8.6. Calc. for C₁₀H₉ON: C, 75.5; H, 5.65; N, 8.8%). Allen *et al.* (*loc. cit.*) give m. p. 76° from ethyl alcohol.

(b) Crude β -diethylaminopropiophenone hydrochloride contaminated with diethylamine hydrochloride (900 g.) was obtained by refluxing for 2 hours a mixture of acetophenone (422 g.), diethylamine hydrochloride (500 g.), paraformaldehyde (138 g.), concentrated hydrochloric acid (7 c.c.), and ethyl alcohol (280 c.c.) and adding dry ether to the cooled reaction mixture until no more solid precipitated. The crude salt (24.1 g.), potassium cyanide (13 g.), and boiling water (520 c.c.) were refluxed for 20 minutes, and the nitrile, m. p. 76°, isolated and purified as under (a). The yield of nitrile was 48% based on the diethylamine hydrochloride.

β -*p*-Toluyloxypropionitrile (II; R = *p*-MeC₆H₄).— β -Dimethylamino-4-methylpropiophenone hydrochloride (22.7 g.; 0.1 mol.), potassium cyanide (13.0 g.; 0.2 mol.), and boiling water (520 c.c.) were refluxed for 20 minutes. The crystalline nitrile (9.0 g.; 52%) obtained on chilling formed glossy needles, m. p. 76°, from ethyl alcohol (Found: N, 8.15. $C_{11}H_{11}ON$ requires N, 8.2%).

β -*p*-Chlorobenzoyloxypropionitrile (II, R = *p*-ClC₆H₄).— β -Chloro- β -dimethylaminopropiophenone hydrochloride (124 g.) (Dhont and Wibaut, *Rec. Trav. chim.*, 1944, **63**, 81), potassium cyanide (65 g.), and boiling water (2600 c.c.) were refluxed together for 30 minutes. On chilling, the oil solidified. It was washed, and dissolved in ethyl alcohol. On cooling, the nitrile (16 g., 16.5%) crystallised. It formed flat, colourless needles, m. p. 72.5°, from ethyl alcohol (Found: N, 7.35. $C_{10}H_8ONCl$ requires N, 7.25%). The primary filtrate on prolonged standing gave a second solid (18.0 g.) which was obtained as fine white needles, m. p. 115°, from ethyl alcohol (Found: C, 63.35; H, 4.3; N, 3.95; Cl, 19.45. $C_{10}H_8O_2NCl_2$ requires C, 63.35; H, 4.15; N, 3.9; Cl, 19.7%). Its monophenylhydrazones formed pale yellow, feathery needles, m. p. 146–148°, from alcohol (Found: N, 8.95. $C_{28}H_{21}ON_3Cl_2$ requires N, 9.35%). The filtrates from the second crystallisation, on concentration, gave a further crop of nitrile (14.4 g.), m. p. 72.5°, so the total yield of the required nitrile was 31.5%. It was readily hydrolysed to β -*p*-chlorobenzoylpropionic acid, m. p. 134° (Skraup and Schwamberger, *Annalen*, 1928, **462**, 135, give m. p. 134°).

β -*p*-Bromobenzoyloxypropionitrile (II; R = *p*-BrC₆H₄).— β -Bromo- β -dimethylaminopropiophenone hydrochloride (14.6 g.), potassium cyanide (6.5 g.), and boiling water (130 c.c.) were refluxed for 20 minutes. On chilling, the oil crystallised. The nitrile (7.2 g.; 62.5%) formed tiny needles, m. p. 81°, from ethyl alcohol (Found: N, 5.65. $C_{10}H_8ONBr$ requires N, 5.9%).

β -*p*-Bromobenzoylpropionic Acid.—The nitrile (1 g.) was refluxed for 1 hour with concentrated hydrochloric acid (10 c.c.), and the acid which crystallised on cooling was dissolved in aqueous sodium carbonate, and the solution filtered and acidified. The acid formed colourless needles, m. p. 148°, from water (Found: Br, 31.2. $C_{10}H_8O_3Br$ requires Br, 31.1%).

β -3-Hydroxybenzoyloxypropionitrile (III; R = 3-OH-C₆H₄).— β -Dimethylamino-3-hydroxypropiophenone hydrochloride (41 g.), potassium cyanide (23.2 g.), and boiling water (900 c.c.) were refluxed for 30 minutes. The chilled liquor gave on acidification with acetic acid an oil which slowly solidified. It crystallised as needles, m. p. 98°, from aqueous alcohol (Found: N, 8.2. $C_{10}H_9O_2N$ requires N, 8.0%). The acid, obtained by refluxing the nitrile (2 g.) with 18% hydrochloric acid (20 c.c.), for 1 hour, formed irregular plates, m. p. 146.5°, from water (Found: C, 61.75; H, 5.0. $C_{10}H_{10}O_4$ requires C, 61.85; H, 5.15%).

β -4-Hydroxybenzoyloxypropionitrile (III; R = 4-OH-C₆H₄).—Prepared as for the 3-isomer, this nitrile was precipitated as a crystalline solid on the addition of acetic acid to the reaction mixture. It was obtained as colourless, flat needles, m. p. 162°, from a little ethyl alcohol in 59% yield (Found: C, 68.35; H, 5.35; N, 7.95. $C_{10}H_9O_2N$ requires C, 68.55; H, 5.15; N, 8.0%). The acid formed colourless needles, m. p. 157°, from hot water. Fieser *et al.* (*J. Amer. Chem. Soc.*, 1940, **62**, 2966) give m. p. 154–156° (Found: C, 61.55; H, 5.05. Calc. for C₁₀H₁₀O₄: C, 61.85; H, 5.15%).

β -3-Methoxybenzoyloxypropionitrile (III; R = 3-MeO-C₆H₄).— β -Dimethylamino-3-methoxypropiophenone hydrochloride (12.2 g.; 0.05 mol.), potassium cyanide (13 g.; 0.2 mol.), and boiling water (520 c.c.) were refluxed for 10 minutes. On chilling, the oil crystallised. It formed colourless needles, m. p. 54°.

in 73% yield from methyl alcohol by repeated concentration of the filtrates (Found: N, 7.2. $C_{11}H_{11}O_2N$ requires N, 7.4%). The acid was obtained on hydrolysis of the nitrile with 18% hydrochloric acid as colourless needles, m. p. 108°, from water (Found: C, 63.2; H, 5.95. $C_{11}H_{11}O_4$ requires C, 63.45; H, 5.75%).

β -4-Methoxybenzoylpropionitrile (III; R = 4-MeO-C₆H₄).— β -Dimethylamino-4-methoxypropionophenone hydrochloride (24.35 g.; 0.1 mol.), obtained in 86% yield by the method given for the unsubstituted product (*Org. Synth.*, 23, 31) (cf. Mannich and Lammering, *Ber.*, 1922, 55, 3510), potassium cyanide (13.0 g.; 0.2 mol.), and boiling water (520 c.c.) were refluxed for 20 minutes and chilled. The nitrile was obtained as glassy needles, m. p. 95°, from ethyl alcohol in 71% yield (Found: C, 69.6; H, 5.7; N, 7.65. $C_{11}H_{11}O_2N$ requires C, 69.85; H, 5.8; N, 7.4%). The acid had m. p. 144°, alone, and mixed with a specimen prepared from anisole and succinic anhydride (Poppenberg, *Ber.*, 1901, 34, 5257).

β -3:4-Dimethoxybenzoylpropionitrile (II, R = (MeO)₂C₆H₃).— β -Dimethylamino-3:4-dimethoxypropionophenone hydrochloride (21 g.) (Mannich and Lammering, *loc. cit.*), potassium cyanide (10 g.), and boiling water (400 c.c.) were refluxed for 20 minutes. The nitrile (13.3 g., 85%) was obtained as glassy needles, m. p. 118°, from ethyl alcohol (Found: N, 6.5. $C_{12}H_{13}O_4N$ requires N, 6.4%).

β -1-Naphthoylpropionitrile (III; R = 1-C₁₀H₇).—1-Naphthyl β -dimethylaminoethyl ketone hydrochloride (5 g.; 1 mol.), potassium cyanide (5.0 g.; 4 mols.), and boiling water (200 c.c.) were refluxed for 30 minutes. The solid obtained on chilling (1.7 g.; 42.5%) formed tiny needle rosettes, m. p. 113–114°, from methyl alcohol (Found: C, 79.8; H, 5.3; N, 6.9. $C_{14}H_{11}ON$ requires C, 80.4; H, 5.25; N, 6.7%).

β -2-Naphthoylpropionitrile (III; R = 2-C₁₀H₇).—2-Naphthyl β -dimethylaminoethyl ketone hydrochloride (50 g.) (Blicke and Maxwell, *J. Amer. Chem. Soc.*, 1942, 64, 431), potassium cyanide (50 g.), and boiling water (1 l.) were refluxed for 30 minutes. The nitrile (15.1 g., 38%), obtained on chilling, formed clusters of yellow needles, m. p. 114°, from ethyl alcohol (Found: N, 6.65%).

2-Furyl β -Dimethylaminoethyl Ketone Cyanohydrin (II; R = 2-C₄H₃O, R' = Me).—2-Furyl β -dimethylaminoethyl ketone hydrochloride (8.15 g.; 0.04 mol.) (Levy and Nisbet, *J.*, 1938, 1055) was dissolved in cold water (5 c.c.), and a solution of potassium cyanide (5.2 g.; 0.08 mol.) in water (10 c.c.) added. Colourless crystals of the cyanohydrin separated. It formed colourless needles, m. p. 45°, from ligroin (Found: C, 62.2; H, 7.2; N, 14.3. $C_{10}H_{11}O_2N_2$ requires C, 62.0; H, 7.2; N, 14.45%).

β -2-Furoylpropionitrile (III; R = 2-C₄H₃O).—2-Furyl β -dimethylaminoethyl ketone hydrochloride (81.5 g.; 0.4 mol.), potassium cyanide (52 g.; 0.8 mol.), and boiling water (2850 c.c.) were refluxed for 30 minutes, and the clear orange liquor was cooled and extracted 4 times with chloroform (100 c.c.). The dried (Na₂SO₄) extract was freed from chloroform to give a brown oil (32 g.; 57%) which crystallised completely. It formed colourless needles, m. p. 74–76°, from ethyl alcohol after treatment with charcoal (Found: C, 64.65; H, 4.65; N, 9.45. $C_8H_7O_2N$ requires C, 64.5; H, 4.7; N, 9.4%).

β -2-Furoylpropionic Acid (IV).—The nitrile (2 g.) was refluxed for 1 hour with 18% hydrochloric acid (20 c.c.), charcoal was added, and after a further 10 mins. refluxing the liquor was diluted with water (50 c.c.), filtered, and the light yellow solution concentrated. The acid (2.1 g., 93%) separated as yellow grains. It had m. p. 115° and was pure. On recrystallising from hot water it was obtained as almost colourless, glistening flakes, m. p. 115°, lowered to 106° with previous softening on repeated crystallisation (Found: C, 57.25; H, 4.75. $C_8H_7O_4$ requires C, 57.15; H, 4.75%).

The acid (2 g.) was boiled for 15 minutes with 10% ethyl-alcoholic sulphuric acid (10 c.c.), cooled, and poured into water. The precipitated oil crystallised rapidly. The ethyl ester formed glistening, colourless plates, m. p. 52–53°, from aqueous alcohol (Found: C, 61.05; H, 5.95. $C_{10}H_{12}O_4$ requires C, 61.2; H, 6.1%).

3-Keto-6-(2'-furyl)-2:3:4:5-tetrahydropyridazine (V).— β -2-Furoylpropionic acid (1.68 g.; 0.01 mol.), aqueous hydrazine hydrate (1 c.c. of 85%), and ethyl alcohol (5 c.c.) were refluxed for 1 hour, then diluted with water (100 c.c.). The pyridazine which separated formed yellow, glassy needles, m. p. 145°, from ethyl alcohol (Found: C, 58.8; H, 4.7; N, 17.0. $C_8H_8O_2N_2$ requires C, 58.55; H, 4.9; N, 17.1%).

β -2-Thienoylpropionitrile (III; R = 2-C₄H₃S).—2-Thienyl β -dimethylaminoethyl ketone hydrochloride (2.2 g.; 0.01 mol.) (Blicke and Burckhalter, *J. Amer. Chem. Soc.*, 1942, 64, 453), potassium cyanide (1.3 g.; 0.02 mol.), and boiling water (52 c.c.) were heated under reflux for 20 minutes. On cooling, the nitrile (0.7% yield) crystallised. It formed colourless needles, m. p. 66°, from benzene-light petroleum (Found: N, 8.4; S, 19.2. C_8H_7ONS requires N, 8.5; S, 19.45%). The acid, obtained on hydrolysis of the nitrile, formed flat needles, m. p. 120°, alone, and mixed with a specimen prepared from thiophen and succinic anhydride (Fieser and Kenelly, *J. Amer. Chem. Soc.*, 1935, 57, 1615) (Found: S, 17.3. Calc. for $C_8H_7O_2S$: S, 17.4%).

2-Benzofuryl β -Cyanooethyl Ketone (VI).—2-Benzofuryl β -dimethylaminoethyl ketone hydrochloride (5.07 g.), potassium cyanide (5.2 g.), and boiling water (130 c.c.) were refluxed for 10 minutes. The hot aqueous layer was decanted from an oil which thickened on chilling. The chilled aqueous layer deposited a mass of crystals which formed colourless needles, m. p. 110–111°, after repeated recrystallisation from methyl alcohol, in 21% yield. The oil was not investigated further (Found: N, 6.9. $C_{12}H_{13}O_2N$ requires N, 7.05%). The acid formed faintly yellow needles, m. p. 148°, from hot water (Found: C, 65.75; H, 4.55. $C_{12}H_{13}O_4$ requires C, 66.05; H, 4.6%).

Chloroimide from β -Benzoylpropionitrile (VIII).—The nitrile (10 g.) and dry benzene (50 c.c.) were cooled in ice, and a rapid stream of dry hydrogen chloride passed into the suspension. The solid dissolved, and crystals soon commenced to separate. After 30 minutes the solid was collected, washed with dry ether, and dried rapidly in a vacuum. The chloroimide salt (7.2 g.) formed pale yellow leaflets, m. p. 99° (efferv.) (Found, for the freshly prepared substance: C, 52.0; H, 4.95; N, 6.35; Cl, 29.6. $C_{10}H_{11}ONCl_2$ requires C, 51.75; H, 4.75; N, 6.05; Cl, 30.55%). On standing over aqueous potassium hydroxide for 14 days the original nitrile, m. p. 76°, was recovered.

Ethyl β -Benzoylpropimino-ether Hydrochloride (VII).—(a) The nitrile (25 g.) was suspended in ethyl alcohol (50 c.c.), and a rapid stream of dry hydrogen chloride was passed into the suspension cooled in ice. The temperature rose to 40°, the solid dissolved, and a deep yellow colour developed. When

saturated, the solution was left to stand for 1 hour, and the salt was precipitated by addition of dry ether. It formed colourless needles, m. p. 130°, in 60% yield after recrystallisation from cold ethyl alcohol-ether. The yield was not improved by keeping the reaction temperature below 10° (Found: C, 58.95; H, 6.7; N, 5.95; Cl, 14.55. $C_{12}H_{10}O_2NCl$ requires C, 59.5; H, 6.65; N, 5.8; Cl, 14.7%).

(b) The chloroimide hydrochloride (VIII) was dissolved in a minimum of hot ethyl alcohol, chilled immediately, and (VII) precipitated as colourless needles, m. p. 130°, by the addition of ether.

The base was obtained as an oil on adding aqueous sodium carbonate to an aqueous solution of the salt. It solidified rapidly and was obtained as colourless, glassy crystals, m. p. 60°, from light petroleum. The crystals turned magenta on keeping (Found: C, 70.4; H, 7.2; N, 7.05. $C_{12}H_{10}O_2N$ requires C, 70.5; H, 7.2; N, 6.85%).

Methyl β -Benzoylpropimino-ether Hydrochloride.—This salt was obtained from (VIII), in the same way as the ethyl homologue, by using methyl alcohol as solvent. It formed colourless needles, m. p. 127°, from methyl alcohol-ether (Found: Cl, 15.55. $C_{11}H_{10}O_2NCl$ requires Cl, 15.6%).

Ethyl β -4-Methoxybenzoylpropimino-ether Hydrochloride.— β -4-Methoxybenzoylpropionitrile (5 g.) and ethyl alcohol (10 c.c.) were treated with dry hydrogen chloride whilst cooling in ice. Precipitation of the salt commenced after a short time and was completed by addition of dry ether. It (5.5 g., 77%) was dissolved in absolute alcohol, the solution saturated with hydrogen chloride, and the salt reprecipitated by ether. It formed colourless needles, m. p. 133° (effervescence) (Found: Cl, 12.1. $C_{13}H_{14}O_3NCl$ requires Cl, 13.1%). On dissolving the salt in alcohol containing 1% water, β -4-methoxybenzoylpropionamide separated. It formed glistening plates or flat needles, m. p. 136°, from ethyl alcohol (Found: C, 63.95; H, 6.2; N, 6.55. $C_{11}H_{12}O_3N$ requires C, 63.75; H, 6.35; N, 6.75%).

β -4-Hydroxybenzoylpropionamide.—The imino-ether hydrochloride prepared analogously from β -4-hydroxybenzoylpropionitrile was dissolved in ethyl alcohol containing 1% of water, and on cooling the amide separated. It formed colourless irregular crystals, m. p. 218° (blue at 210°), from ethyl alcohol (bluish solution) (Found: N, 7.8. $C_{10}H_{11}O_3N$ requires N, 7.5%).

Decomposition of (VII).—(a) The hydrochloride (VII) (3.9 g.) was refluxed in absolute alcohol (20 c.c.) for 30 minutes. The solution turned orange, and ammonium chloride (0.4 g.) separated. On concentration a further crop (0.2 g.) separated. This represented 70% of the total nitrogen. The residue gave an oil on dilution with water, which solidified almost completely. It formed long, orange needles, m. p. 150° (0.6 g.), from ethyl alcohol (Found: C, 76.0; H, 6.1; N, 4.9%).

(b) The same hydrochloride (10 g.) was dissolved in concentrated hydrochloric acid (10 c.c.) and water (20 c.c.), and warmed on the steam-bath. The oil which slowly separated was taken up in ether, dried, and distilled. It (7.5 g.) had b. p. 165°, and was ethyl β -benzoylpropionate (Found: C, 69.6; H, 7.0. Calc. for $C_{13}H_{14}O_3$: C, 70.0; H, 6.8%).

N- β -Benzoylpropionylacetamide (IX).—Ethyl β -benzoylpropimino-ether (1 g.) and acetic anhydride (10 c.c.) were heated for 2 hours on the steam-bath. On decomposition with water, an oil was obtained which partly crystallised. It formed colourless, silky needles, m. p. 139–140°, from ethyl alcohol (Found: C, 65.9; H, 6.0; N, 6.3. $C_{12}H_{13}O_3N$ requires C, 65.75; H, 5.95; N, 6.4%).

Bis-3-(2-ethoxy-5-phenylpyrrole)methin Hydrochloride (X; n = 0).—Ethyl β -benzoylpropimino-ether hydrochloride (4.83 g.; 0.02 mol.), ethyl orthoformate (5.92 g.; 0.04 mol.), and 99% ethyl alcohol (10 c.c.) were refluxed for 15 minutes, by which time the whole had solidified to a mass of red needles. From ethyl alcohol this formed bright red needles, m. p. 175–176°, turning bronze on contact with air (Found: C, 71.2; H, 5.9; N, 6.95; Cl, 8.65. $C_{22}H_{25}O_2N_2Cl$ requires C, 71.5; H, 5.95; N, 6.65; Cl, 8.45%). Its absorption maximum in methyl alcohol lies at 4700 Å. After standing in contact with moist air for 48 hours it shows no absorption peak. Its sodium hydroxide-methyl alcohol solution also give a maximum absorption at 4700 Å. and an absorption curve almost identical with that of the freshly prepared dye in neutral or acid solution. The mother-liquor, freed from dye, deposited yellow needles, m. p. 150°, identical with the product obtained by heating the starting material in ethyl alcohol.

Bis-3-(2-methoxy-5-phenylpyrrole)methin Hydrochloride.—Prepared in the same way as the ethoxy-analogue, but with methyl alcohol as solvent, the dye formed red needles, m. p. 176° (for the freshly prepared substance; 163–164°, after standing in air for 1 hour), on recrystallisation from methyl alcohol (Found: Cl, 9.0. $C_{22}H_{21}O_3N_2Cl$ requires Cl, 9.05%).

Bis-3-(2-ethoxy-5-4'-methoxyphenylpyrrole)methin Hydrochloride.—Ethyl β -4-methoxybenzoylpropimino-ether hydrochloride (2.7 g.), ethyl orthoformate (3.0 g.), and ethyl alcohol (25 c.c.) were refluxed for 30 minutes. The red solution had, by this time, become brown, owing to complete crystallisation of the dye. It is very insoluble and was purified by boiling with *n*-butyl alcohol for 15 minutes and collecting whilst hot. It formed green crystals, m. p. 266° (Found: N, 6.05; Cl, 7.65. $C_{27}H_{29}O_4N_2Cl$ requires N, 5.8; Cl, 7.35%).

Bis-3-(2-ethoxy-5-phenylpyrrole)trimethin Hydrochloride (X; n = 1).—Ethyl β -benzoylpropimino-ether hydrochloride (2.4 g.; 2 mols.), β -ethoxyacetaldehyde acetal (0.8 g.; 1 mol.), and ethyl alcohol (10 c.c.) were refluxed for 10 minutes. The blue solution had then deposited crystals of the dye. They (0.4 g.) were collected after cooling and obtained as green crystals, m. p. 162°, from ethyl alcohol (Found: C, 72.65; H, 6.05; N, 6.0; Cl, 7.55. $C_{27}H_{29}O_4N_2Cl$ requires C, 72.55; H, 6.05; N, 6.25; Cl, 7.95%). In moist methyl alcohol the dye shows a maximum absorption at 4750–4800 Å.; in methyl alcohol containing a little concentrated hydrochloric acid the maximum lies at 6050 Å.; in methyl alcohol containing a little aqueous sodium hydroxide the maximum is also at 6050 Å. but fades rapidly.

225. β -Cycloylpropionitriles. Part II. Conversion into Bis-2-(5-cyclopyrrole)azamethin Salts.

By EDWARD B. KNOTT.

The blue dyes obtained by heating β -cycloylpropionitriles with hydroxylamine salts are salts of bis-2-(5-cyclopyrrole)azamethin (II; R = cyclyl, R' = H). One of the dyes (II; R = Ph, R' = H) was also prepared from α -cyano- β -benzoylpropionic acid and hydroxylamine hydrochloride. Bis-2-(3:5-diphenylpyrrole)azamethin (II; R = R' = Ph) (Rogers, *J.*, 1943, 590) was prepared similarly from β -benzoyl- α -phenylpropionitrile. The new dyes exhibit remarkable colour reactions with concentrated sulphuric acid.

THE remarkable stability of the 2-bis-(3:5-diarylpyrrole)azamethins (II; R = R' = aryl), discovered by Rogers (*loc. cit.*; B.P. 544,101) and less accurately named 2:2':4:4'-tetra-aryldipyrroazamethins by him, prompted the search for similarly constituted products, simpler in nature and of higher general solubility.

One of the methods employed by Rogers for the preparation of the above dyes consisted in heating β -aroyl- α -arylpropionitriles (I; R, R' = aryl) with ammonium formate in the presence of air, whilst Davies and Rogers (*J.*, 1944, 126) heated the same nitriles with formamide to obtain formylated 2-amino-3:5-diarylpyrroles, which can be used as intermediates for the above dyes. Although Rogers had not treated the simple β -aroylpropionitriles (I; R = aryl, R' = H) with either reagent in the expectation of obtaining dyes (II; R = aryl, R' = H), he had found that γ -nitrobutyrophenone gave no dye of this type under conditions which, when applied to γ -nitro- β -arylbutyrophenones, gave good yields of dye (II; R, R' = aryl).

Since a variety of β -cycloylpropionitriles were readily available by the method described in Part I (preceding paper), an investigation of their possible use as intermediates was undertaken.

On heating β -benzoylpropionitrile with ammonium formate in the presence of air at various temperatures, no trace of dye formation could be observed, nor could any formylated 2-amino-5-phenylpyrrole be isolated from a formamide melt. These negative results thus fell into line with the behaviour of γ -nitrobutyrophenone (Rogers, *loc. cit.*). It appeared, therefore, that dye formation required, not only a β -aroyl group in the starting nitrile (where R = Me, R' = aryl, no dye was formed; Rogers, *loc. cit.*, p. 595), but also an α -substituent (aryl?).

It is known, however (Biedermann, *Ber.*, 1891, 24, 4071; Tiemann, *ibid.*, p. 4077), that β -benzoylpropionamide (III; R = Ph) shows a tendency on fusion or dissolution to give a blue coloration, and this was also observed (see Part I) on melting or recrystallising β -*p*-hydroxybenzoylpropionamide. It was also noticed that, in attempting to form the amidine from ethyl β -benzoylpropimino-ether hydrochloride (IV; R = Ph) by solution in alcoholic ammonia and also on boiling (IV) with aqueous ammonia, a blue colour developed. There seemed, therefore, the possibility that this colour could be attributed to the formation of dyes of type (II; R' = H).

It is also known (Klobb, *Ann. Chim. Phys.*, 1897, 10, 184; Bougault, *ibid.*, 1908, 15, 504) that α -cyano- β -benzoylpropionic acid (I; R = Ph, R' = CO₂H) gives a blue dye on evaporation of solutions of its salts or on acidification of an alkaline solution of the acid which has been in contact with air. Klobb also reported that the dye could be sublimed with some decomposition, the vapours being red. This stability to heat is possessed to a greater degree by Rogers's dyes. It seemed therefore possible that this dye also might belong to type (II), in which R' is a carboxyl group.

Attempts to prepare and purify the dyes from (III) or (IV) in sufficient quantities for analysis were unsuccessful, but the dye from (I; R = Ph, R' = CO₂H) was obtained in a small amount. It was insoluble in strong alkalis, but dissolved in concentrated sulphuric acid to give a pale yellow-green solution which gave blue flocks on pouring into water. In aqueous pyridine it was decolorised by sodium dithionite. It was almost insoluble in most

solvents but dissolved in nitrobenzene or pyridine giving a magenta solution. Analysis suggested the formula $C_{20}H_{14}O_2N_2$, which rules out the possibility of its belonging to the dipyrroazamethin class of dye. It is also readily prepared in low yield from β -benzoylpropionamide by a different method, and the proposed structure and mechanism of formation are discussed later. The non-identity of these dyes with dipyrroazamethins was disappointing, and work on the preparation of (II; $R' = H$) was about to be abandoned when, by chance, an unusual reaction was observed. Whilst engaged on the preparation of various derivatives of the β -aroylpropionitriles (I; $R' = H$) for their characterisation, difficulty was encountered in the formation of their oximes. Thus, β -benzoylpropionitrile (I; $R = Ph$, $R' = H$) failed to give an oxime with either hydroxylamine acetate or the base itself on refluxing in ethyl alcohol, most of the original nitrile being recovered unchanged. On refluxing an alcoholic solution of the nitrile with hydroxylamine hydrochloride, however, the mixture darkened and a brilliant blue coloration developed. When a large excess of the hydroxylamine salt was employed the dye crystallised during the refluxing, giving an almost solid mass of needles. The dye was slightly soluble in boiling water, the solution giving an immediate precipitation of silver chloride on addition of silver nitrate. It was soluble in alcohols, acetone, and pyridine. Analysis suggested the formula $C_{20}H_{15}N_3 \cdot 2HCl$. Its alcoholic solution when poured into water gave magenta flocks soluble in alcohol to a blue solution and which on purification gave a second blue dye of the formula $C_{20}H_{15}N_3 \cdot HCl$. Attempts to isolate the base were fruitless since, although it had some stability in solution, it readily decomposed on attempted isolation. The dye salts were very stable to boiling concentrated hydrochloric acid, dissolved in concentrated sulphuric acid to give a blue solution, and were reduced to a colourless leuco-compound by sodium dithionite. The leuco-compound was reoxidised by aerial oxygen to a blue dye. The salts did not sublime on heating under reduced pressure. Apart from the last property (which might be expected of the salts) the behaviour of these dyes is similar to that of Rogers's dye (II; $R = R' = Ph$), and the analysis agrees well with their being the *dihydrochloride* and *monohydrochloride* of bis-2-(5-phenylpyrrole)azamethin (II; $R = Ph$, $R' = H$). Degradation experiments with hydriodic acid, and with an acetic anhydride-sodium acetate mixture which discharged the colour, did not lead to any definite products. Rogers (*loc. cit.*) proved the constitution of his dyes by an alternative synthesis which consisted in the condensation of 3:5-diphenylpyrrole with 2-nitroso-3:5-diphenylpyrrole. Nitrosation of 2-phenylpyrrole, however, either with nitrous acid or with alkaline amyl nitrite, failed to give a pure nitroso-derivative. The dark green solid obtained when employing nitrous acid gave a magenta dye on heating with 2-phenylpyrrole in acetic anhydride-acetic acid mixtures but not in sufficient quantities for isolation. Since 2-phenylpyrrole is readily converted into a magenta dye in the presence of mineral acids and acetic anhydride, it is possible that the green solid causes dye formation by virtue of its being a hydrochloride. Alternatively, if nitrosation occurs in the β -position, as is usual with pyrroles (cf. Fischer and Orth, "Die Chemie des Pyrrols," Vol. I, p. 104), the interaction of 4-nitroso-2-phenylpyrrole hydrochloride with 2-phenylpyrrole might well lead to a magenta dye. The structure of the dye was proved beyond reasonable doubt, however, by obtaining analogously bis-2-(3:5-diphenylpyrrole)azamethin (II; $R, R' = Ph$) from β -benzoyl- α -phenylpropionitrile and hydroxylamine hydrochloride. The reaction proceeded best in boiling butanol to give the unstable dye salt, or in ethylene glycol at 120° to give the dye base. It was also found to proceed rapidly to give a low yield of dye on using formamide as solvent. The salt rapidly lost hydrogen chloride on contact with the atmosphere. The base had all the properties of the dye prepared according to Rogers (*loc. cit.*) and analysis confirmed the identity.

The instability of the new dye base may explain the non-formation of dye on heating γ -nitrobutyrophenone and ammonium formate (Rogers, *loc. cit.*), although further attempts at dye formation by this reaction in the presence of salts such as ammonium chloride or hydroxylamine hydrochloride also failed.

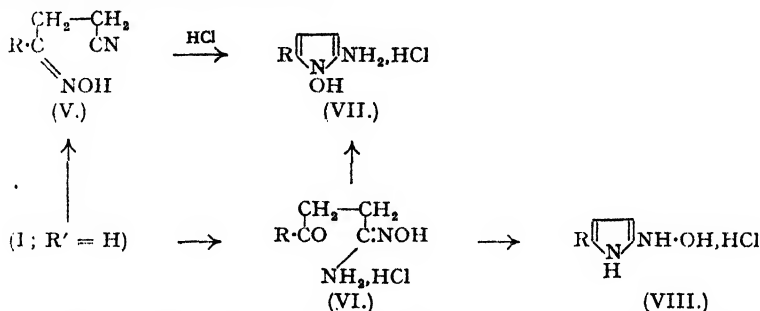

β -Benzoylpropionitrile and hydroxylamine sulphate gave bis-2-(5-phenylpyrrole)azamethin sulphate.

The reaction was then applied to a variety of β -cycloylpropionitriles in order to determine its scope. In every case β -aroylpropionitriles gave the required dye. β -2-Thienoylpropionitrile (I; $R = 2-C_4H_3S$, $R' = H$) gave the corresponding dye in low yield, but β -2-furoylpropionitrile and 2-benzofuryl 2-cyanoethyl ketone gave only brown solutions on similar treatment.

On heating α -cyano- β -benzoylpropionic acid (I; $R = Ph$, $R' = CO_2H$) with alcoholic hydroxylamine hydrochloride a blue, alkali-insoluble dye resulted. Its analysis, and physical

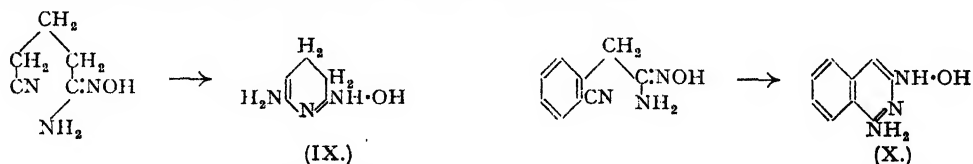

and chemical properties, showed that it was identical with the dye obtained from β -benzoylpropionitrile. The loss of carbon dioxide took place before dye formation occurred, a copious evolution being observed on heating the reactants at 95° in butenol. It is possible that the substituted pyrrole- β -carboxylic acid which may be an intermediate in the dye formation, like other such acids, is readily decarboxylated (cf. Ciamician, *Ber.*, 1880, **13**, 2235; 1881, **14**, 1054).

The mechanism of the reaction is obscure, since no intermediates could be isolated. The first stage reaction could take place in two ways, either by oxime formation (V), or by hydroxylamine addition to the nitrile group to give an amidoxime (VI). At this stage, cyclisation in two ways might occur to give either 2-amino-1-hydroxy-5-R-pyrrole (VII) or 2-hydroxylamino-5-R-pyrrole (VIII) hydrochlorides.

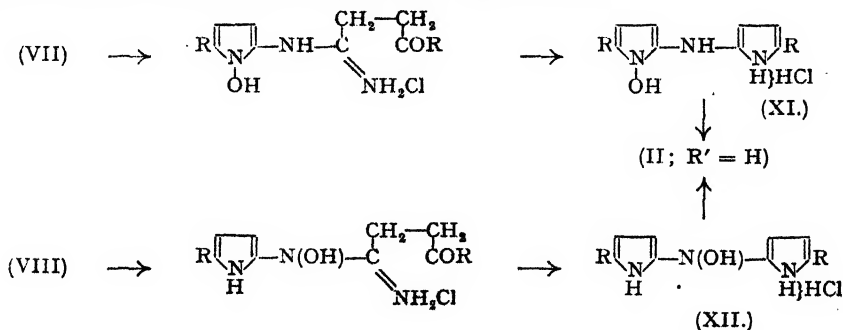

Oxime formation would appear to be the natural step, but it is significant that under no conditions could an oxime be isolated. It is well known (Nordmann, *Ber.*, 1884, **17**, 2747; Tiemann, *Ber.*, 1884, **17**, 126, 1685; 1886, **19**, 1475; 1889, **22**, 2391, 2942, etc.) that aliphatic nitriles, particularly those which are also readily hydrolysable, react with hydroxylamine or its salts to yield amidoximes. Thus the formation of (VI) is quite feasible, although under conditions used by Tiemann no product could be isolated.

There are no indications of the second-stage reaction, although it is known that γ -diketones will react with hydroxylamine to give substances analogous to (VII) (Knorr, *Annalen*, 1886, **286**, 296). It is also known that hydroxylamine will react with 1:3-dicyanopropane (Tiemann, *Ber.*, 1889, **22**, 2945; Biedermann, *ibid.*, p. 2967) or *o*-cyanobenzyl cyanide (Eichelbaum, *ibid.*, p. 2973) to give substances which are not the expected amidoximes, as they are insoluble in alkali. It is possible that cyclisation occurred, not as proposed by the above authors, but so as to give a dihydropyridine (IX) and an isoquinoline (X).

Such ring closures would then be analogous to the formation of (VIII). The third-stage reaction could proceed from either (VII) or (VIII) by addition of a further nitrile molecule followed by cyclisation and elimination of water to give the dye.

The precipitation of the dihydrochloride, which is more soluble in alcohol than the monohydrochloride, is difficult to explain, since it is unlikely that the dye is a stronger base than hydroxylamine.

Rogers (*loc. cit.*) found that 2-amino-3:5-diphenylpyrrole is readily oxidised to the azamethin, but such a mechanism for dye formation cannot be applied here, since no oxygen is present. He found also that 2-nitroso-3:5-diphenylpyrrole gives the azamethin on heating, and it is possible that (VIII) may also undergo self-condensation with the elimination of water and hydroxylamine.

All the dye salts gave similar blue solutions in organic solvents but differed in colour in the crystalline state. Striking differences, however, were shown in their behaviour towards concentrated sulphuric acid. The different colours given in hot and cold sulphuric acid and on precipitating the dye from the latter with water allow the identification of nearly all the dyes so far prepared (see Table I).

* Sulphate gave green solution.

As stated above, the dye obtained by Klobb from α -cyano- β -benzoylpropionic acid does not belong to the azamethin class. Apart from the analysis figures, the pale colour it gives in concentrated sulphuric acid is quite different from the deep colours given by (II). An alternative synthesis was found whilst experimenting with β -benzoylpropionamide with a view to the preparation of the dye observed on fusing the latter. Whereas alcoholic hydroxylamine salts did not give any dye on refluxing them with the amide, yet on replacing the alcohol by formamide and heating to 120° the latter reacted suddenly with the hydroxylamine hydrochloride (shown by separate experiment) with the evolution of ammonia, probably due to the formation of a hydroxamic acid (cf. Hoffmann, *Ber.* 1889, **22**, 2854), and a secondary reaction caused the separation of a crystalline dye. The same dye was formed in very small amounts when the hydroxylamine hydrochloride was omitted. The dye had all the properties of Klobb's dye and analysis confirmed the identity.

Insufficient data have been collected on the dye to prove its structure, but it is suggested that it belongs to the *isoindigotin* class (cf. Wahl and Bagnard, *Bull. Soc. chim.*, 1909, 5, 1039).

1914, 15, 329). Analysis agrees with its being *bis*-3-(2-*keto*-5-*phenyl*-2 : 3-*dihydropyrrolylidene*) (XIII). Its formation from (I; R = Ph, R' = CO₂H) can be explained by hydrolysis by

alkali to the amide, followed by cyclisation, decarboxylation, and oxidation, or by decarboxylation, oxidation, and cyclisation as shown. The hydroxylamine salt-formamide process involves oxidation at one stage and it is not clear how this takes place.

The same dye is also readily formed from β -benzoylpropionamide, acetamide, and hydroxylamine hydrochloride, and the β -benzoylpropionamide may be replaced by the acid or ester. Lævulic acid did not give any dye under similar conditions.

EXPERIMENTAL.

(Microanalyses are by Drs. Weiler and Strauss, Oxford; m. p.s are uncorrected.)

Bis-2-(5-phenylpyrrole)azamethin Dihydrochloride.—(a) β -Benzoylpropionitrile (15.9 g., 0.1 mol.), hydroxylamine hydrochloride (28 g., 0.4 mol.), and industrial methylated spirit (150 c.c.) were refluxed for 2 hours. After the semi-solid reaction mixture had cooled, the dye was collected and washed well with acetone. The yield of crude solid (16.2 g.) was 87.7%. The filtrate gave hydroxylamine hydrochloride (10.1 g.) on concentration. If boiling butanol is used as the solvent a magenta dye is also formed. It is readily removed, however, by washing with acetone. The dye, recrystallised from pyridine, formed purple needles of no definite m. p. (Found: C, 64.4; H, 5.05; N, 11.2; Cl, 20.2. $C_{20}H_{17}N_3Cl_2$ requires C, 64.85; H, 4.6; N, 11.35; Cl, 19.15%). The monohydrochloride was obtained as short needles from butanol or pyridine by pouring an alcoholic solution of the dihydrochloride into water (Found: C, 71.73; H, 4.8; N, 12.5; Cl, 10.5. $C_{20}H_{16}N_3Cl$ requires C, 71.95; H, 4.8; N, 12.6; Cl, 10.65%). The sulphate, obtained in low yield (37%) from the nitrile and hydroxylamine sulphate, was very insoluble in most organic solvents. It was obtained as small bronze needles (Found: N, 10.5. $C_{20}H_{17}O_4N_3S$ requires N, 10.65%).

(b) α -Cyano- β -benzoylpropionic acid hydrate (2.2 g., 0.01 mol.), hydroxylamine hydrochloride (1.4 g., 0.02 mol.), and industrial methylated spirit (10 c.c.) were refluxed for 90 minutes. The dye (1.0 g., 54%) was collected after cooling and recrystallised from pyridine. It formed alkali-insoluble purple needles (Found: C, 64.25; H, 5.0; N, 11.5%).

Bis-2-(3:5-diphenylpyrrole)azamethin.—(a) β -Benzoyl- α -phenylpropionitrile (4.7 g., 0.02 mol.), hydroxylamine hydrochloride (1.4 g., 0.02 mol.), and ethylene glycol (20 c.c.) were heated at 120° in an oil-bath for 2 hours. The dye separated as coppery crystals. These were collected when cold, and recrystallised from nitrobenzene forming short needles (0.3 g., 6.7%), m. p. 286° (Found: C, 84.9; H, 5.05; N, 9.5. Calc. for $C_{22}H_{18}N_3$: C, 85.5; H, 5.1; N, 9.4%). (b) With the same procedure as in (a) but using *n*-butyl alcohol (20 c.c.) as solvent and refluxing for 2 hours, the deep blue solution deposited the dye salt on chilling. The purple solid rapidly acquired a coppery sheen on standing in the atmosphere, owing to hydrolysis to the base (m. p. 286°) (1.2 g.; 26.7%). (c) The nitrile (4.7 g.), hydroxylamine hydrochloride (1.4 g.), and formamide (20 c.c.) were placed in an oil-bath at 120°. The temperature of the mixture rose to 90°, then with evolution of gas the temperature rose to 150° and the dye separated. It (0.8 g., 17.8%) was collected after dilution with alcohol, ground with alcohol, and washed with alcohol and water. It had m. p. 286° and was identical with the sample prepared according to (a).

* Soluble in alkali to green solution.

† Soluble in alkali to blue solution.

Hydroxylamine Hydrochloride and β -Benzoylpropionamide.—The amide (7.08 g., 0.04 mol.), hydroxylamine hydrochloride (2.8 g., 0.04 mol.), and formamide (20 c.c.) were placed in an oil-bath at 120°. After a while the evolution of gas commenced and the dye separated rapidly. After 5 minutes the melt was diluted with alcohol, and the dye collected, and washed with alcohol until the washings were

colourless. It (0.5 g.) formed brassy, irregular plates from pyridine, in which it gives a magenta solution. It sublimed with some decomposition, giving red vapours. It was readily decolorised in pyridine solution with aqueous sodium dithionite (Found: C, 75.7; H, 4.6; N, 9.0. $C_{20}H_{14}O_2N_2$ requires C, 76.45; H, 4.45; N, 8.9%).

226. *The Photochemical Polymerisation of Vinyl Acetate Vapour.*

By H. W. MELVILLE and R. F. TUCKETT.

The kinetics of the polymerisation of vinyl acetate vapour under the influence of ultra-violet light of wave-lengths greater than 2500 Å. have been investigated. Shorter wave-lengths cause decomposition of the molecule into products which inhibit the polymerisation. At high enough pressures the rate of polymerisation is proportional to the first power of the concentration of vinyl acetate and to the square root of intensity of the incident light. At pressures of about 20 mm. the rate falls off very rapidly and becomes immeasurably slow at lower pressures, e.g., 15 mm. This phenomenon is apparently due to the fact that the photo-excited vinyl acetate molecule can lose its energy before another molecule of monomer can add on. This hypothesis is reinforced by the effect of other added gases. Quite small amounts of oxygen and of butadiene retard the reaction by terminating the growing chain. Amounts of inert gases like helium, argon, and hydrogen comparable with the amount of vinyl acetate also retard the polymerisation but these gases function, not by stopping growing chains, but by deactivating by collision the photo-excited vinyl acetate molecule.

THIS paper is a continuation of the work on the systematic examination of polymerisation reactions in the vapour phase. In practically every example of a vinyl derivative that readily polymerises in the vapour phase a number of unique observations have been made which have helped in elucidating the kinetics of such reactions. As will be seen below, the vinyl acetate reaction is no exception. As with methyl methacrylate and chloroprene, it happens that there are two distinct mechanisms whereby macromolecules are formed, and it turns out that it is easy to separate the two modes of polymerisation. Apart from these considerations, however, the polymerisation of vinyl acetate has been studied in the liquid phase, peroxide catalysts (Cuthbertson, Gee, and Rideal, *Proc. Roy. Soc.*, 1939, *A*, **170**, 300; Blaikie and Crozier, *Ind. Eng. Chem.*, 1936, **28**, 1155; Skirrow, *British Plastics*, 1939, **10**, 416, 507; Starkweather and Taylor, *J. Amer. Chem. Soc.*, 1930, **52**, 4708) and ultra-violet radiation (Taylor and Vernon, *ibid.*, 1931, **53**, 2527) being used. The results of these investigations are not sufficiently comprehensive to enable a decision to be made as to whether the mechanisms in the liquid phase are the same for photo- and peroxide-catalysed reactions: nor is it possible to say whether the mechanism in the gas phase is kinetically similar to that in the liquid phase.

It has been shown that in some dimerisations, e.g., of cyclopentadiene (Wassermann, *J.*, 1939, 362, 367, 371, 375), the bimolecular constants are the same in the liquid and in the vapour phase, and hence it seemed necessary to see whether in a suitable polymerisation process a similar identity of rates could be obtained. Vinyl acetate is one of the few monomers which polymerise equally well in both phases, and thus some information on this point might be obtained.

There is, however, another important reason for undertaking this work. In the liquid phase it is believed that polymerisation occurs by the free-radical mechanism, i.e., the active polymer is a large free radical. Although it has been demonstrated that a free radical mechanism *can* occur in the liquid phase, it is by no means certain that every liquid-phase polymerisation proceeds by this mechanism. As will be shown, it is possible to characterise the free-radical polymerisation of vinyl acetate in the vapour phase. If therefore it can be shown that there is in fact a correlation in behaviour of vinyl acetate between the two phases, it may be possible to gain some more precise information about the behaviour in the liquid phase. The present paper is confined to the gas-phase polymerisation, and further communications will deal with the liquid-phase reaction. Polymerisation must be initiated by radiation, by excited mercury atoms, or by free radicals, since purely thermal polymerisation does not occur at all.

EXPERIMENTAL

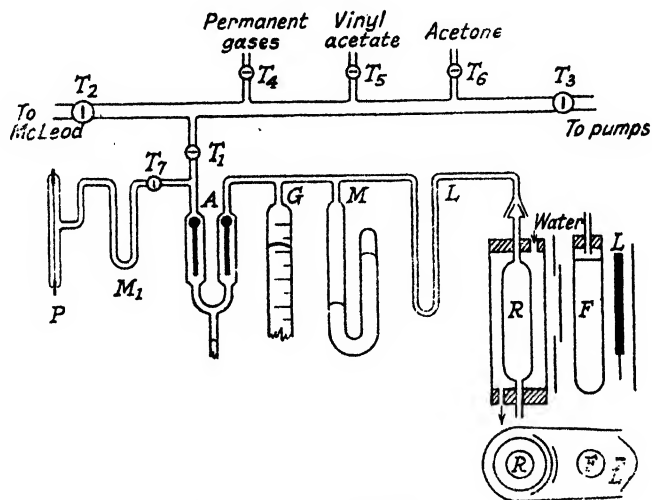

Apparatus.—The apparatus used calls for no special comment, the general arrangement being shown in Fig. 1. The silica reaction vessel was placed in a thermostat, and the polymerisation could be carried out at various temperatures up to 100° either under constant pressure of vapour, using a gas burette, or at constant volume, using a mercury manometer. Mercury cut-offs were employed to isolate the

reaction system to avoid trouble with greased joints. The apparatus was evacuated by a mercury diffusion pump. The sources of light were high- and low-pressure mercury lamps depending on the type of reaction being studied. Care was taken to ensure constancy of light output by controlling the voltage applied to the lamps. Experiment showed that, like other monomers, vinyl acetate is decomposed by the shortest wave-lengths emitted by the mercury lamp. Consequently it was necessary to screen off such radiation by acetic acid filters (30% aqueous solution). McLeod and Pirani gauges were used to measure the pressures of gases not condensable in liquid air.

Particular care was taken in the purification of vinyl acetate. This was originally obtained from Shawinigan Chemicals Ltd. and usually contained some acetaldehyde. The latter substance is a strong inhibitor of the liquid- and also the gas-phase polymerisation and hence its removal is essential. The monomer was first fractionally distilled twice at atmospheric pressure, only the 72–73° fraction being collected. The aldehyde is difficult to separate, and all fractions boiling below 72° were discarded. The nearly pure ester—which only gave a faint pink coloration with Schiff's reagent on standing for 5 minutes—was sealed into a tube on to the vacuum line of the apparatus. The ester was then frozen with liquid air and pumped out to 10^{-5} mm. It was melted and refrozen several times with evacuation between each cycle. Distillation was conducted in a vacuum, only the middle portion being used for experimental purposes.

"A.R." Acetone was used as a source of methyl radicals. It was freed from oxygen in a similar manner to the vinyl acetate. Oxygen came from potassium permanganate; hydrogen was purified by passing through palladium. Butadiene was taken from a cylinder and purified by vacuum distillation.

FIG. 1.

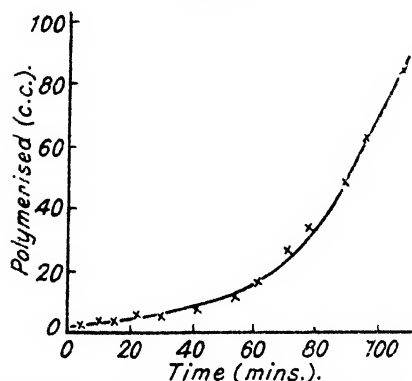

General arrangement of apparatus.

Direct Photo-reaction.—Several precautions have to be taken in measuring the velocity of polymerisation. Fig. 2 shows how the number of molecules polymerised increases with time of illumination, starting with a clean tube. There is a marked induction period, and gradually the rate attains a constant value. If illumination is prolonged, the rate begins to decrease again, but since this only occurs when very thick deposits of polymer are formed it is attributed to scattering and absorption of the effective radiation by the polymer. The long induction period is not due to the presence of gas-phase inhibitors, because a similar phenomenon is observed if successive separate portions of vinyl acetate are used. This points to an effect due to the reaction vessel itself. It is not due to the fact that the polymerisation really takes place in the deposited polymer. There are many reasons for supporting this contention. The customary mist of solid polymer is formed in the gas phase when the lamp is switched on, the polymerisation rate does not increase proportionally to the weight of polymer deposited, inert gases like helium, argon, and hydrogen inhibit the polymerisation, and the intensity exponent in the polymerisation does not tend to zero, as happens in the polymerisation of chloroprene where polymerisation does occur in the solid polymer. As will be shown later, there is little doubt that the induction period is due to the fact that the active polymer molecules are somehow destroyed when they collide with the clean silica walls, and that when these are covered by polymer there is more or less elastic reflection with a consequent lengthening of the chain until mutual destruction occurs in the gas phase. This suggestion is supported by covering the walls with a layer of Gelva 15—commercial polyvinyl acetate—whereby the induction period is diminished but curiously enough not completely eliminated. The other surprising fact is that walls need to be covered by a fairly thick layer of polymer. It might be expected that a monolayer of polymer would be sufficient. Assuming a degree of polymerisation of 100, a monolayer would correspond to a pressure decrease of 10^{-2} mm. whereas a very much greater decrease of pressure is required before the reaction rate is constant. Owing to the necessity for depositing polymer there is a measurable absorption of the monomer by the polymer, and as this amount of polymer increases so the amount of sorbed monomer increases. Corrections are

made for the total observed consumption of monomer to give the true photo-rate. In order to cut down corrections of this kind to a minimum, the method of bracketing must be employed, and tubes are used for a relatively small number of runs just after conditions have become relatively steady. Experiments show there is no measurable induction period and that there is no long-continued reaction in the dark, as occurs with methyl methacrylate. This is in accord with the present experience with molecules of the type $\text{CH}_2=\text{CHX}$. If a heavily coated tube is being used there is sometimes an apparent induction period or even a pressure increase, due apparently to some desorption of monomer from the polymer when the light is switched on.

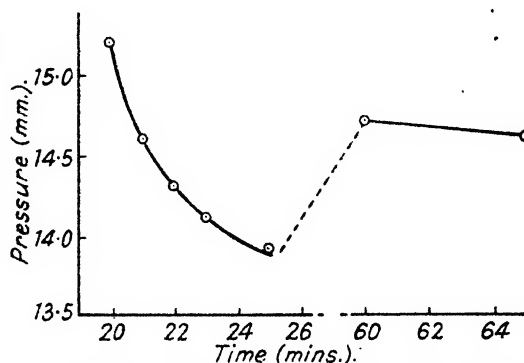

General Kinetics.—Decomposition. As has already been mentioned, unfiltered light from the mercury lamp leads to decomposition of the vinyl acetate, one of the products of decomposition being non-condensable in liquid air. This gas could only be hydrogen, carbon monoxide, or methane. A Pirani gauge was consequently calibrated by using carbon monoxide and hydrogen. The gas from vinyl acetate gave a calibration curve coinciding exactly with that for carbon monoxide. The calibration curve for methane lies very close to that for carbon monoxide and therefore it is difficult to say whether

FIG. 2.

Course of polymerisation at constant pressure starting with a clean tube.

FIG. 3.

Inhibition of polymerisation by the accumulated products of decomposition of vinyl acetate.

the gas is one or the other. The important point of this decomposition is that the products are strong inhibitors for the photo-polymerisation. This behaviour is shown most clearly by the following kind of experiment. Vinyl acetate is illuminated at constant volume for a given period and the rate measured. After this, the pressure is increased to the initial value and the run continued. As Fig. 3 shows, there is a very marked diminution in rate as a result of the accumulation of the products of decomposition. The acetic acid filter completely eliminates this decomposition, and hence it would appear that it has nothing to do with the polymerisation reaction. Another indication in support of this suggestion is that decomposition occurs just as readily below the critical pressure at which vinyl acetate ceases to polymerise. These observations are completely in accord with experience with methyl methacrylate and methyl acrylate. Short-wave radiation, instead of leading to activation and eventual starting of polymerisation, simply results in disruption of the molecule into products incapable of starting polymerisation.

Effect of pressure. The constant-pressure technique being used, the variation of rate with pressure was investigated, due regard being paid to corrections owing to disappearance of monomer by absorption by the polymer. A typical run is shown in Table I, the bracketing pressure being 42.1 mm. Similar

TABLE I.

Direct photo-polymerisation; temp. 20°; high-pressure Hg lamp.

Pressure (mm.).	Observed rate (in c.c./min.) at 42.1 mm. pressure.	Dark "rate" (c.c./min.).	Net polymerisation rate (c.c./min.).
42.1	25.6	0.8	24.8
42.1	27.3	1.9	25.4
37.5	22.1	—	22.1
23.9	3.56	—	3.56
42.1	26.5	1.4	25.1
48.4	31.6	2.0	29.6
55.6	40.4	1.6	38.8
42.1	30.4	2.0	28.4

series of runs were made over other ranges of pressure, the maximum being fixed at about 60 mm., the saturation vapour pressure of vinyl acetate. Rates relative to that at 42.1 mm. are plotted as a function of pressure in Fig. 4. The most striking feature of this plot is the appearance of a limiting pressure below which the reaction rate is immeasurably slow. At high enough pressures the rate is approximately proportional to the first power of the pressure, whereas in the intermediate region 20–40 mm.

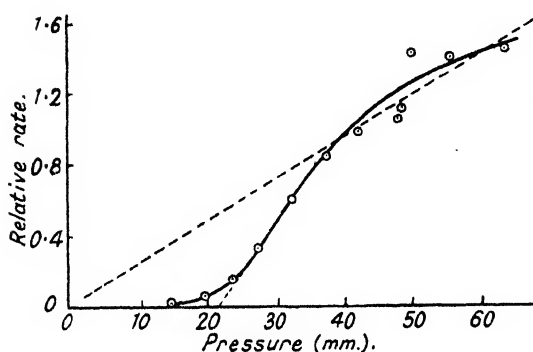

the rate = const. $(p - p_0)$, where p_0 may be defined as a critical pressure of about 21 mm. This limit has nothing to do with inhibition by decomposition products, for if the vapour is illuminated at, say, 20 mm. for a considerable period and the pressure is then raised to say 30 mm., polymerisation proceeds normally. Similarly, if polymerisation is occurring at 30 mm. and the pressure is reduced to 20 mm. polymerisation immediately ceases. To show this more clearly prolonged illumination with use of the acetic acid filter gave the following results:

Vinyl acetate pressure (mm.).	Time of illumination (mins.).	C.c. of vapour polymerised.	Pressure of products of decomposition (mm.) (non-condensable in liquid air).
12.9	120	—	4.0×10^{-2}
15.0	100	8.0	3.5×10^{-2}

It will be seen that a reduction in pressure of only 2 mm. reduces the very small rate of polymerisation at 0.08 c.c./min. to an immeasurable value, yet the decomposition is hardly affected. Likewise there is no photo-decomposition of the polymer and hence this could not be the cause of the appearance of the limit.

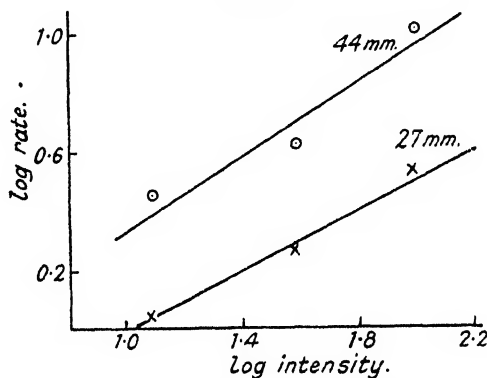

That the phenomenon has something to do with the initiation process is shown by the fact that if a low-pressure mercury lamp is used, and presumably therefore excited mercury atoms are responsible for starting polymerisation, the limit is displaced to a lower pressure at 12 mm.

FIG. 4.

Rate of polymerisation as a function of pressure.

FIG. 5.

Variation of rate with intensity of incident illumination.

Intensity exponent. The variation of polymerisation rate with intensity of light gives useful information in regard to the order of the process in which the active polymer molecule is destroyed. It is particularly important to measure this exponent in view of the gradual increase of rate with the amount of polymer deposited and the existence of the critical limit. The intensity was decreased by using perforated screens which had been previously calibrated by a photoelectric cell. Runs were made at high pressure where the rate is proportional to pressure and at as low pressure as possible to see whether in the vicinity of the limit there was any change in the mechanism of the termination process. A logarithmic plot of the results is given in Fig. 5. The slope of these curves is 0.60 and 0.55 for 44 and 27 mm., respectively, which is a sure indication that polymerisation stops when two active polymers mutually destroy each other. This again furnishes additional proof that the appearance of the limit has nothing to do with the termination process.

The same set-up being used, the value of the critical limit was measured for an intensity only one-eighth of that used in the measurements given on p. 1203. The following results give a limit on extrapolation of 21 mm. Thus, in spite of a diminution in rate of starting of polymerisation by a factor of 8 and an increase in chain length by a factor of 3, the limit is unaffected.

Vinyl acetate press. (mm.)	19.1	25.3	38.2	46.0
Rate (c.c./min.)	0.25	1.05	4.76	5.85

Effect of temperature. Rather a complicated procedure had to be adopted in these experiments, for at each temperature a series of runs at different pressure had to be made in virtue of the existence of the critical limit, since it was essential to find whether the limit itself was dependent on temperature. To ensure that the condition of the tube was as nearly similar as possible during these experiments, before and after each series of runs at elevated temperature standard runs were made at 20° and at 42 mm. pressure. It was not possible to go to temperatures greater than 100° since decomposition of the polymer led to complications and the rate fell off very quickly above this temperature. The results are summarised in Fig. 6, where the relative rates are plotted against pressure for a series of temperatures. At pressures above 30 mm. it will be seen that the rate decreases with increasing temperature. This phenomenon, although observed with methyl acrylate and methyl vinyl ketone, might be due to the intervention of some inhibitor or to a change in the nature of the termination reaction. Using a pressure of 60 mm. at 66°, a measurement of the variation of rate with intensity gave the following results:

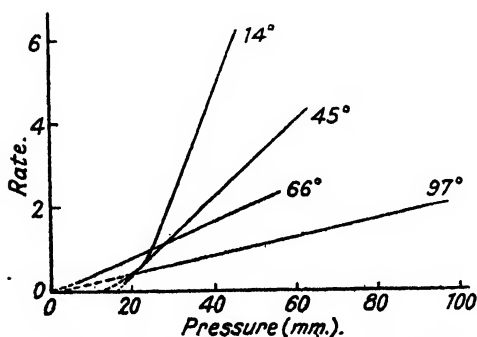

Intensity	1.00	0.384	0.125
Rate (mm./min.)	0.63	0.38	0.185

This corresponds to an exponent of 0.60, in agreement with the results at 20°. Hence, mutual termination of chains still operates at elevated temperatures. At each temperature the variation of rate with pressure is represented by the equation $\text{Rate} = k(p - p_0)$, except in the neighbourhood of the limit, defined for the sake of convenience by p_0 in this equation. The following results show how the value of p_0 varies with temperature:

Temp.	14.0°	46°	66°	97.0°
p_0 (mm.)	21.0	16.0	6.0	5.0

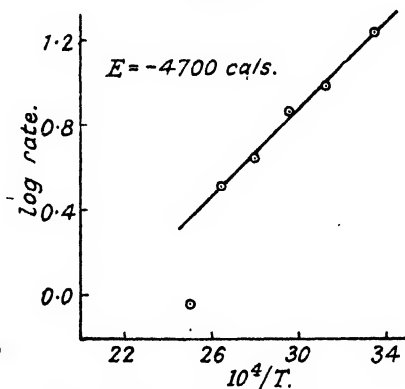

Hence, at above 100° the polymerisation pursues a normal course in which $R = \text{const. } (I_{\text{abs}})^{\frac{1}{2}} (M)$, which are kinetics compatible with the idea that all the light is absorbed and that mutual termination of the polymer chain occurs almost exclusively (Gee and Melville, *Trans. Faraday Soc.*, 1944, **40**, 240). Below 30° an inversion of the temperature coefficient occurs and the rate increases with increase in temperature. This kind of anomalous behaviour is, however, primarily due to the intervention of some reaction responsible for the appearance of the limit—a reaction which itself possesses a temperature coefficient. In absence of this complicating phenomenon, namely, at as high pressure as can be obtained, there is no doubt that the polymerisation rate decreases with increasing temperature. The temperature coefficient was therefore measured for a pressure of 50 mm. and the $\log \text{Rate}-1/T$ plot is shown in Fig. 7. The slope corresponds to an apparent energy of activation of -4700 cal. The point at 128° is obviously

FIG. 6.

Rates of polymerisation as a function of pressure at a series of temperatures.

FIG. 7.

Temperature coefficient of the rate of polymerisation at 50 mm. pressure of vinyl acetate ($T = ^\circ \text{K.}$).

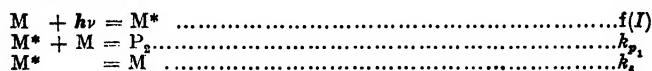

so far off the straight line as to indicate a complete change in mechanism which has not been further investigated. It being assumed that the energy of activation for the initiation process is negligible, this means that there is an energy of activation for the termination process and that it exceeds that of the propagation reactions for with mutual termination $E_{\text{app.}} = E_{\text{prop.}} - \frac{1}{2}E_{\text{term.}}$, where $E_{\text{prop.}}$ and $E_{\text{term.}}$ are the energies for propagation and termination, respectively. Only in the case of methyl acrylate has there been made a *minimum* value for $E_{\text{prop.}}$ and this amounts to 4000 cal. (Melville, *Proc. Roy. Soc.*, 1938, **A**, **167**, 99). Even if it is supposed that $E_{\text{prop.}}$ in the vinyl acetate reaction is 5000 cal., $E_{\text{term.}}$ amounts to about 20,000—a very high value indeed. In fact, considering the small concentration of active polymers, it would appear that the termination reaction would hardly ever occur in the gas phase at room temperature. There is here a peculiarity in a number of photo-gas-phase polymerisations which is kinetically not easily understandable. Yet with methyl acrylate if a strong inhibitor, e.g., oxygen or butadiene, is added to change completely the nature of the termination process the apparent temperature coefficient becomes positive, since a termination process normally requiring activation energy is replaced by one in which the energy of activation is practically zero. The phenomenon is not confined to gas-phase polymerisation, for in some liquid-phase polymerisations the chain length of the polymers decreases with increasing temperature, possibly owing to the energy of activation for termination exceeding that for propagation.

The critical limit. Before attempting to discuss the abnormal pressure dependence of this polymerisation the main kinetic features may be summarised as follows: (a) The rapid falling off in rate at low pressures and temperatures—the reaction being apparently normal at high temperatures and pressures. (b) Dependence of the “limit” on temperature. (c) Independence of limit on intensity and state of the tube, i.e., whether covered or not. (d) Termination mechanism of polymerisation not altered in the low-pressure, low-temperature region. (e) Limit apparently affected by *mode* of initiation.

The limit appears to have no connection with the explosion limit in other chain reactions, for the rate above the limit is in no sense indefinitely fast, the reaction being under complete control. The best proof of this suggestion is that the intensity exponent never falls below 0.5 whereas in an incipient explosion, e.g., in the $\text{H}_2\text{-N}_2\text{O-O}_2$ system sensitised by hydrogen atoms, the exponent may fall below the normal value of 0.5 when the reaction gets out of hand (Melville, *Proc. Roy. Soc.*, 1934, **A**, **146**, 737).

It would appear to be necessary to introduce some mechanism at low pressures which leads to a diminution in velocity rather than introduce some phenomenon which leads to an abnormal increase

in rate at high pressures as in gaseous explosions or in the polymerisation of methyl vinyl ketone (Jones and Melville, *ibid.*, 1946, A, 187, 19). All the above evidence indicates that neither termination nor propagation factors are affected and that therefore the phenomenon has something to do with the initiation process. The shift of the limit by changing from direct to sensitised initiation and the non-existence of the limit in the radical-sensitised reaction are additional certain pointers to this conclusion. It is probable that the primary photochemical efficiency is not high, *i.e.*, some of the energy absorbed by the vinyl acetate molecule is lost before another molecule of monomer can react with it. Thus we may have two competing processes:

As the pressure is reduced, a greater proportion of the M^* molecules lose their energy by some kind of a process not involving a collision with a monomer molecule. Mutual termination being assumed, then

$$d[\text{M}^*]/dt = f(I) - k_s[\text{M}^*] - k_{p_1}[\text{M}^*][\text{M}] = 0$$

and in general

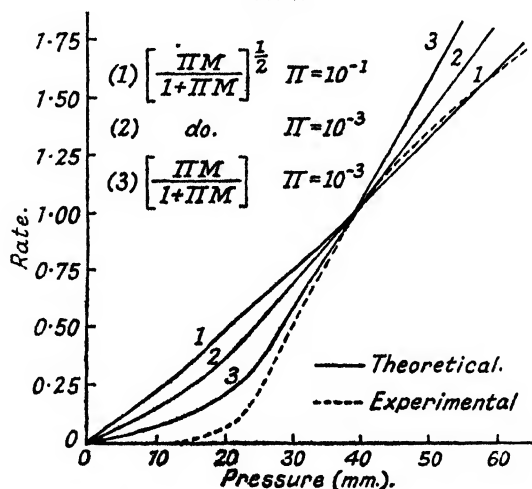

$$d[\text{P}_n]/dt = k_{p_{n-1}}[\text{P}_{n-1}][\text{M}] - k_{p_n}[\text{P}_n][\text{M}] - k_{t_n}[\text{P}_n]\Sigma k_{t_n}[\text{P}_n] = 0$$

Solving these equations in the usual way, we have

$$\begin{aligned} -d[\text{M}]/dt &= [\text{M}]\{f(I)\}^{\frac{1}{2}} \delta^{-1} \{k_s[\text{M}]/[k_s + k_{p_1}(\text{M})]\}^{\frac{1}{2}} \\ &= [\text{M}]f(I)^{\frac{1}{2}} \delta^{-1} \{\pi[\text{M}]/[1 + \pi(\text{M})]\}^{\frac{1}{2}} \end{aligned}$$

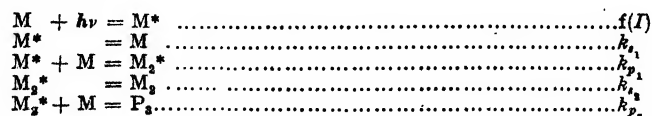

where $\pi = k_{p_1}/k_s$. At high values of $[\text{M}]$, this gives linear dependence of rate on $[\text{M}]$, but at low pressure the rate only varies as $[\text{M}]^{3/2}$ and would obviously not fall off quickly enough to be in accordance with experimental results. This is best shown by computing a value of π from experimental results. Assuming that the reaction is normal at 50 mm. and taking the rate at 24 mm., we have in the region of abnormality $R = 0.16$, $\pi = 3.0 \times 10^{-3}$ with $[\text{M}]$ in mm. At 20 mm. $\pi = 0.6 \times 10^{-3}$. Hence, taking a mean value of 10^{-3} and plotting the rate-pressure curve in Fig. 8 such that at one point, namely,

FIG. 8.

Relationship between theoretical and experimental curves, for the variation of rate with pressure.

40 mm., it is adjusted to coincide with the broken experimental curve, it will be seen that although the shape is approximately right the agreement both at low and at high pressures is such that the theory is not good enough to account for the observations. A better approximation may be obtained if it is assumed that not only the activated monomer but also the dimer may spontaneously lose its energy. Thus the scheme would be:

This leads to an expression

$$- \frac{d[\text{M}]}{dt} = [\text{M}] \delta^{-1} f(I)^{\frac{1}{2}} \left[\frac{k_{p_1}[\text{M}]}{k_s + k_{p_1}[\text{M}]} \right]^{\frac{1}{2}} \left[\frac{k_{p_2}[\text{M}]}{k_{p_2} + k_{p_3}[\text{M}]} \right]^{\frac{1}{2}}$$

If $k_p/k_t = k_{ps}/k_{is} = \pi$, which is a reasonable assumption, this simplifies to

$$-\frac{d[M]}{dt} = [M]\delta^{-1/2}(I)^{1/2} \left(\frac{\pi[M]}{1 + \pi[M]} \right)$$

and as will be seen from Fig. 8 gives a plot agreeing more closely with the results below 40 mm., although the high-pressure agreement is inferior. The intervention of this kind of deactivation process might be extended to higher active polymers, but it is evident that the process cannot extend indefinitely for it would constitute another way in which the active polymers are destroyed, whereas the intensity exponent clearly indicates mutual destruction of the active polymers. Although the above theory does not quantitatively account for the shape of the R - p curve, it is in accordance with the observations made in connection with the position of the so-called limit, namely, independence of intensity and of the state of the vessel. Since the limit depends on temperature, this means that π increases with increasing temperature. This is entirely in accordance with expectation; k_t , k_p are unlikely to be affected by temperature, since spontaneous loss of large amounts of energy is unlikely to be influenced by relatively small changes in energy; k_{ps} , on the other hand, is a propagation coefficient and will certainly increase with increasing temperature. The theory is not good enough to enable π or some similar parameter to be accurately computed, but an approximate estimate may be made in the following manner. Suppose there is no appreciable spontaneous deactivation at 40 mm. and the pressure p_1 is found from Fig. 8 at which the rate is half what it would have been in absence of this effect; then at this pressure the probabilities of propagation and deactivation are equal, and if p_1' and p_1'' are the pressures at two temperatures, the energy of activation of the propagation reaction will be given by

$$E_p = 4.57 \log_{10} \frac{p_1'}{p_1''} \frac{T_1 T_2}{(T_1 - T_2)}$$

where T_1 and T_2 are the corresponding temperatures. For 14° , $p_1' = 28$ mm. and at 45° $p_1'' = 22$ mm.; hence $E_p = 1400$ cals.

Nature of the Photopolymer.—The polymer deposited as a result of the photochemical reaction is insoluble—a drawback which prevents a direct measurement of the chain length of the reaction. In view of the small number of cross-links needed to render a polymer insoluble, it is not unreasonable to suppose that the reaction responsible for branching and the type of links involved in the process may be entirely different from those constituting the main bulk of the polymer. The polymer was therefore formed under carefully controlled conditions by running the experiment at a constant pressure of 30 mm. and 15° until about 0.6 g. of polymer was deposited. The polymer was then washed out of the reaction vessel with acetone, in which it swelled but did not dissolve. The resulting material was suspended in dry methyl alcohol and treated with methyl-alcoholic potassium hydroxide. The white suspension so obtained was poured into water, in which it was completely soluble. Hence, conversion of the polyvinyl acetate into polyvinyl alcohol resulted in a breakdown of the three-dimensional polymer, which points to the fact that a hydrolysable link is responsible for joining the primary chains of the polymer together.

Inhibition.—A study of the effect of inhibitors on a chain reaction throws much light on the mechanism of the reaction. As will be shown, this is particularly true with vinyl acetate where a variety of inhibitory mechanisms may operate. Oxygen and butadiene are both effective inhibitors but, surprisingly enough, chemically inert gases like argon, helium, and hydrogen also function as inhibitors.

Oxygen. According to the theory of polymerisation (Gee and Melville, *Trans. Faraday Soc.*, 1944, 40, 240) the expression for the rate of a completely inhibited reaction is

$$-d[M]/dt = [M]I(I)/\beta[O_2]$$

where $\beta = k_d/k_p$, k_d being the velocity coefficient for the interaction of inhibitor with active polymer. In order to get reliable results, the bracketing technique was employed for these experiments, *i.e.*, every run with the inhibitor present was preceded and followed by a run with pure vinyl acetate. With a pressure of 30 mm., the results of a series of runs are shown in Fig. 9, where reciprocal rate is plotted against oxygen pressure. In accordance with the theory, a straight line may be drawn through the points. Another result of inhibition of a reaction which is normally terminated by mutual destruction of the active polymers is that the intensity exponent should simultaneously increase from 0.5 to a value approaching 1.0 depending on the extent of the inhibition. A typical set of runs is given in Table II, the bracketing technique being employed and decrease of pressure being used for the measurement of rate.

TABLE II.

Vinyl acetate pressure, 31 mm. Temp. 20° .

Oxygen (mm.)	0	1.2	1.2	1.2	0
Intensity	1.00	1.00	0.125	1.00	1.00
Time (mins.) for pressure to fall 1 mm.	1.8	5.0	23.0	5.0	2.1

Intensity exponent = 0.74.

This increase of exponent to 0.74 clearly shows that inhibition is termination of growth of the polymer by the interaction of oxygen with it.

As will be shown in the following paper, it is possible to study the kinetics of the free-radical polymerisation below the critical limit, and thus in absence of the direct photopolymerisation. Table III shows that oxygen has no effect on the reaction initiated by methyl radicals and only a comparatively small effect on that initiated by hydrogen atoms, and this in spite of the fact that the rates of polymerisation are approximately the same as those in Table II. The fact that oxygen slightly inhibits the

hydrogen-atom reaction is quite possibly due to direct interaction of hydrogen atoms and oxygen molecules. The important point is that oxygen clearly discriminates between the two kinds of reaction.

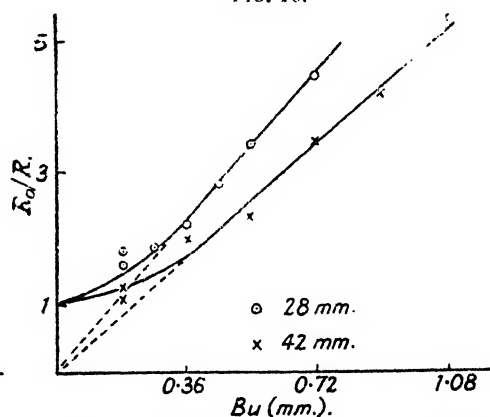

Butadiene. Butadiene is a more powerful inhibitor than oxygen and hence smaller pressures of the gas are needed. A gas pipette method was therefore adopted for introducing butadiene into the reaction system. The results at two vinyl acetate pressures are plotted in Fig. 10, in which the relative reciprocal rate is graphed against butadiene pressure. In these experiments bracketing methods were employed at all stages. Since in this case there is always the possibility of butadiene actually inter-polymerising with the vinyl acetate, with a resultant diminution in velocity, instead of acting as does oxygen, the variation of rate with intensity was measured. In the former case the square-root dependence would

FIG. 9.

Effect of oxygen in retarding polymerisation.

FIG. 10.

Effect of butadiene in retarding polymerisation, at 28 and 42 mm. of vinyl acetate.

still hold, while in the latter a linear dependence should be observed. The detailed results need not be given here except the following summary:

R_0/R	$R_{1.00}/R_{0.125}$	Exponent.	R_0/R	$R_{1.00}/R_{0.125}$	Exponent.	R_0/R	$R_{1.00}/R_{0.125}$	Exponent.
1.0	3.4	0.60	2.8	5.3	0.80	4.2	7.9	0.99

As the degree of inhibition (R_0/R) increases, the ratio of rates ($R_{1.00}/R_{0.125}$) at a fixed ratio of intensities likewise increases, corresponding to a general increase in intensity exponent. Additional confirmation is obtained in the following typical experiment with a vinyl acetate pressure of 33 mm. and butadiene 0.1 mm.: R_0/R at maximum intensity was 2.8, increasing to 3.9 at 0.125 of the maximum intensity. Thus, by reducing intensity and increasing thereby the chain length, the degree of inhibition is correspondingly increased. All these experiments conclusively show that when butadiene reacts with vinyl acetate active polymer it adds on and then the reaction stops. Normal molecules of vinyl acetate cannot react with a butadiene end of the polyvinyl acetate.

There is, however, one discrepancy. For the normal and the inhibited reaction we have respectively for the two rate equations:

$$-d[M]/dt = R_0 = [M]f(I)^{1/2}/\delta \text{ and } R = [M]f(I)/\beta[X]$$

Hence

$$R_0/R = \beta[X]/\delta f(I)^{1/2}$$

As seen above, this relationship is followed in regard to butadiene concentration and light intensity. It will be noted that the value of R_0/R is independent of R_0 and, more important, independent of $[M]$, yet in Fig. 10 the plots for two values of $[M]$ are not coincident. One possibility is that $f(I)^{1/2}$ depends on $[M]$ because of incomplete absorption of radiation. The slope of the R_0/R or $[X]$ curve would be less for higher values of $[M]$, which is in qualitative agreement with observation. The maximum change of slope in this case would be 1.2:1 whereas the observed value is 1.25:1. The linear dependence of R on $[M]$ at high enough temperatures would preclude this explanation. At lower pressures such as

28 mm., however, the vinyl acetate reaction begins to deviate quite markedly from normal behaviour. In order to get an expression for the reaction rate as a function of inhibitor concentration, an additional term, viz., $k_{sa}[P_n][X]$, is introduced into the differential equations defining $[P_n]$. This gives by the usual method

$$-d[M]/dt = [M]\{f(I) - k_{s_1}[P_1^*]\}/\beta[X]$$

But

$$[P_1^*] = f(I)/\{k_{s_1} + k_p[M] + k_{s_1}[X]\}$$

Therefore

$$-d[M]/dt = \frac{[M]f(I)}{[X]\beta} \left\{ \frac{k_{p_1}[M] + k_{s_1}[X]}{k_{s_1} + k_p[X] + k_{p_1}[M]} \right\}$$

Using the expression already obtained for the rate of reaction in absence of inhibitor, we have

$$R_0/R = \frac{\beta[X]}{\delta f(I)^{\frac{1}{2}}} \left\{ \frac{k_{p_1}[M]}{k_{p_1}[M] + k_{s_1}} \right\}^{\frac{1}{2}} \left\{ \frac{k_{s_1} + k_{p_1}[M] + k_{s_1}[X]}{k_{s_1}[X] + k_{p_1}[M]} \right\}$$

It has already been shown that $k_p/k_{s_1} \approx 10^{-3}$, hence $k_s \gg k_p[M]$ or $k_s[X]$ and

$$R_0/R = \frac{\beta k_{s_1}^{\frac{1}{2}}}{\delta f(I)^{\frac{1}{2}}} \cdot \frac{[M]^{\frac{1}{2}}[X]}{[M] + \beta^{-1}[X]}$$

Thus if $[M] \approx \beta^{-1}[X]$, decreasing values of $[M]$ will increase the slope of the R_0/R - $[X]$ curve.

Effect of Inert Gases.—Experiments with polymer-coated tubes seemed to indicate the existence of wall deactivation of the active polymer with clean or partly coated tubes. Thus it might be expected that the decrease in diffusion coefficient effected by the addition of inert gas might accelerate the polymerisation rate. When the experiment was done, precisely the opposite effect was obtained, a marked inhibition being observed. At first sight, this phenomenon is difficult to explain, since it is inconceivable that gases like argon, helium, and hydrogen could effect any chemical change in the active polymer that would lead to deactivation. As will be shown, inhibition does not occur by the termination of growth of the chains but is due to deactivation of excited molecules in the very early stages of polymerisation. This effect, indeed, is not then so unexpected in view of the abnormal pressure dependence of reaction and, in fact, provides further support for the hypothesis advanced to explain the occurrence of an apparent critical limiting pressure. Thus we have the curious phenomenon that inhibition by inert gases leads to an *increase* in chain length of the polymer and not a decrease as is usually the case.

The argon was obtained from a cylinder of the gas and was oxygen free. The helium was purified from more condensable gases by repeated treatment with active charcoal.

The results with argon for a series of vinyl acetate pressures are shown in Fig. 11. R_0/R and also $(R_0/R)^2$ are plotted against argon pressure. It is difficult to say which relationship is the better approximation, but one observation is important. Unlike those for oxygen and butadiene, these lines do not go through the origin but make an intercept of unity in the R_0/R axis. This at once shows that a different kind of inhibition comes into operation apart altogether from the fact that very much higher pressures are needed for inhibition to be observed. This is completely confirmed by measuring the intensity exponent. With a vinyl acetate pressure of 40 mm. and an argon pressure of 67 mm., $R_0/R = 2$, the intensity exponent is 0.60, the same value being obtained in the uninhibited reaction. This evidence certainly points to inhibition occurring in the initial stages of the reaction. Since the theory of the critical limit postulates the existence of an excited monomer which does not necessarily add on another molecule of monomer but may spontaneously lose its energy, probably by some internal rearrangement (it is hardly likely that chemical decomposition occurs, since it was earlier shown that decomposition seems to be an independent process brought about by short wave-lengths), it is natural to suppose that deactivation can also be brought about by collision with another molecule which facilitates this rearrangement or removes some of the energy from the excited molecule. In the expression for the value of $[P_1]$ another term has therefore to be added and the appropriate equation becomes

$$d[P_1]/dt = f(I) - k_{p_1}[P_1^*][M] - k_{s_1}[P_1^*] - k_{A_1}[P_1^*][A] = 0$$

Hence

$$R_0 = [M]\delta^{-\frac{1}{2}}f(I)^{\frac{1}{2}}\{k_{p_1}[M]/k_{s_1} + k_{p_1}[M]\}^{\frac{1}{2}}$$

and

$$R = [M]\delta^{-\frac{1}{2}}f(I)^{\frac{1}{2}}\{k_{p_1}[M]/(k_{p_1}[M] + k_{s_1} + k_{A_1}[A])\}^{\frac{1}{2}}$$

Therefore

$$R_0/R = \left\{ 1 + \frac{k_{A_1}[A]}{k_{s_1} + k_{p_1}[M]} \right\}^{\frac{1}{2}}$$

If argon deactivation is extended to P_2^* and we assume that $k_{p_1} : k_{s_1} : k_{A_1} = k_{p_2} : k_{s_2} : k_{A_2}$, then

$$R_0/R = 1 + k_{A_1}[A]/(k_{s_1} + k_{p_1}[M])$$

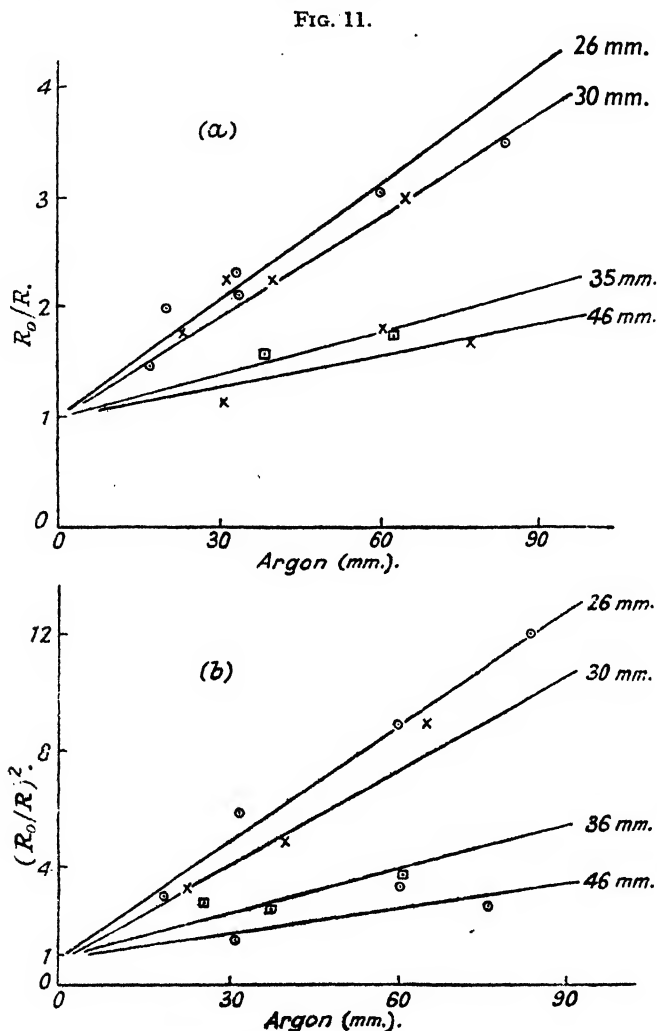

Rearranging these expressions, we have

$$\{(R_0/R)^2 - 1\}^{-1} = \frac{k_{s_1}}{k_{A_1}[A]} + \frac{k_p}{k_{A_1}[A]}[M]$$

$$(R_0/R)^2 - 1 = k_{A_1}[A]/k_{s_1} + k_{p_1}[M] \text{ and } R_0/R - 1 = k_{A_1}[A]/(k_{s_1} + k_{p_1}[M])$$

1210 The Photochemical Polymerisation of Vinyl Acetate Vapour.

Fig. 11 shows that a linear plot of R_0/R against argon pressure is obtained, and that the slopes of the lines are inversely proportional to the pressure of vinyl acetate. The intercept on the ordinate does not vary with argon pressure. This is not unexpected in view of the close approach to the critical limit when such relationships will break down. Experimentally it is difficult to decide between these two mechanisms.

Effect of argon in retarding the rate of polymerisation at various vinyl acetate pressures indicated. Figs. 11a and 11b show alternative ways of plotting the results.

Helium and hydrogen function in a similar manner, the intensity exponent not being affected when inhibition takes place. According to the above theory, the relative efficiencies of these gases can be obtained by plotting $(R_0/R)^2$ against the pressure of inert gas for a given vinyl acetate pressure. The relative slopes of these lines give the ratio of collision efficiencies $A : \text{He} : \text{H}_2 = 1 : 0.6 : 0.5$. If allowance is made for the different speeds, the collision efficiencies have the following values relative to argon: $\text{He } 0.085$, $\text{H}_2 \ 0.036$. In passing it is worth noting that inert gases have absolutely no effect on the free-radical polymerisation.

227. Radical-sensitised Polymerisation of Vinyl Acetate Vapour.

By H. W. MELVILLE and R. F. TUCKETT.

The kinetics of the polymerisation of vinyl acetate vapour initiated by hydrogen atoms and by methyl radicals has been investigated, with the following results. Owing to the fact that the direct photochemical polymerisation does not occur at room temperatures below 20 mm., the free-radical reaction can be studied alone by working at pressures below this limit. The reaction rate is proportional to the first power of the vinyl acetate pressure and to the square-root of the rate of production of radicals. The kinetic chain length of the reaction has been measured by the method of end-group analysis. The reaction has a high negative temperature coefficient.

These results show that the direct photo-reaction also proceeds by means of a radical mechanism, the correlation between the two reactions being close. The direct reaction initially involves the production of di-radicals which are subject to deactivation spontaneously or by collision with inert added gases. These gas-phase reactions exhibit the so-called gel effect to a maximum degree and thus the termination velocity coefficients are reduced to small values. This gives rise to overall apparent negative energies of activation.

In the previous paper it has been shown that vinyl acetate does not apparently undergo photochemical polymerisation at room temperature at pressures below 20 mm. In this respect it is unique but the phenomenon can be put to good use in the following way. With some molecules, *e.g.*, methyl methacrylate, it is comparatively easy to study the kinetics of the free-radical polymerisation without complications arising out of the occurrence of the direct photo-reaction; with other molecules like methyl acrylate this cannot conveniently be done for a variety of reasons. It is, however, important to study the kinetics of the radical reaction and thus characterise the type of polymerisation for purposes of reference so that by comparison it is possible to say whether or not the direct reaction, for example, goes by way of free radicals. At pressures below 20 mm. it proves to be possible to induce radical polymerisation and to study it to the complete exclusion of the direct reaction. The present paper describes the results obtained in this way.

The apparatus used was identical with that described in the previous paper. Special methods and modifications are described in the appropriate places.

Hydrogen-atom-sensitised Reaction.—Although molecular hydrogen is an inhibitor for the direct photo-polymerisation, it indirectly becomes a sensitiser if mercury vapour is present and instead of a high-pressure mercury lamp a low-pressure type emitting unreversed 2537 Å. radiation is employed. This phenomenon is well marked below the limiting pressure where, of course, no direct reaction can be detected. There is no doubt the accelerating effect of hydrogen is due to its sensitised dissociation to atomic hydrogen, which adds on to vinyl acetate to give a free radical, thus initiating polymerisation. There are some complications in the use of this indirect method. Excited mercury atoms will be deactivated by vinyl acetate molecules as well as by hydrogen and thereby start off a mercury-sensitised polymerisation, as has been shown in the previous paper. Fortunately, there is a pressure limit to this reaction (below) and hence its contribution to the total observed rate of polymerisation can easily be eliminated. Even at low pressures, mercury atoms will still be deactivated by vinyl acetate. The fraction f_{H_2} of excited mercury atoms deactivated by hydrogen molecules is simply given by

$$f_{H_2} = \frac{\sigma_{H_2}^2 [H_2] \mu_{H_2-Hg}^{-1}}{\sigma_{H_2}^2 [H_2] \mu_{H_2-Hg}^{-1} + \sigma_{VA}^2 [VA] \mu_{VA-Hg}^{-1}}$$

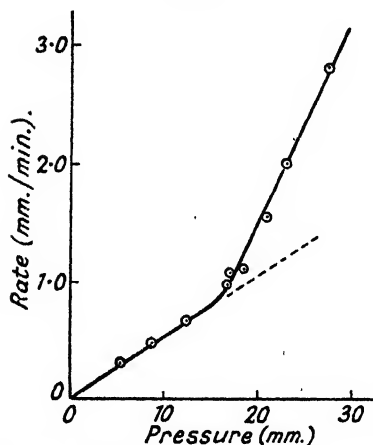

where σ is the sum of the quenching radii and μ is the reduced mass of the pairs of molecules concerned; $\sigma_{H_2}^2 = 6.0 \times 10^{-16}$ cm.² and σ_{VA}^2 is not known: it is probably about 20×10^{-16} cm.², for methyl methacrylate, for example, has $\sigma^2 = 25 \times 10^{-16}$ cm.² (Bolland, unpublished experiments). This value being taken, it is calculated that $f_{H_2} = 0.8$ for $H_2 : VA = 2.3 : 1$, and $f_{H_2} = 0.9$ for $H_2 : VA = 5.8 : 1$. Consequently, high hydrogen pressures were invariably used to eliminate complication of the kinetics in the above manner. The reproducibility of the free-radical reaction is much better than that of the direct photo-reaction, mainly because of the shorter chain lengths involved. Although the rate of reaction does not immediately attain its maximum value in a clean tube, a very light coating suffices to prevent completely any wall termination. Corrections due to absorption of monomer by polymer are practically absent.

The mixtures of hydrogen and vinyl acetate were prepared in two ways. In one procedure the reaction vessel was filled with vinyl acetate to a given pressure. This was condensed out, the side tube cooled in liquid air, and then hydrogen admitted. In the second procedure vinyl

acetate was admitted first, followed by hydrogen, the pressure of which was maintained at a high value in its reservoir so that little if any vinyl acetate vapour could diffuse out into the hydrogen reservoir. The former method was the more convenient where it was necessary to measure accurately the initial pressure of the hydrogen rather than the total pressure of the mixture.

A pressure of 30 mm. of hydrogen being used, the variation of initial rate of polymerisation with pressure of vinyl acetate is shown in Fig. 1. In the first place it will be seen there is a

FIG. 1.

Variation of total rate of polymerisation with vinyl acetate pressure.

marked acceleration in presence of hydrogen which can only occur because of the free-radical reaction induced by atomic hydrogen. Secondly, quite a fast reaction occurs at vinyl acetate pressures when the mercury-sensitised polymerisation of vinyl acetate does not proceed at all. At a pressure of 15 mm., however, this type of reaction seems to proceed in parallel with the hydrogen atom sensitised reaction. Below 15 mm. the free-radical reaction rate is proportional to the first power of the concentration of the acetate. Fig. 2 is a plot of the log of this rate as a function of radiation intensity. The slope of the line is 0.7, showing that quite a large proportion of the free radicals combines in the gas phase. Thus the kinetics are approximately expressed simply by

$$-d[M]/dt = \text{const. } [M]^{1/2}$$

characteristic of a normal reaction in which mutual termination occurs and in which the rate of initiation is independent of monomer concentration. When individual runs are examined, however, and allowance is made for the disappearance of the appropriate amount of hydrogen, the first-order "constant" decreases with decreasing pressure as shown in Table I. Even a second-order "constant" exhibits a slight tendency to decrease. It is evident that this

TABLE I.

Temp. 15°. Hydrogen pressure 27.2 mm.

Time (mins.)	0.	1.	2.	3.5	5.	7.	9.	10.
Press. (mm.) of vinyl acetate, uncorr.	18.6	15.5	13.1	10.9	9.5	8.1	7.0	6.5
Press. (mm.) of vinyl acetate, corr. for loss of H ₂	18.6	15.6	13.4	11.4	10.3	9.2	8.4	8.1
k (min. ⁻¹) (1st order)	—	0.177	0.164	0.140	0.118	0.100	0.088	0.083
k (min. ⁻¹ mm. ⁻¹) (2nd order)...	—	0.0100	0.0105	0.0095	0.0086	0.0079	0.0072	0.0070

diminution in velocity must be due to the accumulation of some rate-retarding molecule produced as a result of secondary reactions.

The addition of hydrogen actually inhibits the mercury photosensitised polymerisation since the hydrogen molecule deactivates quite a proportion of the excited mercury atoms. In fact it is possible to obtain an approximate estimate of the quenching radius of the vinyl acetate molecules from such data. Table II gives the relevant data for low vinyl acetate pressures.

TABLE II.

Monomer pressure (mm.)	18.0	22.3
Rate of mercury-sensitised reaction	0.9	2.2
Total rate of reaction with 30 mm. of hydrogen	1.00	1.85
Estimated rate of Hg-sensitised reaction in presence of hydrogen	0.79	0.66
Fraction of H ₂ molecules deactivating excited Hg atoms (f _{H₂})	0.79	0.69

At a pressure of 18.0 mm. the mercury-sensitised rate is reduced from 0.9 to 0.19 mm./min., since a fraction f_{H_2} of the mercury atoms is deactivated by hydrogen. The value of f_{H_2} at 22.3 mm. is 0.69. But f_{H_2} is given by the equation

$$f_{H_2} = \frac{\sigma_{H_2}[H_2]/[VA] \cdot \mu_{H_2-Hg}^{1/2}}{\sigma_{H_2}[H_2]/[VA]\mu_{H_2-Hg}^{1/2} + \sigma_{VA}^2\mu_{H_2-Hg}^{1/2}}$$

If σ_{H_2} is taken as 6.0×10^{-16} mm.², then since $[H_2]/[VA]$ is known, σ_{VA-H_2} may be computed. The figures are 20 and 25×10^{-16} mm.², respectively, in good agreement with the experimentally determined value of 25×10^{-16} mm.² for methyl methacrylate.

Inhibitors.—Although an examination of the course of an individual run showed unmistakable evidence of the production of an inhibitor, more direct evidence was desirable. This was obtained in the following manner. Unfortunately, the constant pressure-variable volume method cannot be used, but a modification is possible. A mixture of monomer and hydrogen at a suitable pressure is irradiated for such a time that 2 mm. of vinyl acetate are polymerised. The gases are then thoroughly mixed by moving the mercury in the gas burette, and the pressure is adjusted so that the original vinyl acetate pressure is obtained. Next, another 2 mm. of vinyl acetate are polymerised and the time is noted. If no inhibitor had been produced the

FIG. 2.

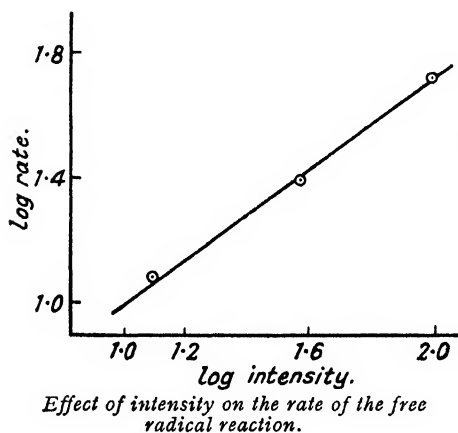

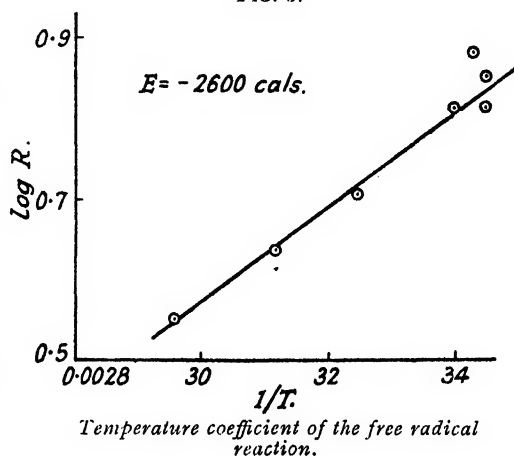

FIG. 3.

time should have been slightly shorter because of the slight diminution in volume of the system. Table III shows that, in fact, these times for 2 mm. polymerisation increased continually.

TABLE III.

	Vinyl acetate 18.8 mm.				Hydrogen 24.2 mm.			
Initial vol. of system (c.c.) ...	210	198	187	176	167	159	150	
Time (mins.) for $-\Delta p = 2$ mm.	1.23	1.18	1.63	2.58	3.50	4.75	6.75	

Further conclusive proof of the presence of an inhibitor can be obtained by examining the intensity exponent, which should increase as inhibitor accumulates. This is best done by carrying out two runs with different intensities and comparing the ratio of times required for the same pressure decrease throughout the course of the reaction. The following results were obtained in two such runs.

Ratio of intensities 8.0 : 1. Vinyl acetate 19.0 mm. Hydrogen 27.5 mm.			
Pressure range (mm.)	18—11	6.0—3.5	4.5—3.5
Ratio of times	2.3	3.16	3.8

The increase in ratio shows that the exponent is increasing from about 0.5 towards unity at the end of the run.

The inhibitor is not produced by short-wave radiations from the 2537 Å. lamp, for an acetic acid filter does not cut down inhibitor production. It is condensable in liquid air and solid carbon dioxide. This was shown by condensing the contents of the reaction vessel after a run into a suitable trap and pumping off all non-condensable gas. Fresh hydrogen was then added, and the run continued. At -183° and -80° the inhibitor was retained in the trap.

Temperature Coefficient.—The temperature coefficient of the free-radical reaction can only be studied over a comparatively small range since at higher temperatures the direct reaction begins to make its appearance and thus complicates the interpretation of the kinetics. Fig. 3 shows how the rate varies with temperature, the rate being measured by taking the reciprocal of the time for the pressure of vinyl acetate to fall 4 mm. It will be seen that the temperature

coefficient is negative, with a value of -2600 cal. So far as is known, the addition of atomic hydrogen to an unsaturated molecule proceeds with such a small energy of activation that the temperature coefficient of the polymerisation process must certainly be due to that of the propagation and termination reactions. Since the polymerisation ends by mutual destruction of active molecules, the apparent energy of activation is equal to $E_p - \frac{1}{2}E_T$, E_p and E_T being the energies of activation for propagation and termination. These temperature coefficients were measured at different intensities and the results are given in Table IV.

TABLE IV.
Chain length at 17° :

8.		12.		50.	
Temp.	τ (mins.) for $\Delta p = 4$ mm.	Temp.	τ (mins.) for $\Delta p = 4$ mm.	Temp.	τ (mins.) for $\Delta p = 4$ mm.
17.5°	4.00	17.0°	6.25	18.0°	10.0
19.5	3.6	18.6	5.3	19.0	11.4
25.0	5.2	21.3	6.2	32.0	19.7
35.5	4.3	34.5	7.9	48.0	38.4
55.0	5.5	47.6	9.3	—	—
—	—	65.0	11.2	—	—
$E = -1900$ cal.		$E = -2600$ cal.		$E = -8200$ cal.	

This reaction thus falls into line with the direct photo-polymerisation and with the polymerisation of methyl acrylate and of methyl vinyl ketone in the gas phase in that negative energies of activation are observed. With the free-radical reaction it is probable that the value would not change with further increase in chain length. The mere fact that the value is negative would imply that E_T is greater than E_p by a substantial amount. This fact is anomalous since it would imply that the two free radicals must become activated before they react with each other; in other words, more activation energy is required for the interaction of two radicals than is required for the interaction between a radical and a double bond. Such a state of affairs is hardly conceivable, but there appears to be no valid alternative explanation. The variation of the apparent energy of activation with chain length may quite well be due to a variation in E_p or E_T , especially when the chain length is so short.

Chain Length.—If after a hydrogen-atom-sensitised polymerisation all the vinyl acetate vapour is condensed out by passing the mixture through a trap cooled in liquid air, the hydrogen pressure is less than that at the start of the run. For example, with 18.6 mm. of vinyl acetate and 27.15 mm. of hydrogen a time of illumination of 10 mins. gives a total pressure decrease of 12.3 mm., the hydrogen pressure being now 25.85 mm. The reason for the small fall in pressure is that the hydrogen atom responsible for starting polymerisation is incorporated in the polymer itself. Thus the decrease may be made the basis of measuring the kinetic chain length of the reaction and therefore the number average molecular weight of the polymer.

Owing to the small pressure decrease certain precautions have to be taken. Only tubes lightly coated with polymer may be used since atomic hydrogen may reduce the polymer and so be removed in a non-polymerisation reaction. The most convenient method of measuring the decrease in hydrogen pressure consists in admitting the appropriate amount of vinyl acetate, freezing this out, and then admitting hydrogen. After the run the vinyl acetate is once more frozen out, and the hydrogen pressure measured. After correction for the cooling of the trap, the decrease in pressure of hydrogen is subtracted from the total observed pressure decrease to give the diminution in vinyl acetate pressure.

In considering the kinetics of the reaction as a whole it is necessary first to determine whether there is any possibility of a hydrogen atom terminating polymerisation as well as starting it. If this kind of termination occurred exclusively, then it can be shown (Melville, *Proc. Roy. Soc.*, 1937, *A*, 163, 511) that $R \sim \text{const.} [M]^2$, the rate being independent of intensity. Since the observed kinetics are $R \sim \text{const.} [M]I^{\frac{1}{2}}$, it is evident that this kind of termination does not enter into the question. As has been seen in Table IV, the kinetic chain length is comparatively short, and this introduces a slight complication. The general expression for the concentration of the active polymer is

$$d[P]/dt = I - k_t[P]^2 = 0$$

where $I = k[H][M]$, k being the bimolecular coefficient for the reaction of hydrogen atoms with the monomer. For short chains, then

$$-d[M]/dt = I + I^{\frac{1}{2}}[M]k_p/k_t$$

Thus the rate will not be strictly proportional to the square-root of the intensity. The deviation may be computed in the following way. Suppose $-d[M]/dt \sim I^x$; then for two intensities

$$x = [\log R_2/R_1]/[\log (I_2/I_1)]$$

Let $I_2/I_1 = 8$, as was used in some experiments, then, if $\delta = k_t/k_p$,

$$\begin{aligned} x \log 8 &= \log \frac{I_2 + [M]\delta^{-1}I_2^{\frac{1}{2}}}{I_1 + [M]\delta^{-1}I_1^{\frac{1}{2}}} \\ &= \log \sqrt{8} + \log \frac{v_2}{v_2 - 0.65} \end{aligned}$$

where v_2 is the chain length at intensity I_2 ; or

$$x = 0.50 + 1.11 \log v_2/(v_2 - 0.65)$$

Hence x may be obtained for various different values of v_2 as follows :

$v_2 =$	4	5	6	12	∞
$x =$	0.586	0.567	0.55	0.53	0.500

For example, with a vinyl acetate pressure of 19 mm. and $H_2 = 27.5$ mm. at 17° , the chain length is greater than 10 for full intensity and over 30 at the 0.125 full intensity x (experimental) = 0.47.

Independent evidence also indicates mutual termination of polymer growth. In such a mechanism the chain length should be inversely proportional to the square-root of the intensity of incident light. Instantaneous values of the chain length cannot, of course, be computed because of the impossibility of measuring accurately small decreases in hydrogen pressure; hence the following procedure was adopted. The hydrogen-vinyl acetate mixture is illuminated, and the chain length measured by the above-mentioned method. A second measurement is made by resuming the run. In this way the corrected vinyl acetate pressure-time curve is constructed. The rate of polymerisation at say two given pressures can then be read off. The rate of hydrogen loss is assumed to be the average rate of loss over the run. The whole procedure is then repeated at a lower intensity. The results in Table V show the expected dependence of chain length on intensity, and the observed figures are in reasonably good agreement with the theoretical values calculated from the ratio of the intensities.

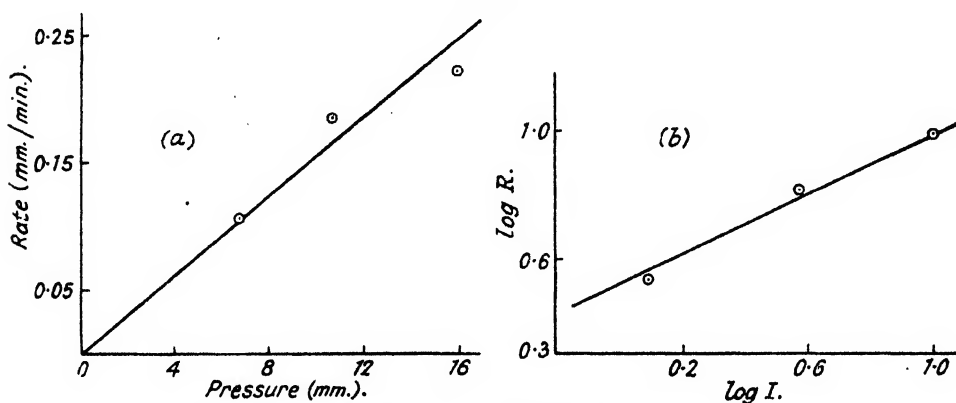

TABLE V.

Intensity.	Chain length at vinyl acetate pressures (mm.) of :		Ratio of chain lengths obs. at vinyl acetate pressures (mm.) of :		Calculated ratio of chain lengths.
—	13.0	6.0	13.0	6.0	—
1.00	13.5	2.7	3.6	2.5	2.83
0.125	49	6.8	—	—	—

Methyl-radical-sensitised Reaction.—Hydrogen atoms are not always the most suitable type of initiator for a free-radical reaction. In addition, it has been shown with butadiene, for example (Jones and Melville, *Proc. Roy. Soc.*, 1946, A, **187**, 87), that whereas methyl radicals initiate polymerisation, hydrogen atoms lead to hydrogenation of the butadiene. It was therefore desirable to see whether methyl radicals from photodecomposing acetone could effect polymerisation of vinyl acetate vapour and so find whether the kinetics of the two reactions are identical. With acetone as a source of methyl radicals there is a very marked acceleration of polymerisation, for at 22 mm. vinyl acetate pressure the rate was 0.02 mm./min. but on addition of 40 mm. of acetone the rate jumped to 0.45 mm./min. Even well below the critical limit with VA = 16 mm., the rate was 0.22 mm./min., the rate of the direct reaction being negligible. In Fig. 4 the kinetics are briefly summarised. In Fig. 4(a) it will be seen that the rate is proportional to pressure, the upper limit of pressure being fixed by the limit for the direct reaction. In Fig. 4(b) log rate is plotted against log intensity. The slope of the straight line is 0.46. Thus the kinetics of the hydrogen-atom- and of the methyl-radical-sensitised reaction are exactly similar. There is, however, a further interest in this similarity. If matters are so adjusted that the two reactions occur at the same speed, then the chain length must be identical and the rate of initiation must also be identical. But the rate of production of hydrogen atoms is known, and hence it should in principle be possible to measure the rate of production of methyl radicals from acetone, and thus throw some further light on the photochemistry of this molecule. Much has already been written about the photochemistry

of acetone, and it is usually presumed that when the molecule does dissociate the first act is the production of acetyl and methyl radicals and that the former subsequently decompose to methyl and carbon monoxide, though under some conditions they may combine to diacetyl. In a recent paper evidence is presented to show that apparently the excited acetone molecule may decompose to fragments of ethane and carbon monoxide *without* the production of radicals. The production of acetyl does complicate matters. In some acetone-catalysed polymerisations (Jones and Melville, *loc. cit.*) it has been found that the rate of production of carbon monoxide from acetone is diminished when monomer is present. This would imply that the acetyl radical reacts with the monomer before it has time to decompose. Similar experiments were made with acetone and vinyl acetate, pressures of 16–17 mm. of vinyl acetate and 35.40 mm. of acetone being used; thus, in 5 mins. 11.7×10^{-3} mm. of carbon monoxide were produced with acetone alone; with vinyl acetate present, 4.6 mm. of gas were polymerised and the pressure of monoxide was 11.2×10^{-3} mm. In another series of experiments, carbon monoxide production was 29×10^{-3} and 28×10^{-3} mm., respectively, in presence and in absence of vinyl acetate. Thus acetyl radicals do not initiate polymerisation, unless, of course, the carbon monoxide molecule is eliminated just when the acetyl radical meets a vinyl acetate molecule, an unlikely state of affairs.

FIG. 4.

(a) Effect of pressure on the methyl-radical-sensitised reaction.

(b) Effect of intensity on the radical-sensitised reaction.

The experimental procedure is somewhat complicated. First of all two lamps are used, the first a low-pressure lamp emitting the 2537 Å. line to dissociate the hydrogen, the second a high-pressure lamp to dissociate the acetone. The distances of these lamps from the reaction vessel are so adjusted that with a given acetone pressure the rates of polymerisation are the same. First, a hydrogen atom run is made, the chain length being measured at two points. Next another hydrogen atom run is made for approximately half the period, and the chain length re-measured. Acetone is then admitted to a pressure of 50 mm. The hydrogen pressure is then measured again since a small amount escapes on introduction of the acetone. The hydrogen-vinyl acetate-acetone mixture is then irradiated with the high-pressure lamp for a time such that polymerisation occurs to the same extent as with the first hydrogen atom run. The data from the first run then give the hydrogen molecule consumption during the second part of the run. Finally, the vinyl acetate and acetone are condensed out, and the total pressure due to hydrogen and to carbon monoxide is measured.

By this method it was found over the same range of vinyl acetate pressures, *viz.*, 17.5–12.5 mm., that the carbon monoxide produced from the photodecomposing acetone was equal to volume of hydrogen consumed in the corresponding part of the hydrogen run. The data for a run of this type are given below.

Vinyl acetate = 22.0 mm. Hydrogen 35.0 mm. Acetone 50.0 mm.

Type of run.	Rate of 1st half of polymerisation.	Rate of 2nd half of polymerisation.	
Me	1.38	0.80	0.25 mm. CO produced
H	1.32	0.73	0.30 mm. H ₂ consumed
Me	1.46	0.98	0.25 mm. CO produced

General Discussion of the Vinyl Acetate Reaction.

It now remains to discuss and compare the free-radical and the direct polymerisation reactions. The former is at first sight the simpler, for the mechanism consists in the addition of the hydrogen atom or methyl radical to the vinyl acetate molecule to form another free radical, to which are subsequently added further vinyl acetate molecules until two of these comparatively large free radicals interact. It is not yet certain whether this results in combination or disproportionation. The anomalous feature of this and other gas-phase reactions is the negative temperature coefficient. This may be due to a variety of factors. First, even if the radical polymers are small, it may be that in course of growth a new solid phase appears with the consequence that monomer will presumably be adsorbed on this growing particle as a necessary preliminary to addition. The rate of polymerisation will then be proportional to the concentration of monomer in the polymer particle. Increase of temperature will consequently decrease this concentration so that this factor alone will give rise to an apparent negative temperature coefficient. Second, quite a different factor may also give rise to a diminished temperature coefficient. It has now been established (Burnett and Melville, *Nature*, 1946, 158, 553) that when polymerisation of vinyl acetate occurs in a solvent such as hexane in which the polymer is not very soluble, the effect of precipitating out the growing polymer is to diminish the magnitude of the bimolecular reaction coefficient for the termination of polymer growth. The coefficient which is not normally affected by temperature acquires in these circumstances a positive temperature coefficient. A similar precipitation will occur even more readily in the gas phase. It is not therefore surprising that an overall negative temperature coefficient is observed, and that the larger the kinetic chain length the higher the value of the negative energy of activation. It is possible that both factors operate together.

With the direct reaction at sufficiently high pressures, the general kinetics are similar to those of the pure radical reaction. For comparable rates of initiation the overall polymerisation velocities of the radical and of the direct reaction are quite similar. It would therefore seem probable that the direct reaction also proceeds by a free-radical mechanism. The problem then is to understand why the critical pressure limit and inert gas effects make their appearance. The matter is most satisfactorily accounted for if it is assumed that absorption of ultra-violet light by monomer results in the production of a di-radical. Such a radical is simply an electronically excited molecule. The results show clearly that such a molecule can spontaneously give up its electronic energy or give it up to an inert gas at quite low pressures. At high enough pressures, however, further monomer molecules will add on to both ends of this di-radical. It is unfortunate that the photopolymer is made insoluble by some secondary reactions and thus its molecular weight cannot be compared with that of the free-radical polymer. The negative temperature coefficient of the direct reaction then is explained in a similar manner to that of the radical reaction.

Experimental evidence has been given elsewhere to suggest that the polymerisation of vinyl acetate in the liquid phase or in solution goes by way of free radicals. Here there should be an exact correlation between the reaction in the two phases. The obstacle to establishing a numerical correlation is due wholly to the so-called gel effect, *i.e.*, to the influence of environment or polymer shape on the velocity coefficient for the termination of molecular growth. In the liquid phase precisely similar overall kinetics are observed, but it is evident that the magnitudes of the velocity coefficients cannot be compared. For the gas phase the termination coefficient will not have its maximum value but some lower and ill-defined value. For these reasons the liquid-phase reaction with either pure monomer or monomer in a good solvent is far simpler than the gas-phase reaction.

The experiments described in this and the preceding paper were carried out in 1938–39 in the Colloid Science Department, The University, Cambridge. We should like to thank Professor E. K. Rideal for his great encouragement and interest in this work. These researches were made possible owing to the generosity of Aero Research Limited, Duxford, Cambridgeshire, who kindly provided a maintenance grant to one of us (R. F. T.).

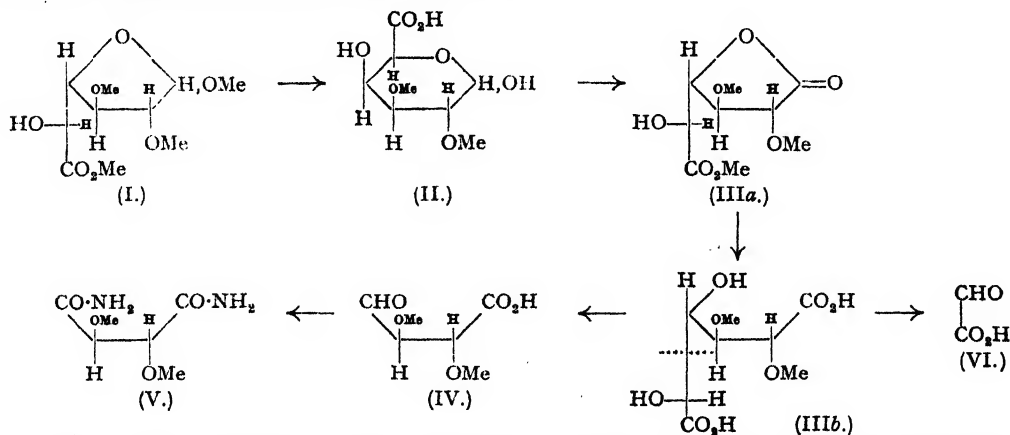

228. Pectic Substances. Part V. The Molecular Structure of Strawberry and Apple Pectic Acids.

By G. H. BEAVAN and J. K. N. JONES.

Degradation products prepared from strawberry pectin and apple pectin by boiling with methanolic hydrogen chloride have been converted into their methylated derivatives. Hydrolysis of the latter with methanolic hydrogen chloride yielded the methyl ester of 2:3-dimethyl methyl-*d*-galacturonoside as the main product. The bearing of these observations on the chemical structure of pectic acid is discussed.

PECTINS commonly occur in fruit and have been the subject of chemical investigation by many workers, and it is now generally accepted that they are mixtures of polysaccharides, amongst which galactan, araban, and polygalacturonosides predominate (for a review of the evidence see the article by Hirst and Jones, "Advances in Carbohydrate Chemistry", Vol. II, 1946). These polysaccharides are in close physical union, and great difficulty is experienced in separating the components in a pure condition, particularly those of the polygalacturonoside fraction. Arabans from peanut, apple, and citrus pectins have been shown to consist of *l*-arabofuranose residues linked to form a branched chain polymer (Hirst and Jones, *J.*, 1938, 496; 1939, 453, 454; Beavan, Hirst, and Jones, *J.*, 1939, 1865), whilst the galactan from *Lupinus albus* consists of β -*d*-galactopyranose residues in the form of a linear polymer (Hirst, Jones, and Walder, *J.*, forthcoming publications). These two polysaccharides could not therefore be derived one from the other by oxidation and decarboxylation at C₆ of the pyranose residues. In view of these results it became of special interest to determine whether any correlation exists between the structures of the pectic acid and of either of the polysaccharides associated with it, and whether pectic acids from different sources possess similar structures.

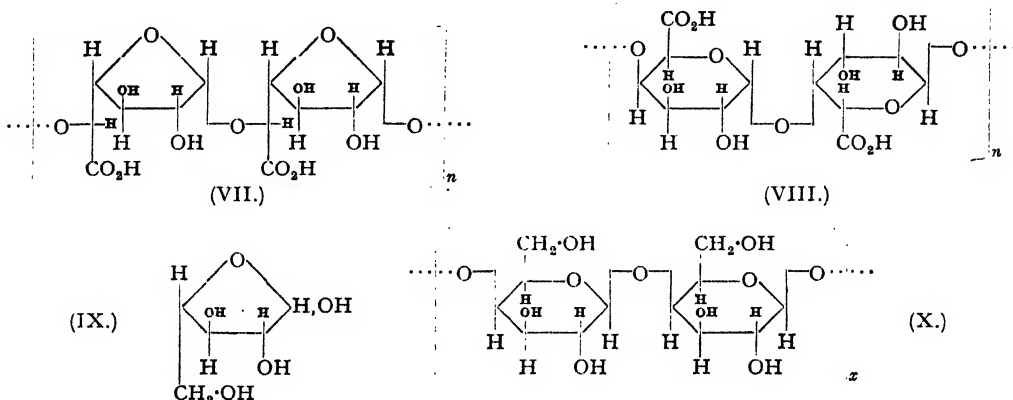

The investigation of the pectic acid component was rendered all the more difficult by reason of the special physical and chemical properties of the polysaccharide. In a previous publication (Beavan and Jones, *Chem. and Ind.*, 1939, 58, 363) attention was drawn to the difficulties encountered in methylating pectic acid both by the methyl sulphate and by the thallium methylation technique. This difficulty was in part overcome by methylating a degraded pectic acid derivative prepared by boiling crude pectin with methyl alcoholic hydrogen chloride (Morrel, Bauer, and Link, *J. Biol. Chem.*, 1935, 105, 1; Hirst, Jones, and Jones, *J.*, 1939, 1880). This procedure destroyed the more labile araban and galactan and converted the pectic acid into the methyl ester of a degraded polygalacturonide of approximately eighteen residues. The physical properties of this material, designated "polyester" by Morrel, Bauer, and Link, made it more amenable to methylation by the thallium technique (Menzies, *J.*, 1926, 937; Hirst and Jones, *J.*, 1938, 497) and by this method the methylated derivatives of strawberry and apple polyesters were prepared and examined. The present results indicate that these polyesters are similar in constitution to the methylated polygalacturonic acids which have been previously examined (Smith, *Chem. and Ind.*, 1939, 58, 363; Beavan and Jones, *loc. cit.*; Luckett and Smith, *J.*, 1940, 1106).

Proof of the constitution of the methylated polyester was furnished by the following observations: the methylated polyuronide gave, on hydrolysis with methyl alcoholic hydrogen

chloride under pressure, 2:3-dimethyl methyl-*d*-galacturonoside methyl ester (I) as a mixture of its pyranose and furanose forms (cf. Lockett and Smith, *loc. cit.*). On hydrolysis with aqueous acid (I) was converted into 2:3-dimethyl *d*-galacturonic acid (II) identified after oxidation and esterification as the crystalline γ -lactone methyl ester (IIIa) of 2:3-dimethyl *d*-mucic acid (IIIb). The constitution of this crystalline product followed from its reaction with periodic acid, which gave the half-aldehyde of *l*(+)-dimethoxysuccinic acid (IV), identified as *l*(+)-dimethoxysuccinamide (V), and glyoxylic acid (VI), identified by its colour reaction with casein and sulphuric acid.

The polyester from both strawberry and apple pectin must therefore be a polymer built up of *d*-galacturonic acid residues in which the hydroxyl groups on C₂ and C₃ are free. The two structures which are in agreement with this evidence are (VII) and (VIII), of which the pyranose form (VIII) is by far the more probable since the pyranose structure alone would display the resistance to acidic hydrolysis so characteristic of the pectic acid molecule. That the linkage

between the galacturonic acid residues is of the α -type is shown by the high positive rotation of pectic acid. It is clear, therefore, that a polygalacturonide with this structure cannot be transformed directly by decarboxylation at C₆ into an araban of the type found associated with pectic acid, since this araban is known to possess a branched chain structure of *l*- α -arabofuranose residues (IX) linked to each other in three different ways—namely, through C₁ (A1...), through C₁ and C₆ (...5A1...), and through C₁C₃ and C₅ (...⁵A1...). Nor can the pectic acid arise from the galactan (X) by oxidation of the primary alcohol groups, since the sugar residues in (X) are linked by β -links. It follows, therefore, that if galactan (X) is the source of araban, then hydrolysis followed by re-synthesis of the oxidised and decarboxylated sugar must intervene.

EXPERIMENTAL.

Strawberry Pectic Acid.—The pectin was obtained from strawberry juice, for a supply of which we wish to express our thanks to Dr. V. L. S. Charley and Carter and Co. of Bristol. The crude pectin was contaminated with kieselguhr; it was triturated with 90% alcohol and filtered to remove colouring matter. The solid was dried at 40°/12 mm. and extracted with the calculated quantity of dilute sodium hydroxide solution. The sludge was spun on the centrifuge and the top clear, light blue solution poured with stirring into 5 vols. of 90% alcohol acidified with hydrochloric acid. Pectic acid was precipitated; it was filtered off, washed with alcohol until free from hydrochloric acid, and dried under reduced pressure; $[\alpha]_D^{20} + 251^\circ$ (in neutral aqueous solution) [Found: Uronic anhydride, 84.0 (calc. from the yield of carbon dioxide evolved on boiling with 12% hydrochloric acid); pentosan, 4.1 (calc. from the yields of furfuraldehyde and carbon dioxide evolved on boiling with 12% hydrochloric acid); galactan, 9.9 (by difference); OMe, 0.2%; equiv., 225].

Strawberry Pectin Polyester (see Morrel, Bauer, and Link, *loc. cit.*).—Strawberry pectic acid (100 g.) was refluxed with stirring with 3% methyl alcoholic hydrogen chloride (1 l.). After 24 hours sufficient concentrated methyl alcoholic hydrogen chloride was added to bring the concentration up to 5% and the refluxing continued for a further 66 hours. The cooled reaction mixture was spun on the centrifuge and the dark slimy solid thus obtained washed with methyl alcohol until free from hydrogen chloride. The solid was dried at 60°/12 mm. and then extracted thrice with boiling water (500 c.c.). The extracts were spun on the centrifuge and the clear solution was poured into alcohol (2½ l.). The precipitated polyester (65 g.) was separated on the centrifuge, washed with alcohol and acetone, and dried at 50°/12 mm.; $[\alpha]_D^{20} + 234^\circ$ (c, 1.2) (Found: OMe, 17.4%; equiv., 200).

A sample of the polyester was titrated with the calculated quantity of barium hydroxide and the resulting barium salt precipitated with alcohol. The white solid was filtered off, washed with alcohol,

and dried in a vacuum (Found: Ba, 25.1; OMe, 1.8. A methylpolygalacturonoside methyl ester containing eight units requires Ba, 27.7; OMe, 1.6%).

Methylation of Strawberry Polyester.—The polyester (5.7 g.) was dissolved in water (20 c.c.) and to it was added a hot concentrated solution of thallium hydroxide (30 c.c. of 6*N*). The cream-coloured precipitate was filtered off, washed with methyl alcohol and ether, and dried at 40°/12 mm. The orange solid was ground to a powder (120 mesh) and boiled with methyl iodide for 72 hours under reflux with the exclusion of light and moisture. Excess of methyl iodide was distilled off and the residue extracted exhaustively with methyl alcohol. The extracts on concentration gave partially methylated strawberry polyester as a pale brown solid (4.6 g.). The partially methylated material was dissolved in alcohol and evaporated to dryness with the addition of a benzene solution of thallous ethoxide (5 equivs.). The resulting brown solid was powdered (120 mesh) and boiled with methyl iodide until the thallium iodide was neutral to litmus. Methylated strawberry polyester was isolated, as described above, as a stiff brown syrup (4.35 g.) (Found: OMe, 42.4%). The syrup was separated into two fractions by precipitation from a chloroform solution with ether. (A) Ether-insoluble (2.15 g.); $[\alpha]_D^{20} + 144^\circ$ (c, 0.66 in methyl alcohol) (Found: OMe, 39.9%). A dimethyl uronic methyl ester polymer requires OMe, 42.7%. (B) A stiff brown syrup obtained on evaporation of the ethereal extract (2.20 g.), which was not further examined.

Hydrolysis. The methylated polyester was extremely resistant to hydrolysis, but this could be effected by the use of methyl alcoholic hydrogen chloride under pressure. The material (2.10 g.) was dissolved in 3% methyl alcoholic hydrogen chloride (35 c.c.) and heated at 140° in a sealed tube for 24 hours. The hydrolysis mixture was nearly neutral and a considerable pressure developed in the tube owing to the formation of methyl chloride and carbon dioxide. The solution was neutralised with silver carbonate, filtered, and evaporated under diminished pressure to a dark brown syrup (1.85 g.). This was separated into two fractions by extraction with ether—(1) an ether insoluble solid which consisted of incompletely hydrolysed material, and (2) an ether-soluble syrup consisting of the methyl ester of 2:3-dimethyl methyl-*d*-galacturonoside [1.5 g., $n_D^{18} 1.473$, $[\alpha]_D^{20} - 27^\circ$ (in acetone)]. This was fractionally distilled in a vacuum giving: (a) the methyl ester of 2:3-dimethyl methyl-*d*-galacturonoside (0.90 g.), b. p. 150°/0.001 mm. (bath temp.), $n_D^{18} 1.4618$, $[\alpha]_D^{21} - 38^\circ$ (c, 3.0 in water) (Found: OMe, 48.2; equiv., 254. Calc. for $C_{10}H_{14}O_7$: OMe, 49.6%; equiv., 250); (b) a fraction, b. p. 180°/0.01 (0.3 g.), $n_D^{18} 1.4738$, which was partly crystalline, the crystals which separated after tiling having m. p. 211° not raised on recrystallisation from ether; (c) still residue (0.3 g.).

The distilled ester (0.87 g.) was hydrolysed with *N*-hydrochloric acid (30 c.c.) at 90–95°: $[\alpha]_D^{21} - 38^\circ$ (initial value); + 31° (25 minutes); + 52° (1 hour); + 59° (1½ hours, constant value). The solution was neutralised with silver carbonate and filtered before and after the passage of hydrogen sulphide. Removal of the solvent at 40°/12 mm. left 2:3-dimethyl *d*-galacturonic acid (0.8 g.), $[\alpha]_D^{20} + 63^\circ$ (c 1.11 in water) (Found: OMe, 25.9; equiv., 212. Calc. for $C_8H_{14}O_7$: OMe, 27.9%; equiv., 222), which was oxidised with bromine water; the resultant 2:3-dimethyl *d*-mucic acid (0.8 g.) was isolated as a syrup, $[\alpha]_D^{21} - 20^\circ$ (c, 0.99 in methyl alcohol) (Found: OMe, 25.0; equiv., 122. Calc. for $C_8H_{14}O_8$: OMe, 26.9%; equiv., 119). The acid (0.70 g.) was esterified by boiling with 2% methyl alcoholic hydrogen chloride for 15 hours. The cooled solution was neutralised with silver carbonate, filtered, and evaporated to a syrup, which was extracted with ether. The solvent was distilled off, leaving the syrupy ester (0.72 g.), $n_D^{18} 1.4688$, $[\alpha]_D^{20} - 5^\circ$ (c, 0.78 in methyl alcohol) (Found: OMe, 38.8%), a portion of which (0.40 g.) was distilled under reduced pressure giving the methyl ester of the 1:4-lactone of 2:3-dimethyl *d*-mucic acid (0.33 g.), b. p. 160°/0.001 mm. (bath temp.), $n_D^{18} 1.4658$, $[\alpha]_D^{20} - 40^\circ$ (in water) (Found: equiv., 118). This crystallised on standing and was recrystallised from ether. It had m. p. 77–78°, raised to 96° on drying in a vacuum (Found, on a dried sample: C, 46.2; H, 5.8; OMe, 38.4. Calc. for $C_8H_{14}O_7$: C, 46.2; H, 6.0; OMe, 39.7%).

The ester lactone (0.26 g.), m. p. 96°, was oxidised with the calculated quantity of periodic acid in water (10 c.c.): $[\alpha]_D^{22} - 40^\circ$ (initial value); - 10° (5 minutes); + 12° (12 hours, constant value). The solution was neutralised with barium carbonate, filtered, and concentrated to about 5 c.c. A small portion of the solution at this stage gave with casein and sulphuric acid a strong positive test for glyoxylic acid. Barium carbonate (1 g.) and bromine (1 c.c.) were added to the solution which became non-reducing towards Fehling's solution after 12 hours. The solution was aerated to remove excess of bromine and filtered. The filtrate was evaporated to dryness and the residue esterified by boiling with 2% methyl alcoholic hydrogen chloride (90 c.c.). The cooled solution was neutralised with silver carbonate and filtered, and the solvent evaporated at 60°/12 mm. The solid residue was exhaustively extracted with ether and the extracts were concentrated in a vacuum to a syrup (0.20 g., $n_D^{20} 1.4348$) which was distilled giving the dimethyl ester of *l*(+)-dimethoxysuccinic acid (0.15 g.), b. p. 90–110°/0.001 mm. (bath temp.), $n_D^{21} 1.4322$, $[\alpha]_D^{20} + 77^\circ$ (c, 2.46 in methyl alcohol) (Found: OMe, 58.2. Calc. for $C_8H_{14}O_8$: OMe, 60.2%). The ester (120 mg.) with methyl alcoholic ammonia gave needle-shaped crystals of the diamide of *l*(+)-dimethoxysuccinic acid (75 mg.), m. p. and mixed m. p. 280° (decomp.), $[\alpha]_D^{20} + 96^\circ$ (c, 0.73 in water).

Apple Pectin Polyester.—Apple pectic acid (Hirst and Jones, *J.*, 1939, 456) (uronic anhydride, 73.0; OMe, 10.2%; equiv., 250; $[\alpha]_D^{28} + 230^\circ$) was converted by boiling with methyl alcoholic hydrogen chloride in the usual manner into the polyester which was isolated, as described above, as a snow-white powder. Yield, 65%; $[\alpha]_D^{29} + 226^\circ$ (in neutral aqueous solution) (Found: OMe, 17.4%; equiv., 195). A sample of the polyester was treated with the calculated quantity of barium hydroxide and the resulting barium salts were precipitated by alcohol. The white solid was filtered off, washed with alcohol, and dried in a vacuum (Found: Ba, 24.6; OMe, 1.5. A methylpolygalacturonoside methyl ester containing eight units requires Ba, 27.7; OMe, 1.6%).

Methylation. The polyester (6.0 g.) was dissolved in water (30 c.c.) and a hot solution of 2*N*-thallous hydroxide (100 c.c.) was added. The precipitated white thallium derivative was filtered off, washed with alcohol and ether, and dried at 60°/12 mm. The powdered solid (120 mesh) was boiled with methyl iodide under reflux with the exclusion of light and moisture until the solid no longer had an alkaline

reaction. The solution was worked up as described for the strawberry polyester. Two further methylations with thalious ethoxide solution gave methylated apple polyester as a syrup (5.4 g.). This was dissolved in chloroform and separated by the addition of ether into (a) a crisp brown solid {1.8 g., $[\alpha]_D^{20} + 146^\circ$ (in methyl alcohol); OMe, 39.9%}, and (b) a syrup which was not further examined.

Hydrolysis. Methylated apple polyester (1.10 g.) was dissolved in 4% methyl alcoholic hydrogen chloride (25 c.c.) and heated under pressure at $140-150^\circ$ for 24 hours. The cooled solution was neutralised with silver carbonate, filtered, and evaporated to a syrup (0.95 g.) which was exhaustively extracted with ether. Evaporation of the ether left a syrup (0.80 g.), $n_D^{21} 1.4842$, $[\alpha]_D^{20} - 15^\circ$ (c, 1.0 in acetone), which was distilled in a vacuum giving: (1) 0.10 g., b. p. up to $130^\circ/0.001$ mm. (bath temp.), $n_D^{21} 1.4805$; (2) the methyl ester of 2:3-dimethyl methyl-*d*-galacturonoside (0.39 g.), b. p. $160^\circ/0.001$ mm. (bath temp.), $n_D^{19} 1.4645$, $[\alpha]_D^{30} - 30^\circ$ (c, 1.5 in water) (Found: OMe, 48.1%); (3) 0.1 g. of syrup which partly crystallised, b. p. $175-200^\circ/0.001$ mm.

Fraction (2) (0.37 g.) was hydrolysed with *N*-hydrochloric acid (25 c.c.): $[\alpha]_D^{20} - 30^\circ$ (initial value); $+ 47^\circ$ ($1\frac{1}{2}$ hours); $+ 51^\circ$ (3.75 hours, constant value). The cooled solution was neutralised with silver carbonate, and filtered before and after the passage of hydrogen sulphide. Evaporation of the solvent gave 2:3-dimethyl *d*-galacturonic acid (0.32 g.), $[\alpha]_D^{20} + 35^\circ$ rising to $+ 58^\circ$ in 1 hour (c, 6.0 in water) (Found: OMe, 26.9; equiv., 226. Calc. for $C_6H_{10}O_7$: OMe, 27.9%; equiv., 222). The acid (0.30 g.) was dissolved in water (7 c.c.) and oxidised with bromine (1 c.c.) for 12 hours. The solution was then non-reducing. Bromine was removed by aeration and the solution neutralised with silver carbonate and filtered before and after the passage of hydrogen sulphide. Evaporation of the solution gave 2:3-dimethyl *d*-mucic acid (0.30 g.) which was converted into the methyl ester of the 1:4-lactone of 2:3-dimethyl *d*-mucic acid by boiling 3% methyl alcoholic hydrogen chloride (50 c.c., 7 hours). The solution was worked up in the usual manner and the crude ester lactone (0.31 g.) distilled giving the methyl ester of the 1:4-lactone of 2:3-dimethyl *d*-mucic acid (0.26 g.), b. p. $160^\circ/0.001$ mm. (bath temp.), $n_D^{20} 1.4650$. The distillate crystallised on nucleation with an authentic specimen of the ester lactone. Trituration with ether and filtration gave crystals (0.20 g.), m. p. and mixed m. p. with an authentic specimen, 96° (Found: OMe, 38.6%).

229. Pectic Substances. Part VI. The Structure of the Araban from *Arachis Hypogaea*.

By E. L. HIRST and J. K. N. JONES.

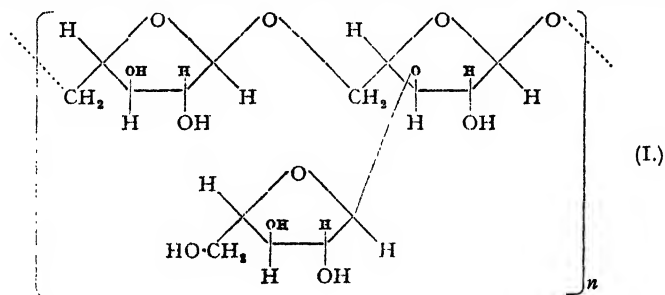

The constitution of the araban component of the pectic material present in the peanut (*Arachis Hypogaea*) has been further investigated. On hydrolysis of the methylated araban, trimethyl methyl-*l*-arabofuranoside, 2:3-dimethyl methyl-*l*-arabinoside, and a monomethyl methyl-*l*-arabinoside were isolated in the approximate proportions 1:1:1. The monomethyl arabinose has now been identified as the 2-methyl derivative, and no other monomethyl *l*-arabinose could be detected. The bearing of these results on the structure of araban is discussed.

ARABANS isolated from several sources of pectin have already been examined, and in all cases it has been demonstrated that on hydrolysis the methylated polysaccharide gave rise to three derivatives of arabinose in approximately equal proportions (Hirst and Jones, *J.*, 1938, 496; 1939, 454, 456, 1865). These arabinose derivatives were identified as 2:3:5-trimethyl *l*-arabofuranose, 2:3-dimethyl *l*-arabinose, and a monomethyl *l*-arabinose which was provisionally identified as 3-methyl *l*-arabinose. The identification of this substance was dependent upon the following observations: (1) The sugar had no methoxyl group on C_5 , since on acidic hydrolysis of the glycoside it gave a derivative of *l*-arabopyranose characterised by its high positive rotation; (2) it had a hydroxyl group on C_4 , since on oxidation it gave a furano-lactone showing a negative rotation and a characteristic slow rate of hydrolysis. Moreover, the rate of hydrolysis of the original araban indicated that all the arabinose components were present in the furanose form and therefore that the hydroxyl group on C_4 was engaged in ring formation and could not be replaced by a methoxyl group after methylation (Hirst and Jones, *J.*, 1939, 454). Only two possibilities, therefore, for the monomethyl derivative remained. It could be either 2- or 3-methyl *l*-arabinose. The latter was thought to be the sugar present in the hydrolysis products of the methylated araban since the amide from the syrupy hydrolysis product gave a positive Weerman test, indicating the presence of an α -hydroxy-amide. It has now been ascertained that this positive test was due to the presence of a small quantity of *l*-arabonamide in the crude syrupy amide, a trace of *l*-arabinose being present in the monomethyl arabinose fraction owing to the difficulty encountered in separating

these two high boiling fractions. In order to obtain further insight into the constitution of the monomethyl arabinose the two sugars, 2- and 3-methyl *l*-arabinose were synthesised and crystalline derivatives of them were prepared (Jones, Kent, and Stacey, in the press; Hirst, Jones, and Williams, in the press). Crystalline derivatives have now been obtained from the monomethyl fraction of the hydrolysis products from methylated araban, and by comparison of these with the synthetic material it has been established beyond doubt that the monomethyl fraction consists almost exclusively of 2-methyl *l*-arabinose (see experimental section). The isolation of the crystalline 2-methyl *l*-arabinose phenylhydrazone, 2-methyl 3:4-monoacetone *l*-arabinose, and 2-methyl *l*-arabonamide derivatives from the monomethyl fraction was aided by the previous preparation of synthetic crystalline derivatives and by the fact that larger quantities of methylated araban of higher purity were available. This was rendered possible by the observation that araban, which was the major component of the pectin, was methylated much more rapidly than galactan and pectic acid and that the latter can be converted into soluble acid products on heating with 30% sodium hydroxide in the presence of air without destruction of the araban.

With the larger quantities of methylated araban available, it was possible to carry out a rigorous fractionation of the methylated product and thus to obtain a homogeneous product which showed $[\alpha]_D^{20} - 180^\circ$ in methyl alcohol. It was demonstrated, from observation of the refractive indices and methoxyl values of the fractions obtained on distillation of the products of methanolysis of the methylated araban, that trimethyl, dimethyl, and monomethyl arabinoses are present in equimolecular proportions. The trace of unmethylated arabinose which is also present appears to arise either through incomplete methylation of the polysaccharide or by demethylation of the arabinose fractions during methanolysis.

From these observations the general type of structure present in the araban becomes apparent. The polysaccharide contains only the three residues $41 \dots, \dots 541 \dots$, and $\dots 341 \dots$ present in equimolecular proportions, *A* representing an arabofuranose unit linked through the positions indicated. A branched chain structure with terminal arabofuranose residues is clearly present, but the present data do not enable us to differentiate between a main chain of arabofuranose residues composed solely of $\dots 341 \dots$ residues and one comprising both this residue and $\dots 541 \dots$. From rotational data the *l*-arabofuranoside links have the α -configuration, and the general lines of the structure are illustrated in (I) which represents one

of the formulæ consonant with the experimental observations, but it is obvious that certain simple variations of this formula are also in agreement with the available experimental evidence. The problem of distinguishing between these requires the development of novel methods of attack, and experimental work is now being undertaken with this object in view. The branched chain of this polymer, which is composed only of *l*-arabofuranose residues, proves that the araban cannot be formed in the plant directly, as a polymer, by simple processes of oxidation and decarboxylation from either the galactan or the pectic acid associated with pectin. The origin and mechanism of the formation of araban remains therefore to be determined.

EXPERIMENTAL.

The seeds (14 kg.) were defatted with benzene and the protein was removed in the usual manner. The residual material was extracted with aqueous potassium hydroxide and crude araban isolated using the conditions described by Hirst and Jones (*loc. cit.*). A portion (50 g.) of the isolated polysaccharides (100 g.) was methylated with sodium hydroxide and methyl sulphate. After two methylations crude methylated araban was isolated by the addition of acetone followed by filtration of the solution to remove insoluble sodium salts and polysaccharide material. After the insoluble methylated material had been separated the aqueous solution was acidified and extracted with chloroform. Concentration of the extract gave some methylated pectic acid (4 g.), $[\alpha]_D^{25} + 114^\circ$ (*c*, 0.57 in methyl alcohol) (Found: OMe,

38%). The filtered acetone solution on evaporation gave a pale yellow sticky solid which was further methylated by use of Purdie's reagents. The polysaccharide (35 g.) was fractionated from chloroform (100 c.c.) by the gradual addition of light petroleum (b. p. 40–60°), giving:

Fraction A (0.9 g.), mainly inorganic material.

Fraction B (6.2 g.), $[\alpha]_D^{25} = 144^\circ$ (c, 1.1 in methyl alcohol) (Found: OMe, 38.7%).

Fraction C (15 g.), $[\alpha]_D^{25} = 176^\circ$ (c, 1.3 in methyl alcohol) (Found: OMe, 38.3%).

Fraction D (8.1 g.), $[\alpha]_D^{25} = 180^\circ$ (c, 0.7 in methyl alcohol) (Found: OMe, 38.0%).

Fraction E (4.0 g.), $[\alpha]_D^{25} = 179^\circ$ (c, 0.9 in methyl alcohol) (Found: OMe, 38.0%).

All these fractions were pale yellow sticky solids. The residue (1.0 g.) was discarded.

Trial Hydrolysis.—Fraction D (7.9 g.) was dissolved in methyl alcohol (75 c.c.)–water (25 c.c.) containing oxalic acid dihydrate (0.1 g.) and boiled under reflux in an attempt to bring about a graded hydrolysis of the polysaccharide (see Hirst and Young, *J.*, 1939, 1480). The optical rotation (-184°) remained constant and no hydrolysis occurred during 20 hours under these conditions even when the oxalic acid concentration was raised to 0.5 g./100 c.c. Accordingly, oxalic acid was removed by neutralisation with calcium carbonate and the unchanged polysaccharide submitted to hydrolysis with boiling methyl alcohol (100 c.c.) containing hydrogen chloride (2 g.) for 30 hours. Change of optical rotation could not be observed owing to darkening of the solution. The cooled solution was neutralised by cautious addition of ethereal diazomethane and the solvents were removed at 60°. The residual syrup (9.4 g.) was then fractionated by continuous extraction from aqueous solution (Z) with light petroleum (b. p. 40–60°) giving an extract—*Fraction 1* (2.89 g.), $n_D^{20} 1.4360$ —which was distilled yielding *Fraction 1a* (2.54 g.), b. p. 130°/12 mm., $n_D^{20} 1.4352$ (Found: OMe, 60.0%), and a still residue (0.28 g.). The aqueous solution (Z, above) was then extracted continuously with ether and the extracts concentrated at 40° to a syrup—*Fraction 2* (3.68 g.)—which was added to the still residue (0.28 g. above) and the whole fractionally distilled giving *Fraction 2a* (1.3 g.), b. p. 120°/0.2 mm., $n_D^{20} 1.4452$ (Found: OMe, 52.3%); *Fraction 2b* (1.87 g.), b. p. 125°/0.01 mm., $n_D^{20} 1.4487$ (Found: OMe, 47.8. Calc. for $C_8H_{14}O_5$: OMe, 48.4%); still residue (S, 0.62 g.). The aqueous solution (Z) after extraction with light petroleum and ether was evaporated in a vacuum to a syrup which was combined with the still residue (S, 0.62 g.) and the mixture (2.8 g.) distilled under reduced pressure giving *Fraction 3a* (0.25 g.), b. p. 125°/0.01 mm., $n_D^{20} 1.4582$ (Found: OMe, 43.7%); *Fraction 3b* (1.06 g.), b. p. 125°/0.01 mm., $n_D^{20} 1.4662$ (Found: OMe, 42.2%); *Fraction 3c* (0.68 g.), b. p. 125°/0.01 mm., $n_D^{20} 1.4750$ (Found: OMe, 24.8%), and a still residue (0.76 g.) (Found: OMe, 25.1%).

Fraction 1a on hydrolysis gave 2:3:5-trimethyl *l*-arabofuranose in quantitative yield, $[\alpha]_D^{20} = 38^\circ$ (in water), identified by conversion into the crystalline lactone, m. p. 29°, of 2:3:5-trimethyl *l*-arabonolactone and into 2:3:5-trimethyl *l*-arabonamide, m. p. 139°. Fraction 2a was a mixture of the methyl glycosides of 2:3:5-trimethyl *l*-arabofuranose and 2:3-dimethyl *l*-arabinose since it was separated into 2:3:5-trimethyl methyl-*l*-arabinoside (0.90 g.), identified as crystalline 2:3:5-trimethyl *l*-arabonolactone, m. p. 29°—prepared in the usual manner—and 2:3-dimethyl methyl-*l*-arabinoside (0.35 g.), $n_D^{20} 1.4454$, on fractional extraction from aqueous solution with light petroleum (b. p. 40–60°). This last fraction was combined with Fraction 2b and the whole (2.1 g.) hydrolysed with *N*-hydrochloric acid at 100°; $[\alpha]_D^{20} = 35^\circ \rightarrow [\alpha]_D^{20} = 92^\circ$ (constant value). The resultant syrup (1.9 g.) ($[\alpha]_D^{18} + 104^\circ$, c, 1.1 in water) (Found: OMe, 34.4. Calc. for $C_7H_{14}O_5$: OMe, 34.6%), isolated in the usual manner, was mainly if not entirely 2:3-dimethyl *l*-arabinose since it gave, in good yield, the corresponding 2:3-dimethyl anilino-*l*-arabinose, m. p. and mixed m. p. 139°. On refluxing it with alcoholic aniline, no other derivative of arabinose could be detected.

Fractions 3a and 3b were combined (1.80 g.) and separated by fractional extraction from water with ether into 2:3-dimethyl methyl-*l*-arabinoside (0.8 g.), identified, after hydrolysis to 2:3-dimethyl *l*-arabinose with *N*-hydrochloric acid, as 2:3-dimethyl anilino-*l*-arabinose, m. p. and mixed m. p. 139°. The more water-soluble fraction (1.0 g.) was 2-monomethyl methyl-*l*-arabinoside which was combined with Fraction 3c and the whole (1.65 g.) hydrolysed with boiling *N*-sulphuric acid (25 c.c.); $[\alpha]_D^{20} + 81^\circ$ (constant value) $\rightarrow +94^\circ$ (constant value after 6 hours). The residual syrup (1.3 g.) did not crystallise (Found: OMe, 19.4. Calc. for $C_6H_{12}O_5$: OMe, 18.9%). A sample, on refluxing with alcoholic phenylhydrazine, gave 2-methyl *l*-arabinose phenylhydrazone, m. p. and mixed m. p. 115° (see below). On shaking a sample of the syrup with acetone and anhydrous copper sulphate, 2-methyl monoacetone *l*-arabinose was formed in quantitative yield, m. p. and mixed m. p. 117° (Found: C, 52.7; H, 7.8; OMe, 15.2. Calc. for $C_9H_{16}O_5$: C, 52.9; H, 7.8; OMe, 15.2%).

A portion (0.66 g.) of the still residue was hydrolysed with hot *N*-sulphuric acid (18 c.c.). The syrup (0.56 g.), $[\alpha]_D + 92^\circ$ (Found: OMe, 17.4%), isolated in the usual manner was almost entirely 2-methyl *l*-arabinose since it gave the corresponding crystalline phenylhydrazone, m. p. and mixed m. p. 115°, on refluxing with an alcoholic solution of phenylhydrazine. Some *l*-arabinose was also present since the syrup gave, in small yield with an alcoholic solution of benzoylhydrazine, a precipitate of *l*-arabinose benzoylhydrazone, m. p. 184°.

Large Scale Hydrolysis of Methylated Arabin.—Fraction C (14.46 g.) was hydrolysed by boiling with methanolic hydrogen chloride (100 c.c.; 1%) for 12 hours. Changes in optical rotation were not observable owing to darkening of the solution. The cooled solution was neutralised with a slight excess of diazomethane in ether and the solvents were removed as quickly as possible at 70°. The syrupy residue (17.1 g.) was then dissolved in water (50 c.c.) and extracted continuously for 24 hours in an all-glass apparatus with light petroleum (sulphur-free, b. p. 35–37°). After removal of the solvent at 40° there remained a syrup (7.05 g., $n_D^{20} 1.4388$). The aqueous solution was then extracted continuously for a further 24 hours with ether. Concentration of the extracts gave a syrup (4.75 g.). The residual aqueous solution on removal of water gave a syrup (5.2 g.) which was extracted with chloroform, giving a syrup (5.0 g.) soluble in chloroform and leaving crystalline β -methyl-*l*-arabopyranoside (0.2 g.), m. p. 164–168° not depressed on admixture with an authentic specimen.

Fractional Distillation of the Syrups.—The light-petroleum-soluble syrup (7.05 g., $n_D^{20} 1.4388$) was

distilled at 20 mm., giving: *Fraction 4* (4.94 g.), b. p. 145° (bath temp.), n_D^{20} 1.4359 (Found: OMe, 59.2. Calc. for $C_9H_{18}O_5$: OMe, 60.2%); *Fraction 5* (1.46 g.), b. p. 155°, n_D^{20} 1.4432 (Found: OMe, 54.0. Calc. for $C_9H_{18}O_5$: OMe, 48.4%). The still residue (0.69 g.) was added to the ethereal extract (4.75 g.) and the whole distilled at 0.01 mm. giving *Fraction 6* (2.34 g.), b. p. 110° (bath temp.), n_D^{20} 1.4515 (Found: OMe, 48.4. Calc. for $C_8H_{16}O_5$: OMe, 48.4%). The syrup soluble in chloroform (5 g., see above) was added at this stage and the distillation continued. *Fraction 7* (2.55 g.), b. p. 140° (bath temp.), n_D^{20} 1.4565 (Found: OMe, 48.1. Calc. for $C_8H_{16}O_5$: OMe, 48.4%); *Fraction 8* (2.11 g.), b. p. 155° (bath temp.), n_D^{20} 1.4672 (Found: OMe, 40.3. Calc. for $C_7H_{14}O_5$: OMe, 34.8%); *Fraction 9* (1.06 g.), b. p. 160° (bath temp.), n_D^{20} 1.4715 (Found: OMe, 34.9. Calc. for $C_7H_{14}O_5$: OMe, 34.8%); *Fraction 10* (0.65 g.), b. p. 190° (bath temp.), n_D^{20} 1.4745 (Found: OMe, 32.1. Calc. for $C_7H_{14}O_5$: OMe, 34.8%). The still residue (1.20 g.) (Found: OMe, 30.5%) was methylated with Purdie's reagents (see below).

Examination of the Fractions.—A portion of *Fraction 4* (4.84 g.) was dissolved in *N*-sulphuric acid (25 c.c.) and hydrolysed at 90° for 3½ hours; $[\alpha]_D^{20} - 86^\circ \longrightarrow -30^\circ$ (constant value). The sugar (4.5 g.) was isolated by continuous extraction of the solution with chloroform (Found: OMe, 48.0. Calc. for $C_8H_{16}O_5$: OMe, 48.4%). The sugar was converted into 2:3:5-trimethyl *l*-arabonolactone by the following general method. The sugar (4.5 g.) was dissolved in *N*-sodium hydroxide (150 c.c.), and iodine (12 g.) added. After 12 hours, excess of iodine was removed with sulphur dioxide and the solution then acidified with sulphuric acid and extracted continuously with chloroform. Concentration of the chloroform extract gave a syrup (4.3 g.), n_D^{20} 1.4448, which crystallised on nucleation with 2:3:5-trimethyl *l*-arabonolactone, m. p. and mixed m. p. with an authentic specimen, 28°. This fraction therefore consists entirely of 2:3:5-trimethyl methyl-*l*-arabinoside.

Fraction 5 (1.45 g.) was dissolved in *N*-sulphuric acid (25 c.c.) and hydrolysed on the steam-bath; $[\alpha]_D^{20} - 81^\circ \longrightarrow [\alpha]_D^{20} + 30^\circ$ (final value). The free sugars (1.35 g.) isolated in the usual manner (Found: OMe, 41.8%) were oxidised with bromine (2 c.c.) in water (5 c.c.) for 12 hours. The lactones—isolated by chloroform extraction of the solution after removal of excess of bromine—were distilled in a vacuum giving impure 2:3:5-trimethyl *l*-arabonolactone (0.7 g.), m. p. 20°, and impure 2:3-dimethyl *l*-arabofuranolactone, b. p. 130° (bath temp.)/0.4 mm., n_D^{20} 1.4578. The lactones gave, with alcoholic ammonia, the corresponding crystalline amides, *viz.*, 2:3:5-trimethyl *l*-arabonamide, m. p. 138°, and 2:3-dimethyl *l*-arabonamide, m. p. 161°. It is inferred that this fraction consists of 2:3:5-trimethyl and 2:3-dimethyl methyl-*l*-arabinoside in approximately equal proportion.

Fraction 6 (2.22 g.) was hydrolysed by boiling with *N*-sulphuric acid (20 c.c.) for 3 hours; $[\alpha]_D^{20} - 51^\circ \longrightarrow +101^\circ$ (constant value). The resultant 2:3-dimethyl *l*-arabinose (2.0 g.) was isolated by exhaustive chloroform extraction of the solution after neutralisation with *N*-sodium hydroxide. Since this fraction showed an inversion of sign the material was 2:3-dimethyl methyl-*l*-arabinoside mainly in the furanose form.

Fraction 7 (2.42 g.) was dissolved in *N*-sulphuric acid and hydrolysed by heating the solution to 90°; $[\alpha]_D^{20} + 56^\circ \longrightarrow +102^\circ$ (constant value). The syrupy sugar was isolated from the neutralised solution by exhaustive chloroform extraction (yield, 2.2 g.). This fraction was 2:3-dimethyl methyl-*l*-arabinoside mainly in the pyranose form.

The sugars from *Fractions 6* and *7* were combined (4.2 g.), $[\alpha]_D^{20} + 104^\circ$ (c, 1.3 in water) (Found: OMe, 34.6. Calc. for $C_7H_{14}O_5$: OMe, 34.8%), and oxidised by dissolving in water (10 c.c.) containing bromine (5 c.c.). The solution became hot and was left for 12 hours. Bromine was then removed, first by aeration, and then by passage of sulphur dioxide. The solution was then extracted exhaustively with chloroform and the resultant 2:3-dimethyl *l*-arabofuranolactone (4.1 g.) purified by distillation in a vacuum; b. p. 140° (bath temp.)/0.5 mm., n_D^{20} 1.4575. With alcoholic ammonia the lactone gave 2:3-dimethyl *l*-arabonamide, m. p. 162°, in quantitative yield.

Fraction 8 was a mixture of 2:3-dimethyl methyl-*l*-arabinoside and 2-methyl methyl-*l*-arabinoside. Partial separation of the components was achieved by the following method. The glycosides (2.0 g.) were dissolved in acetone (25 c.c.) containing hydrogen chloride (1 g.) (see Hirst and Jones, *J.*, 1939, 456). After 20 hours the solution was poured into an aqueous solution of sodium hydrogen carbonate and the neutral solution extracted with chloroform. The extracts were dried (K_2CO_3), filtered, and concentrated to a syrup (1.74 g.) which was distilled under reduced pressure giving a first fraction, b. p. 106° (bath temp.)/0.5 mm. (0.6 g.), n_D^{20} 1.4500 (Found: OMe, 30.0. Calc. for 2-methyl monoacetone methyl-*l*-arabinoside: OMe, 28.4%), and a second fraction, b. p. 120°/0.5 mm. (0.8 g.), n_D^{20} 1.4610 (Found: OMe, 43.0. Calc. for 2:3-dimethyl methyl-*l*-arabinoside: OMe, 48.4%). The still residue was mainly 2-methyl methyl-*l*-arabinoside (Found: OMe, 36.0. Calc. for $C_7H_{14}O_5$: OMe, 34.8%). The impure 2-methyl monoacetone methyl-*l*-arabinoside (0.5 g.) was hydrolysed with boiling *N*-sulphuric acid, $[\alpha]_D^{20} + 100^\circ$ (final value), and the sugar (0.3 g.) isolated in the usual manner. It was identified, after boiling with alcoholic phenylhydrazine, as 2-methyl *l*-arabinose phenylhydrazone, m. p. and mixed m. p. 115°. This same derivative was isolated after boiling the free sugar, obtained from the hydrolysis of the still residue with hot *N*-sulphuric acid, with alcoholic phenylhydrazine. The second fraction (above) on hydrolysis with boiling *N*-sulphuric acid (20 c.c.) gave 2:3-dimethyl *l*-arabinose which was identified as its anilide, obtained by boiling an alcoholic solution of the sugar with aniline, m. p. 138° not depressed on admixture with an authentic specimen.

Fractions 9 and *10* consisted of 2-methyl methyl-*l*-arabinoside. These fractions were combined and the syrup (1.65 g.) hydrolysed with boiling *N*-sulphuric acid (20 c.c.); $[\alpha]_D^{20} + 104^\circ$ (final value; initial value not observable). The free sugar (1.5 g.) was isolated after neutralisation of the solution with barium carbonate followed by filtration and concentration under reduced pressure (Found: OMe, 18.7. Calc. for $C_6H_{12}O_5$: OMe, 18.9%).

A portion of the syrup (0.1 g.) on heating with alcoholic phenylhydrazine gave 2-methyl *l*-arabinose phenylhydrazone (0.1 g.), m. p. 115° not depressed on admixture with an authentic specimen. The syrup (0.4 g.) was oxidised with bromine (1 c.c.) in water (5 c.c.) at 30° for 12 hours. Bromine was removed by aeration and the 2-methyl *l*-arabonolactone isolated by exhaustive extraction of the solution

with chloroform. The lactone (0.35 g.) did not crystallise, but with an alcoholic solution of ammonia it gave 2-methyl *l*-arabonamide (0.3 g.), $[\alpha]_D + 51^\circ$ (*c*, 1.1 in water), m. p. 130° depressed to 124° on admixture with 3-methyl *l*-arabonamide, m. p. 131° (Found: C, 40.1; H, 7.4; N, 7.8; OMe, 17.2. $C_6H_{13}O_5N$ requires C, 40.2; H, 7.3; N, 7.8; OMe, 17.3%). 2-Methyl *d*-arabonamide has $[\alpha]_D - 53^\circ$ (in water), m. p. 131° (Schmidt and Simon, *J. pr. Chem.*, 1942, **152**, 199).

To prove the absence of any quantity of 3-methyl *l*-arabinose, the following procedure was adopted. The syrupy sugar (1.0 g.) was boiled with 3% methyl-alcoholic hydrogen chloride for 24 hours to ensure a maximum conversion into the pyranoside derivative. The solution was neutralised with silver carbonate and filtered, and the residual non-reducing syrup (0.92 g.), $[\alpha]_D^{20} + 143^\circ$ (*c*, 0.9 in water), was dissolved in water and oxidised with excess of sodium periodate solution (30 c.c.; 0.3M) for 24 hours. The aqueous solution was then extracted, first with ether, which is known to extract monomethyl methyl-*l*-arabinoside very slowly indeed, and then with chloroform. Concentration of the ethereal extract gave a mobile reducing syrup (0.7 g.) from which no identifiable product could be isolated. The chloroform extract on concentration gave a sticky brown solid (0.2 g.), which on hydrolysis with *n*-sulphuric acid was completely decomposed with the formation of resinous products. No 3-methyl *l*-arabinose, which would not have been oxidised with sodium periodate, could be detected, nor could any derivative of 3-methyl *l*-arabinose be isolated. It is concluded that any appreciable quantity of 3-methyl *l*-arabinose is absent from the products of hydrolysis of methylated araban.

The still residue (1.2 g.) was methylated with silver oxide and methyl iodide (twice) and the syrupy sugar distilled in a vacuum giving a mobile syrup (0.9 g.), n_D^{20} 1.4480 (Found: OMe, 59.1%), which on hydrolysis with boiling *n*-sulphuric acid gave 2:3:4-trimethyl *l*-arabinose, n_D^{20} 1.4540, $[\alpha]_D^{20} + 112^\circ$ (*c*, 1.1 in water) (Found: OMe, 46.0%).

On oxidation with bromine water the syrup (0.4 g.) gave the corresponding δ -lactone, isolated as the crystalline amide, m. p. 95° (Found: OMe, 44.2. Calc. for $C_8H_{17}O_5N$: OMe, 44.9%).

From an examination of the various fractions, it may be calculated from the values of refractive index and methoxyl of each fraction that the sugars 2:3:5-trimethyl *l*-arabinose, 2:3-dimethyl *l*-arabinose, and 2-methyl *l*-arabinose are present in a ratio approximating very closely to 1:1:1.

230. Pectic Substances. Part VII. The Constitution of the Galactan from *Lupinus albus*.

By E. L. HIRST, J. K. N. JONES, and (MRS.) W. O. WALDER.

A galactan has been isolated from the pectin component of *Lupinus albus*. This polysaccharide is a linear polymer built up of *d*-galactose residues which, after methylation followed by hydrolysis, yields 2:3:6-trimethyl *d*-galactose together with a small amount of 2:3:4:6-tetramethyl *d*-galactose from the end group. The amount of this latter sugar corresponds to an average repeating unit of approximately 100 galactose residues. The isolation of this polysaccharide is further evidence that galactan is not converted into araban by a simple process of oxidation followed by decarboxylation of the resultant uronic acid residue.

Most samples of pectin on hydrolysis furnish a mixture of the three sugars *d*-galactose (I), *d*-galacturonic acid (II), and *l*-arabinose (III), and at one time it was considered possible that pectin was a single substance which possessed a cyclic structure built up from these residues. Ehrlich, however, demonstrated that pectin contained an araban as a separate entity, and subsequent work has indicated that at any rate most of the arabinose encountered in pectic

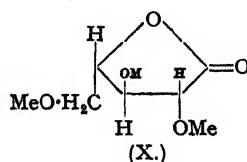

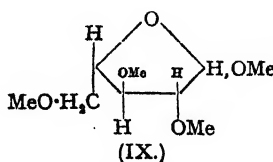

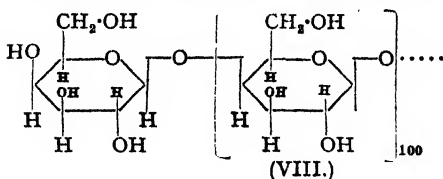

materials is present in the form of this araban component. It seemed probable that the galactose residues also might be present as a separate polysaccharide, and it is shown in the

present communication that the pectic material of the seeds of the white lupin does in fact contain a galactan, which can be separated from the pectic acid and the araban components. Since the conversion of (I) into (III) may proceed in Nature through (II), which then undergoes decarboxylation, it was of considerable interest to examine in detail the constitution of this galactan and to determine whether it was unbranched, as in pectic acid, or branched, as in araban, and thus to decide whether it could be structurally related to either the pectic acid or the araban component of pectin. In the former case the sugar residues should be of the pyranose form and linked through α -linkages, whilst in the latter case the *d*-galactose residues should be of the furanose form.

In common with many other plant materials the seed of the white lupin contains material which on hydrolysis is converted into *d*-galactose and *l*-arabinose ("The Principles of Plant Biochemistry", M. W. Onslow, Cambridge University Press, 1931 Edtn., p. 72). Professor M. Skene of the University of Bristol had informed us that these seeds were a particularly rich source of pectin, and we investigated their carbohydrate content with the object of isolating the galactan component. We found that the carbohydrate fraction of the seed contained a pectin-like material in which the percentage of uronic acid component and of araban was much lower than any other sample of pectin we had hitherto encountered, and thus enabled us to obtain, in a relatively easy manner, a sample of the galactan. Associated with this galactan there was an araban which could be partly removed by extraction with 70% alcohol and a pectic acid which could be precipitated as calcium pectate. The araban showed the same ease of hydrolysis and high negative rotation as the araban associated with apple, citrus, and peanut pectins. The pectic acid component could be converted into a degraded product (see Morrel, Baur, and Link, *J. Biol. Chem.*, 1934, 105, 1) which had properties close to those of the corresponding polysaccharides from apple and citrus pectins.

It was inferred, therefore, that we were dealing with a true pectin which was, however, particularly rich in galactan. This galactan, which could not be obtained completely free from adsorbed araban and pectic acid, had $[\alpha]_D^{20} + 38^\circ$ in water. This value is low since the material still contained some 19% of pentosan and the corrected figure is therefore more likely to be about $+70^\circ$. After methylation with thallium hydroxide and methyl iodide (Menzies, *J.*, 1926, 937; Hirst and Jones, *J.*, 1938, 496) a methylated product was isolated which contained methylated araban and methylated galactan. The small quantity of pectic acid present was very difficult to methylate and was lost during the process (Hirst and Jones, *loc. cit.*). Methylated araban was separated from methylated galactan by extraction of the former from the mixture with ether. The ether-insoluble material had $[\alpha]_D^{20} - 12^\circ$ in methyl alcohol, this negative value being an indication that in methylated galactan the sugar residues are joined together by β -linkages and that the galactan cannot be directly related to pectic acid in which the sugar residues are joined together by α -linkages. Methylated galactan (IV) was resistant to hydrolysis and the rate of reaction corresponded to that of a typical galactopyranoside. Fractional distillation of the sugars formed on methanolysis of the methylated galactan led to the identification of tetramethyl *d*-galactopyranose (V), isolated as its crystalline anilide, and 2:3:6-trimethyl *d*-galactose (VI), identified after oxidation as its crystalline furanolactone (VII). The inferences are, therefore, that the galactan is built up of *d*-galactopyranose residues linked through carbon atoms 1 and 4 and that the molecule is linear. The optical rotatory power of the galactan points to the occurrence of β -galactosido-linkages, and the amount of tetramethyl galactose isolated suggests that there is approximately one end group per 100 galactose residues.

In the absence of evidence concerning molecular weight it is not possible at present to say whether this figure represents the molecular size or the size of the repeating unit in a larger molecule. The type of structure present is shown in (VIII). The methylated araban could

not be obtained in a pure state, and a complete examination of it could not be attempted. Nevertheless, methanolysis of the crude material, which still contained much galactan, gave some 2:3:5-trimethyl methyl-*l*-arabinoside (IX) identified as crystalline 2:3:5-trimethyl

l-arabonolactone (X), the identity of which was confirmed by conversion into the corresponding crystalline amide. These arabofuranose residues were therefore terminal groups of the type previously found to be present in arabans associated with other pectic materials.

It is clear from these results that the araban cannot be formed directly from this galactan by processes of oxidation and decarboxylation at position 6. If phytochemical changes of this type do occur it would be necessary to postulate the participation of three types of galactan and two types of pectic acid in the reactions concerned (cf. Hirst, *J.*, 1942, 70). No evidence for the presence of isomeric pectic acids and galactans in pectic materials has yet been obtained, and it would appear much more likely that the various polysaccharides are formed by separate synthetic reactions. In addition, there remains the problem, still quite unsolved, as to whether the plant can utilise the *d*-galactose residues present in the galactan and convert them after hydrolysis into pectic acid and araban, or whether the synthesis proceeds from material other than *d*-galactose. On the basis of present knowledge the possibility cannot be ruled out that the simultaneous occurrence of the three stereochemically closely related substances *d*-galactose, *d*-galacturonic acid, and *l*-arabinose may have no immediate phytochemical significance.

EXPERIMENTAL.

Extraction of the Polysaccharides from the Seeds of Lupinus albus.—After being soaked overnight in water, the seeds were stripped of their skins and milled twice. The protein matter was then extracted by stirring the finely ground material with aqueous sodium chloride solution (10%) for 3 hours, followed by filtration and repetition of the process thrice. The solid residue was then stirred with aqueous sodium hydroxide (0.2%) thrice for 12 hours at a time. Addition of hydrochloric acid to the filtrate then gave no precipitate, indicating the absence of any appreciable quantities of protein. The solid residue was then boiled with aqueous sodium hydroxide (0.2%) for 3 hours, after which it was filtered and the filtrate poured into methylated spirit (4 vols.). The precipitated polysaccharide was filtered off, washed with alcohol, and dried in a vacuum at 90°. The resulting product was extracted with water, the solution was centrifuged to separate insoluble material, and the polysaccharide was precipitated by addition of methylated spirit acidified with hydrochloric acid. The precipitate was then filtered off, washed until free from acid, and dried in a vacuum at 90°. The product (A) was a non-reducing cream-coloured powder. Yield, 4%. $[\alpha]_D^{20} + 52^\circ$ (as sodium salt in water) [Found: furfuraldehyde, 26.5; uronic anhydride, 8% (corresponding to an equiv. of 2200 and 2% of the total furfuraldehyde); N, nil; OMe, nil; equiv., 1430 (by titration with 0.1N-sodium hydroxide)].

Hydrolysis of the Polysaccharide Material (A).—This material (15 g.) was boiled with N-sulphuric acid (250 c.c.) for 6 hours. Hydrolysis was then complete since the optical rotation and reducing power had become constant. A small quantity of flocculent material (0.8 g.) was removed on the centrifuge and the solution was neutralised with barium carbonate and filtered. The filtrate was concentrated under reduced pressure at 40° and poured into methyl alcohol (50 c.c.), and the precipitated barium salts were removed by filtration. The filtrate from the barium salts was concentrated under reduced pressure to a syrup which crystallised. The crystalline solid, m. p. 157° (3.6 g.), separated by filtration after trituration with methyl alcohol, was *d*-galactose since it gave mucic acid, m. p. 210°, after oxidation with nitric acid, and with methylphenylhydrazine it gave the phenylmethylhydrazone, m. p. and mixed m. p. with an authentic sample 186°.

After removal of crystalline galactose the filtrate was concentrated to a syrup and made up to 250 c.c. with water. An iodometric titration at this stage showed that the solution contained 10.3 g. of sugar calculated as hexose, or 8.6 g. calculated as pentose. Furfuraldehyde determinations on the solution indicated that pentose (3.9 g.) was present. Confirmation of this figure was obtained by determination of arabinose as its diphenylhydrazone by the method of Wise and Peterson (*Ind. Eng. Chem.*, 1930, 22, 362). This determination indicated the presence of arabinose (3.9 g.). Other pentoses, except in traces, were therefore absent. Determination of galactose by the mucic acid method as modified by Wise and Peterson (*loc. cit.*) indicated the presence of galactose (6.1 g.). These figures for arabinose (3.9 g.) and for galactose (6.1 g.) are in agreement with the total sugar content obtained by iodometric titration and show that (A) contains approximately 6% of galactose residues and 26% of arabinose residues. Some pectic acid is also present.

(A) (100 g.) was shaken with 70% methyl alcohol (2½ l.) for 3 months. The slurry was then centrifuged and the supernatant liquid evaporated to dryness. The residual solid (0.1 g.) had $[\alpha]_D^{20} - 119^\circ$ (c. 1.0 in water) and yielded 32% of furfuraldehyde on distillation with 12% hydrochloric acid, corresponding to the presence of 64% of pentose.

Since (A) was possibly a mixture of an araban and galactan, a portion of it (3 g.) was boiled with 0.01N-oxalic acid at 100° until the optical rotation was constant. A small amount of insoluble material which separated appeared to be impure pectic acid; it had $[\alpha]_D^{20} + 157^\circ$ (in water) (Found: equiv., 370). The solution was filtered before and after neutralisation with calcium carbonate, and concentrated to dryness. The residual solid was extracted with methyl alcohol and the solution filtered and concentrated to a syrup (0.285 g.) which had $[\alpha]_D^{20} + 91^\circ$ in water and contained 36% of pentosan (calculated from the yield of furfuraldehyde obtained on distillation with 12% hydrochloric acid). The methyl alcohol-insoluble solid (2.0 g.) gave a negative test for pentoses and had $[\alpha]_D^{20} + 77^\circ$ in water. On hydrolysis with 1% sulphuric acid it gave *d*-galactose, m. p. and mixed m. p. 158°. The phenylmethylhydrazone had m. p. 184°. No other sugar could be detected.

Purification of (A) by removal of calcium pectate. Crude (A) contained some uronic acid (see above) which was largely removed in the following manner. The polysaccharide (80 g.) was dissolved in cold water and neutralised with 0.1N-sodium hydroxide, and calcium chloride solution was added to

precipitate the polyuronide as its calcium salt. The insoluble material was then removed on the centrifuge and the water soluble polysaccharide mixture (B) was precipitated by addition of alcohol (5 vols.); $[\alpha]_D^{20} + 38^\circ$ in water (Found: uronic anhydride, 2%; furfuraldehyde, 9.6%; equiv., 3060).

All attempts to separate completely the pentosan, galactan, and uronic acid fractions of (A) either by acid treatment or by fractional precipitation were unsuccessful. Accordingly, (B) (15 g.) was methylated by the standard thalious hydroxide-methyl iodide procedure (Menzies, *loc. cit.*; Hirst and Jones, *loc. cit.*). The methylation was completed by boiling with methyl iodide and silver oxide. The product (12 g.) (Found: OMe, 42%) was isolated in the usual manner.

Fractionation. The methylated product (12 g.) was dissolved in chloroform (50 c.c.) and fractionated by the portionwise addition of light petroleum (b. p. $40-60^\circ$). By this means the following fractions were obtained: Fraction I (0.9 g.), $[\alpha]_D^{20} - 16^\circ$ in methyl alcohol (Found: OMe, 40.3%). Fraction II (8.1 g.), $[\alpha]_D^{20} - 12^\circ$ in methyl alcohol (Found: furfuraldehyde (on boiling with 12% hydrochloric acid, see Bott and Hirst, *J.*, 1932, 2621), 3.1; OMe, 39.1%). Fraction III (2 g.), $[\alpha]_D^{20} - 12^\circ$ in methyl alcohol (Found: OMe, 39.9%). Fraction IV (0.5 g.), $[\alpha]_D^{20} - 13^\circ$ in methyl alcohol (Found: OMe, 39.2%). Fraction V (0.4 g.), $[\alpha]_D^{20} - 15^\circ$ in methyl alcohol (Found: furfuraldehyde, 9.5; OMe, 37.5%).

Fractions I, II, III, and IV were combined and re-methylated with silver oxide and methyl iodide since their methoxyl content was still low. The product, isolated in the usual manner, was separated into two fractions by extraction with boiling methyl iodide. This separation of the methylated polysaccharide into methyl iodide-soluble and -insoluble fractions indicated that there was a substantial difference in the physical properties of the two components. The analytical figures and optical rotations, however, showed little difference between the two fractions. This was confirmed on examination of the products of methanolysis of the two fractions (see below). The solubility difference observed is due probably to difference in molecular weight and not to a substantial difference in chemical constitution. No pentose could be detected in the products of hydrolysis of either fraction.

The methyl iodide-soluble material (4.0 g.) had $[\alpha]_D^{20} - 15.7^\circ$ in methyl alcohol (Found: C, 51.0; H, 7.7; OMe, 39.5%). No acidic groups (uronic acids) were present. The methyl iodide-insoluble material (7.4 g.) had $[\alpha]_D^{20} - 17^\circ$ in methyl alcohol (Found: C, 51.6; H, 7.9; OMe, 41.6%). No acid groups (uronic acids) were present.

Hydrolysis of the Fraction Soluble in Methyl Iodide.—This polysaccharide derivative was very resistant to methanolysis even on prolonged boiling with fairly high concentrations of hydrogen chloride. Accordingly the methylated polysaccharide (3.9 g.) was dissolved in a solution (50 c.c.) containing glacial acetic acid (2 vols.), concentrated hydrochloric acid (1 vol.), and water (1 vol.) and heated on a water-bath until the rotation was constant (8 hours). The solution was partially neutralised with barium carbonate (to remove all the hydrochloric acid) and filtered, and the filtrate and washings were evaporated to dryness under reduced pressure to remove acetic acid and water. The solid residue was extracted exhaustively with chloroform and the extracts were concentrated under reduced pressure and converted into the methyl glycosides by boiling with methyl alcoholic hydrogen chloride (3%, 7 hours). The resulting methyl glycosides (3.9 g.) were isolated and fractionally distilled giving: Fraction 1 (0.30 g.), b. p. $129/0.001$ mm., $n_D^{20} 1.4495$ (Found: OMe, 54.1%). Fraction 2 (2.45 g.), b. p. $140-160/0.001$ mm., $n_D^{20} 1.4568$ (Found: OMe, 50.7%). Fraction 3 (0.38 g.), b. p. $160-175/0.001$ mm., $n_D^{20} 1.4560$ (Found: OMe, 50.6. Calc. for $C_{10}H_{20}O_6$: OMe, 52.5%). Fraction 4 (0.33 g.), b. p. $175-240/0.001$ mm., $n_D^{20} 1.4686$ (Found: OMe, 41.4%). Still residue (0.44 g.), not further examined.

Examination of the fractions. Fractions 1 and 2 (2.7 g.) were combined and hydrolysed with *N*-hydrochloric acid (20 c.c.) at $90-95^\circ$. $[\alpha]_D^{20} + 20^\circ$ (initial value) $\rightarrow + 81^\circ$ (3 hours, constant value). The solution was cooled, neutralised with barium carbonate, filtered, and concentrated under reduced pressure to a solid which was exhaustively extracted with chloroform. On concentration the extracts gave a syrup (2.4 g.); $n_D^{20} 1.4772$; $[\alpha]_D^{20} + 37^\circ$ (in methyl alcohol) (Found: OMe, 40.9. Calc. for $C_6H_{12}O_6$: OMe, 41.8%). A sample of the syrup (0.039 g.) on dissolving in 3% methyl alcoholic hydrogen chloride (5 c.c.) showed a change of optical rotation identical with that given by 2:3:6-trimethyl *D*-galactose. $[\alpha]_D^{20} + 36^\circ$ (initial value); $+ 8^\circ$ ($8\frac{1}{2}$ hours); $+ 0^\circ$ (14 hours); $- 16^\circ$ (20 hours); $- 26^\circ$ (36 hours, constant value). The sugar (0.89 g.) was dissolved in water (5 c.c.) and bromine (1.5 c.c.) added. The solution was heated to 55° for 4 hours; a test sample after aeration to remove bromine then showed no reduction when heated with Fehling's solution. Bromine and hydrobromic acid were removed and the syrupy 2:3:6-trimethyl *D*-galactonolactone was isolated after removal of solvent at 40° . On standing, the lactone crystallised; it was purified by sublimation in a vacuum; m. p. 92° . Yield, 0.8 g. This product, further purified by recrystallisation from ether-light petroleum, had m. p. and mixed m. p. with an authentic sample, 98° . $[\alpha]_D^{20} - 41^\circ$ in water, initial value (Found: OMe, 41.0; equiv., 220. Calc. for $C_6H_{12}O_6$: OMe, 42.4%; equiv., 220). The lactone was converted quantitatively by solution in liquid ammonia into the amide, m. p. and mixed m. p. with an authentic specimen, 133° .

Fractions 3 and 4 were combined (0.7 g.) and hydrolysed with *N*-hydrochloric acid for 6 hours. The isolated sugars (0.55 g.) gave on oxidation crystalline 2:3:6-trimethyl *D*-galactonolactone, m. p. and mixed m. p. 98° , in 50% yield.

Hydrolysis of the Fraction Insoluble in Methyl Iodide.—A portion of the methylated polysaccharide (4.0 g.) was hydrolysed as described above and the methyl glycosides (4.5 g.) distilled giving: Fraction 5 (0.28 g.), b. p. $115-135/0.001$ mm., $n_D^{20} 1.4532$ (Found: OMe, 50.2%). Fraction 6 (1.59 g.), b. p. $135-145/0.001$ mm., $n_D^{20} 1.4535$ (Found: OMe, 51.4%). Fraction 7 (1.44 g.), b. p. $145-175/0.001$ mm., $n_D^{20} 1.4548$ (Found: OMe, 51.1%). Fraction 8 (0.47 g.), b. p. $175-190/0.001$ mm., $n_D^{20} 1.4588$ (Found: OMe, 49.8%). Fraction 9 (0.33 g.), b. p. $> 190/0.001$ mm., $n_D^{20} 1.4672$ (Found: OMe, 43.5%). Still residue, 0.3 g. (not further examined).

Fractions 5, 6, 7, and 8 had substantially the same constants; they were combined and hydrolysed with *N*-hydrochloric acid for 4 hours ($[\alpha]_D^{20} + 88^\circ$ constant value). The solution was neutralised with

barium carbonate and the sugar isolated (3.5 g.); n_D^{20} 1.4770; $[\alpha]_D^{20} + 36^\circ$ (in methyl alcohol) (Found: OMe, 40.5. Calc. for $C_8H_{10}O_6$: OMe, 41.8%).

A sample of the syrup showed a change of rotation in cold 2% methyl alcoholic hydrogen chloride, similar to that shown by 2:3:6-trimethyl *d*-galactose. $[\alpha]_D^{20} + 36^\circ$ (initial value); $+ 5^\circ$ (24 hours); 0° (36 hours); $- 11^\circ$ (56 hours); $- 26^\circ$ (70 hours, constant value). On oxidation with bromine (1 c.c.) in water (3 c.c.) the syrup (1.04 g.) gave 2:3:6-trimethyl *d*-galactonolactone, m. p. 97° , isolated in 85% yield. $[\alpha]_D^{20} - 41^\circ$ (initial value, in water) (Found: OMe, 41.2; equiv., 220. Calc. for $C_8H_{10}O_6$: OMe, 42.4%; equiv., 222).

A portion of the syrup (0.58 g.) was boiled with aniline (0.3 c.c.) and alcohol (3 c.c.) for 3 hours. On concentration a syrup was formed which crystallised only after 3 months. The crystals were tiled and purified by recrystallisation from absolute alcohol. Yield, 30 mg.; m. p. 189° , not depressed on admixture with an authentic specimen of 2:3:4:6-tetramethyl *d*-galactose anilide. Some 2:3:4:6-tetramethyl *d*-galactose (end group) is therefore present in the sugar syrup. No arabinose derivative could be detected in the products of hydrolysis.

Examination of Polysaccharide Fraction V.—Fraction V, the last fraction from the fractionation of the methylated polysaccharides with light petroleum (b. p. $40-60^\circ$), was purified by extraction with boiling light petroleum. The residual white solid (1.8 g.) [Found: dimethyl pentosan (by furfuraldehyde estimation), 19.4%; OMe, 40%] was subjected to methanolysis with boiling methyl alcoholic hydrogen chloride (3%) for 7 hours. The resulting methylglycosides (1.8 g.) were fractionally distilled giving: Fraction 10 (0.21 g.), b. p. $100^\circ/0.01$ mm., n_D^{20} 1.4355 (Found: OMe, 61%). Fraction 11 (0.24 g.), b. p. $100-120^\circ/0.001$ mm., n_D^{20} 1.4440. Fraction 12 (0.57 g.), b. p. $130-150^\circ/0.01$ mm., n_D^{20} 1.4568.

Fraction 10 (0.21 g.) was hydrolysed with *N*-hydrochloric acid (10 c.c.). $[\alpha]_D^{21} - 47^\circ$ (initial) fell to $- 15^\circ$ (constant value) in 2 hours. The syrupy sugar (0.19 g.) [Found: OMe, 43. Calc. for trimethyl *l*-arabinose ($C_8H_{10}O_6$): OMe, 45.4%], after isolation, was oxidised with bromine (0.3 c.c.) in water (5 c.c.) for $2\frac{1}{2}$ hours at 55° . Bromine was removed by aeration, the solution neutralised with silver carbonate, and the lactone isolated as a sticky solid which was purified on the tile and then by recrystallisation from ether-light petroleum; m. p. 29° , not depressed on admixture with an authentic specimen of 2:3:5-trimethyl *l*-arabonolactone. The lactone on treatment with methyl alcoholic ammonia gave 2:3:5-trimethyl *l*-arabonamide in quantitative yield, m. p. 134° , m. p. 135° on admixture with an authentic specimen of 2:3:5-trimethyl *l*-arabonamide.

The estimated yield of 2:3:5-trimethyl *l*-arabinose was about 8% of Fraction V, approximately one-third of the total pentosan content of the crude methylated polysaccharide. Fraction 11 was not further investigated. Fraction 12 (0.5 g.) on hydrolysis and oxidation (for details see under Fractions 1 and 2) gave 2:3:6-trimethyl *d*-galactonolactone, m. p. 98° , in 80% yield.

Identification of the Acidic Portion of the Polysaccharide as Pectic Acid by Preparation of the Degraded Poly-ester.—The polysaccharide (75 g.) was treated with boiling *N*-sulphuric acid at 90° for 6 hours. This process destroyed the araban and most of the galactan leaving a partly degraded pectic acid which separated as a flocculent precipitate. The insoluble portion (5 g.; equiv., 700) was filtered off and washed free from sulphuric acid, first with water and then with methanol. The solid was then boiled with 2% methyl alcoholic hydrogen chloride for 7 hours, and the insoluble residue was filtered off and washed free from hydrochloric acid with methanol. The solid was purified by dissolving in water and precipitating with ethanol. Yield 3 g. $[\alpha]_D^{20} + 170^\circ$ (in water) (Found: OMe, 17.9; equiv., 210. Calc. for methyl pectate: OMe, 16.3%; equiv., 190). On oxidation a sample gave mucic acid in 46% yield. Pectic acid was therefore a component of the mixture of polysaccharides (A).

231. *The Reactions of N-Benzenesulphonylbenzisoctiazolone with Aromatic Amines.*

By (the late) ERNEST W. MCCLELLAND and RAYMOND H. PETERS.

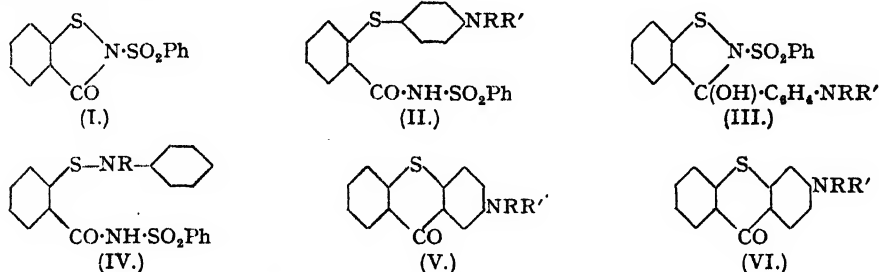

N-Benzenesulphonylbenzisoctiazolone (I) reacts readily with aromatic amines, the hetero-ring being opened and the sulphur atom becoming attached to the *p*-position of the amine to give substances of type (II). Hydrolysis of (II) yields the 4-amino-2'-carboxydiphenyl sulphide, which by the action of sulphuric acid undergoes ring closure to give a 2-amino-thioxanthone (V). When the *p*-position of the aromatic amine is occupied by a substituent R (Me, OMe, or Cl) the sulphur atom becomes attached in the ortho-position relative to the amino-group of the amine and the product isolated is the lactam of the 2-amino-5-R-2'-carboxydiphenyl sulphide (XI), benzenesulphonamide having been eliminated. The lactam yields the free amino-acid on hydrolysis. Sulphuric acid converts these acids into 4-aminothioxanthones (XIII). 2-Amino-2'-carboxydiphenyl sulphide yields a similar lactam when boiled in xylene with phosphoric oxide.

THE reaction of *N*-benzenesulphonylbenzisoctiazolone (I) with aniline had been observed by McClelland and Hart (J., 1939, 760), and preliminary experiments had also been made with dimethylaniline (Barton and McClelland, unpublished observations). In the present

investigation the reactions with a number of aromatic amines have been studied and the nature of the products established.

The benzisothiazolone condenses with one molecular proportion of the amine and several possible formulae were considered for the products, such as (II), (III), and (IV).

The compound from dimethylaniline is converted by heating with sulphuric acid into a dimethylaminothioxanthone. The formation of an aminothioxanthone is compatible with either formula (II) or (III) which would, however, give rise, respectively, to the 2- and 3-dimethylaminothioxanthones (V) and (VI).

2-Dimethylaminothioxanthone (V, R = R' = Me) was synthesised by a variation of Mayer's method (*Ber.*, 1909, 42, 3046) as follows. The action of *p*-dimethylaminothiophenol on diazotised anthranilic acid yielded 4-dimethylamino-2'-carboxydiphenyl sulphide, which was converted by sulphuric acid into the required 2-dimethylaminothioxanthone found to be identical with the substance under discussion above. The condensation product from dimethylaniline is therefore of type (II) and not (III).

Similar results were obtained on using methylethylaniline and benzylmethylaniline, the aminothioxanthone being independently synthesised in the former case.

The product of reaction with monomethylaniline was hydrolysed to an acid which must be (VII) since it gives an acetyl derivative. This excludes formula (IV) for this condensation product, and points to formula (II, R = H, R' = Me). The substance also yields a thioxanthone, which by analogy must be 2-methylaminothioxanthone.

The substance formed by condensation of the benzisothiazolone with aniline is now found to contain a free primary amino-group and is converted by sulphuric acid into 2-aminothioxanthone. This compound therefore has the structure (II, R = R' = H). In the production of the thioxanthones, sulphonic acids of the type (VIII) are also obtained. With *o*-toluidine an analogous condensation occurred.

Benzylamine and phenylhydrazine do not condense with the benzisothiazolone in boiling alcohol, but cause opening of the ring and yield di-*N*-benzenesulphonyl-2:2'-dithiobenzamide.

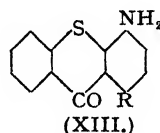

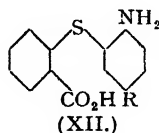

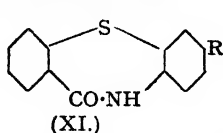

On the other hand when the *N*-benzenesulphonylbzisothiazolone was condensed with para-substituted amines a different reaction occurred, benzenesulphonamide being eliminated. The thiazolone reacted in this manner with *p*-toluidine, *p*-anisidine, and *p*-chloroaniline, but did not react with weaker bases such as the nitroanilines or anthranilic acid. The products were of high melting point and inert to bromine; they gave no colour with ferric chloride, were neither acidic nor basic, and gave no reaction for a keto-group. Their composition corresponded with that of the respective arylisothiazolone (I, C₆H₄X in place of SO₂Ph) or an isomer of it.

N-*p*-Tolylbenzisothiazolone, however, prepared by the action of 2-chlorothiobenzoyl chloride on *p*-toluidine, was found to be an entirely different substance from the condensation product from *p*-toluidine.

In view of the mode of reaction of benzylamine and phenylhydrazine with the benzisothiazolone, mentioned above, the possibility was considered that a disulphide (C₆H₄-S-CO-NHR), had been formed, the difference in composition being negligible. But, again, the disulphide prepared by the action of *p*-toluidine on 2:2'-dithiobenzoyl chloride was entirely different from the product under discussion: moreover the molecular weight of the corresponding substance

resulting from the reaction of *p*-anisidine with the benzothiazolone was not double as would be required for the disulphide.

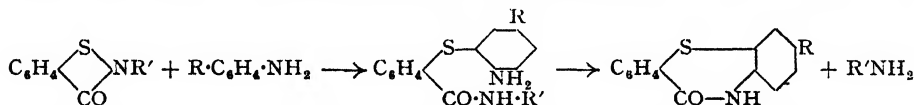

The condensation product yielded a *dioxide* soluble in aqueous sodium hydroxide and reprecipitated unchanged on acidification. Both the condensation product and its dioxide yielded monoacetyl derivatives. These were finally identified as lactams of the structure (XI) since hydrolysis with 55–65% sulphuric acid yielded in each case an aminocarboxylic acid. A thioxanthone is formed at the same time, which is evidently the result of further action of the sulphuric acid on the amino-acid. The acids must have the structure (XII) which should give 4-aminothioxanthenes (XIII). This was confirmed by preparing 4-amino-1-methylthioxanthone from *o*-mercaptobenzoic acid and *p*-toluenesulphon-*p*-toluidide in sulphuric acid (cf. Ullmann and Glenck, *Ber.*, 1916, 49, 2499); the product was identical with the thioxanthone from the amino-acid derived from the condensation product of *p*-toluidine and the benzenesulphonylbenzothiazolone.

The condensation products in question are thus lactams of the amino-acids of type (XII). These acids when heated with alcoholic hydrochloric acid were partly converted into the lactam. Acetic anhydride or phosphoric oxide also regenerated the lactam (XI) together with some of the thioxanthone in the latter case.

The seven-membered ring here present is not unusual in view of the presence of two *o*-phenylene groups, but it was thought desirable to provide the following confirmatory evidence. The parent sulphide, 2-amino-2'-carboxydiphenyl sulphide (Mayer, *loc. cit.*) with phosphoric oxide yielded a corresponding cyclic lactam together with some 4-aminothioxanthone. This was entirely similar in behaviour to the condensation products from *N*-benzenesulphonylbenzothiazolone with para-substituted amines. Oxidation also gave a sulphone of similar properties, and this too was prepared independently from the sulphone of 2-nitro-2'-carboxydiphenyl sulphide.

The reaction of the benzothiazolone with para-substituted amines therefore proceeds thus :

and it follows that the products should be independent of the particular radical *R'* present. This was confirmed by causing the *N*-*p*-toluenesulphonylbenzothiazolone to react with *p*-anisidine; the product was identical with that from *N*-benzenesulphonylbenzothiazolone.

Attempts to bring about reaction between dimethylaniline and *N*-methyl-, *N*-phenyl-, *N*-*p*-tolyl-, *N*-*p*-nitrophenyl-, or *N*-benzoyl-benzothiazolone gave negative results, and it appears that this type of reaction of the arylsulphonylbenzothiazolones depends on the joint action of the SO_2 and CO groups attached to the same nitrogen atom, the simultaneous presence of which facilitates the rupture of the heterocyclic ring.

EXPERIMENTAL.

Reaction of *N*-Benzenesulphonylbenzothiazolone with Tertiary Aromatic Amines.—The benzothiazolone (5 g.) was boiled in alcohol (20 ml.) with the amine (5 g.) until all the former had dissolved (3 hrs.). The product crystallised on cooling. 4-Dimethylamino-2'-*N*-benzenesulphonylcarbamyldiphenyl sulphide was thus obtained from dimethylaniline, as yellow needles from alcohol, m. p. 172° (Found: C, 61.6; H, 4.7. $\text{C}_{21}\text{H}_{19}\text{O}_2\text{N}_3\text{S}_2$ requires C, 61.1; H, 4.9%). In his examination of this substance Dr. A. W. H. Barton isolated a sodium salt sparingly soluble in water crystallising from alcohol in white needles, m. p. 308° (Found: Na, 5.4. $\text{C}_{21}\text{H}_{18}\text{O}_2\text{N}_3\text{S}_2\text{Na}$ requires Na, 5.3%), and by methylation with methyl sulphate a methyl derivative, white needles from methyl alcohol, m. p. 144° (Found: C, 62.0; H, 5.2. $\text{C}_{22}\text{H}_{21}\text{O}_2\text{N}_3\text{S}_2$ requires C, 62.0; H, 5.2%), which on hydrolysis with acid yielded benzenesulphonmethylamide, m. p. 31°. The original condensation product was hydrolysed by boiling for 2 hours with concentrated hydrochloric acid, and the mixture poured into water, made alkaline with sodium hydroxide, and finally acidified with acetic acid. The greenish precipitate was purified by crystallisation of the sodium salt, reversion into the acid and crystallisation from alcohol; it formed small greenish needles, m. p. 250–260° (decomp.). 4-Dimethylamino-2'-carboxydiphenyl sulphide so obtained was identical with that prepared synthetically as follows. *pp'*-Bisdimethylaminodiphenyl disulphide (10 g.) prepared by the method of Merz and Weith (*Ber.*, 1889, 22, 1571) was reduced by

warming with tin (3 g.) and concentrated hydrochloric acid (30 c.c.), the solution made alkaline (100 c.c. of 35% aqueous sodium hydroxide) and heated while a stream of nitrogen was passed through the flask, and a diazotised solution of anthranilic acid (8.8 g.) slowly added. After 5 minutes' boiling and cooling the grey-green sodium salt which separated was collected and dissolved in water, and the free acid precipitated by adding acetic acid. It was apparently identical with the hydrolysis product described above (Found on a sample from alcohol, dried in a vacuum: C, 64.9; H, 5.7. After drying at 110°: C, 66.4; H, 5.9. $C_{18}H_{15}O_2NS.C_6H_5O$ requires C, 64.0; H, 6.6%. $C_{18}H_{15}O_2NS$ requires C, 66.0; H, 5.5%). The presence of alcohol in the former specimen was confirmed by an iodoform test.

In view of the indefiniteness of the melting point of this substance the *ethyl* ester was prepared from both the hydrolysis product and the synthetic acid. In each case it formed white needles from alcohol, m. p. 143° (not depressed by mixture of the two). For analysis the substance was purified by molecular distillation (Found: C, 67.5, 67.5; H, 6.8, 6.4. $C_{17}H_{13}O_2NS$ requires C, 67.7; H, 6.4%). Other amines yielded the corresponding 4-aminodiphenyl sulphides. 4-Methylethylamino-2'-N-benzenesulphonylcarbamyldiphenyl sulphide formed pale yellow plates from alcohol, m. p. 141° (Found: C, 61.1, 60.6; H, 5.6, 6.0. $C_{22}H_{22}O_2N_2S_2$ requires C, 61.7; H, 5.2. $C_{22}H_{22}O_2N_2S_2.C_2H_5O$ requires C, 61.0; H, 6.0%). On hydrolysis with concentrated hydrochloric acid it yielded 4-methylethylamino-2'-carboxydiphenyl sulphide as a greenish microcrystalline powder, m. p. ca. 230° (decomp.) (Found: C, 66.8; H, 5.9. $C_{16}H_{11}O_2NS$ requires C, 66.8; H, 6.0%). This acid was also synthesised. 4:4'-Bis-methylethylaminodiphenyl disulphide prepared by Merz and Weith's method (*loc. cit.*) formed an amorphous mass which did not crystallise and was used in the crude form. It was reduced to the thiol as described above, and with diazotised anthranilic acid gave the 4-methylethylamino-2'-carboxydiphenyl sulphide as a pale green microcrystalline powder, m. p. ca. 230° (decomp.) (Found: C, 66.8; H, 5.9%). 4-Benzylmethylamino-2'-N-benzenesulphonylcarbamyldiphenyl sulphide crystallised in pale green needles from alcohol, m. p. 123°. The crystals contain alcohol of crystallisation as shown by direct test (Found: C, 65.1; H, 5.2. $C_{27}H_{24}O_2N_2S_2$ requires C, 66.4; H, 4.9. $C_{27}H_{24}O_2N_2S_2.C_2H_5O$ requires C, 65.1; H, 5.6%). Hydrolysis with 60% sulphuric acid yielded 4-benzylmethylamino-2'-carboxydiphenyl sulphide, which crystallised from alcohol as a pale green microcrystalline powder, m. p. 194° (Found: C, 71.7; H, 5.0. $C_{21}H_{19}O_2NS$ requires C, 72.1; H, 5.5%).

4-Methylethylamino-2'-N-benzenesulphonylcarbamyldiphenyl sulphide separated from alcohol in white plates which turned green on exposure to air, m. p. 142° (Found: C, 60.5; H, 4.4. $C_{20}H_{18}O_2N_2S_2$ requires C, 60.3; H, 4.5%). The *nitroso*-derivative crystallised from alcohol in golden needles, m. p. 170° (Found: C, 56.0; H, 4.1. $C_{20}H_{17}O_2N_3S_2$ requires C, 56.1; H, 4.0%). Hydrolysis with 60% sulphuric acid yielded 4-methylamino-2'-carboxydiphenyl sulphide, small needles from butyl alcohol, m. p. 215° (Found: C, 64.9; H, 5.5. $C_{14}H_{13}O_2NS$ requires C, 64.8; H, 5.1%). The *acetyl* derivative formed white plates, m. p. 209° (Found: C, 63.4; H, 5.3. $C_{15}H_{15}O_2NS$ requires C, 63.8; H, 5.0%).

4-Ethylamino-2'-N-benzenesulphonylcarbamyldiphenyl sulphide separated from aqueous alcohol in cream coloured crystals, m. p. 150° (Found: C, 61.0; H, 5.1. $C_{21}H_{20}O_2N_2S_2$ requires C, 61.1; H, 4.9%). The *nitroso*-derivative crystallised from alcohol in small red prisms which turned yellow on heating, m. p. 138° (Found: C, 56.7; H, 4.3. $C_{21}H_{19}O_2N_3S_2$ requires C, 57.1; H, 4.4%). Hydrolysis with 60% sulphuric acid yielded 4-ethylamino-2'-carboxydiphenyl sulphide, which crystallised from butyl alcohol in buff needles, m. p. 224° (Found: C, 65.6; H, 5.4. $C_{15}H_{15}O_2NS$ requires C, 65.0; H, 5.5%). The *acetyl* derivative separated from aqueous alcohol in almost colourless needles, m. p. 184° (Found: C, 64.7; H, 5.4. $C_{17}H_{17}O_2NS$ requires C, 64.7; H, 5.4%).

4-Amino-2'-N-benzenesulphonylcarbamyldiphenyl sulphide, obtained by using aniline, crystallised from aqueous alcohol in small white needles, m. p. 167° (analysed, but incorrectly formulated by McClelland and Hart, *J.*, 1939, 760). The *perchlorate* separated in minute needles from dilute perchloric acid, m. p. 221° (decomp.) (Found: C, 45.3, 45.7; H, 4.1, 4.0. Found after drying at 100°: C, 45.0; H, 3.4. $C_{19}H_{17}O_7N_2ClS_2.H_2O$ requires C, 45.4; H, 3.8%. $C_{19}H_{17}O_7N_2ClS_2$ requires C, 45.4; H, 3.8%). Diazotisation and coupling with alkaline β -naphthol gave the corresponding *azo*- β -naphthol, which crystallised in red prisms from ethyl acetate or acetone, m. p. 148° (Found: C, 64.0, 64.0; H, 4.1, 4.1. $C_{20}H_{19}O_4N_3S_2$ requires C, 64.5; H, 3.9%). The filtered diazo-solution after addition of urea and boiling yielded 4-hydroxy-2'-N-benzenesulphonylcarbamyldiphenyl sulphide, which separated from hot water in small white needles, m. p. 143°. Hydrolysis with 60% sulphuric acid yielded 4-amino-2'-carboxydiphenyl sulphide, which after crystallisation from aqueous alcohol had m. p. 193° not depressed by admixture of an authentic specimen prepared from the nitro-acid obtained from *p*-nitrothiophenol and anthranilic acid (*cf.* Mayer, *loc. cit.*).

Reaction with *o*-toluidine produced 4-amino-2'-N-benzenesulphonylcarbamyldiphenyl-3-methyldiphenyl sulphide, which after purification through the perchlorate crystallised from alcohol in white needles, m. p. 118° (Found: C, 59.7; H, 5.3. $C_{26}H_{25}O_2N_2S_2.C_2H_5O$ requires C, 59.4; H, 5.4%). The *perchlorate* formed cream coloured needles from dilute perchloric acid, m. p. 225° (decomp.) (Found: C, 48.6; H, 4.0. $C_{26}H_{25}O_2N_2ClS_2$ requires C, 48.2; H, 3.8%). The corresponding *azo*- β -naphthol crystallised from ethyl acetate in dark red prisms, m. p. 136° (Found: C, 65.0; H, 4.6. $C_{30}H_{23}O_4N_3S_2$ requires C, 66.1; H, 4.2%).

Action of Sulphuric Acid on the Foregoing Aminodiphenyl Sulphides.—The 4-substituted 2'-N-benzenesulphonylcarbamyldiphenyl sulphides were warmed at 50° for 1 hour with concentrated sulphuric acid (20 c.c. for 5 g.). The resulting solution on being poured into water gave a white precipitate of a sulphonic acid, and addition of alkali to the filtered solution yielded an aminoxanthone, a further yield of which was obtained by redissolving the sulphonic acid in alkali.

2-Dimethylaminothioxanthone crystallised from alcohol in orange needles, m. p. 122° (Found: C, 70.4; H, 5.3; N, 5.7. $C_{18}H_{15}ONS$ requires C, 70.5; H, 5.1; N, 5.5%). The substance gave a green fluorescence in sulphuric acid solution. It was found by m. p. and mixed m. p. to be identical with the xanthone produced by the action of concentrated sulphuric acid on synthetic 4-dimethylamino-2'-carboxydiphenyl sulphide (see above).

The sulphonic acid was purified by precipitation from alkaline solution, redissolved and boiled in

alkali with charcoal, reprecipitated, and finally boiled with water. It was a white microcrystalline powder, m. p. 318°, presumably 4-dimethylamino-2'-carboxydiphenyl sulphide-3-sulphonic acid, but the position of the sulphonic acid group was not proved (Found: C, 50.9; H, 4.1; N, 3.6. $C_{18}H_{15}O_6NS_2$ requires C, 51.0; H, 4.2; N, 3.9%). When this substance was heated in concentrated sulphuric acid (10 parts) for $\frac{1}{2}$ hour at 150° a brown solution with green fluorescence was formed. The solution was diluted and made alkaline, the dark red mass deposited was dissolved in water, and the solution was acidified. The acid precipitated was crystallised from hot water and formed a light brown microcrystalline powder not melting at 310°. The substance was hygroscopic and analyses were unsatisfactory, but it was presumably 2-dimethylaminothioxanthone-3-sulphonic acid (Found: C, 49.8; H, 4.3. Found after drying at 100° in a vacuum: C, 51.9; H, 4.5. $C_{18}H_{15}O_6NS_2 \cdot H_2O$ requires C, 51.0; H, 4.3%. $C_{18}H_{15}O_4NS_2$ requires C, 53.7; H, 3.9%). The sodium salt had m. p. 310°; the potassium salt was a dihydrate (Found: H_2O , 6.8. $C_{18}H_{15}O_4NS_2K \cdot 2H_2O$ requires H_2O , 6.8%) and had m. p. 95° or, after heating at 100° in a vacuum, m. p. 230°.

2-Methylethylaminothioxanthone was similarly obtained and crystallised from alcohol in pale orange needles, m. p. 120° (Found: C, 70.9; H, 5.6. $C_{16}H_{13}ONS$ requires C, 71.3; H, 5.6%). This compound was identified by m. p. and mixed m. p. with that obtained by the action of sulphuric acid on synthetic 4-methylethylamino-2'-carboxydiphenyl sulphide (see above).

The accompanying sulphonic acid formed white needles from hot water, m. p. 314° (decomp.), and was 4-methylethylamino-2'-carboxydiphenyl sulphide-3-sulphonic acid (Found: C, 52.6; H, 4.6. $C_{18}H_{17}O_6NS_2$ requires C, 52.3; H, 4.6%). The sodium salt had m. p. 272°, the potassium salt m. p. 215°. 2-Benzylmethylaminothioxanthone crystallised from alcohol in yellow needles, m. p. 149.5° (Found: C, 76.2; H, 5.4. $C_{21}H_{17}ONS$ requires C, 76.1; H, 5.2%). 4-Benzylmethylamino-2'-carboxydiphenyl sulphide-3-sulphonic acid was a microcrystalline powder sparingly soluble in hot water, m. p. 286° (decomp.) (Found: C, 58.9; H, 4.6. $C_{21}H_{19}O_6NS_2$ requires C, 58.7; H, 4.5%).

2-Methylaminothioxanthone crystallised from aqueous alcohol in small yellow needles, m. p. 158°, or minute red crystals becoming yellow at ca. 144° (Found: C, 70.0; H, 4.5. $C_{14}H_{11}ONS$ requires C, 69.7; H, 4.6%). The accompanying 4-methylamino-2'-carboxydiphenyl sulphide-3-sulphonic acid formed white needles from hot water, m. p. 321° (decomp.) (Found: C, 46.3; H, 4.2. $C_{14}H_{13}O_6NS$ requires C, 46.6; H, 3.8. $C_{14}H_{13}O_6NS \cdot H_2O$ requires C, 47.0; H, 4.2%).

2-Ethylaminothioxanthone was obtained as orange plates or needles from alcohol, m. p. 134° (Found: C, 70.3; H, 5.1. $C_{14}H_{13}ONS$ requires C, 70.5; H, 5.1%). No sulphonic acid was isolated in this case.

2-Amino-1-thioxanthone formed yellow needles from alcohol or plates from nitrobenzene, m. p. 227° (Found: C, 69.3; H, 3.7; N, 4.3. Calc.: C, 68.7; H, 4.0%. Cf. Mayer, *loc. cit.*, who also reports poor analyses). It was shown to be identical with the aminothioxanthone synthesised (in poor yield) by the method of Smiles (*J.*, 1911, 2046) or by that of Mayer (*loc. cit.*).

This substance, boiled with acetic anhydride in toluene solution for 4 hours, yielded a diacetyl derivative which crystallised from toluene in yellow crystals, m. p. 245° (Found: C, 65.3; H, 3.9. $C_{17}H_{13}O_5NS$ requires C, 65.6; H, 4.2%). On hydrolysis it furnished the parent amino-1-thioxanthone.

In its production from the condensation product from aniline it was accompanied by 4-amino-2'-carboxydiphenyl sulphide-3-sulphonic acid, which separated in small white crystals from water, m. p. > 320° (Found: C, 48.0; H, 3.5. $C_{13}H_{11}O_6NS_2$ requires C, 48.0; H, 3.4%).

Reaction of N-Benzenesulphonylbenzothiazolone with p-Substituted Aromatic Amines. Formation of the Lactams of the 2-Amino-2'-carboxydiphenyl Sulphides.—The thiazolone was heated for 5 hours in boiling alcohol with an equal weight of p-toluidine, the solution evaporated to dryness, and the product recrystallised from alcohol or glacial acetic acid. The lactam of 2-amino-2'-carboxy-5-methyldiphenyl sulphide was thus isolated as glistening plates, m. p. 274° (Found: C, 69.2; H, 4.5. $C_{14}H_{11}ONS$ requires C, 69.7; H, 4.6%). Benzenesulphonamide was found in the mother liquors. The lactam was oxidised by hydrogen peroxide in acetic acid to its sulphone, a white microcrystalline powder, m. p. > 320° (Found: C, 61.5; H, 4.1. $C_{14}H_{11}O_5NS$ requires C, 61.4; H, 4.1%). The lactam was hydrolysed by boiling it for 4 hours with 65% sulphuric acid. On dilution a precipitate was formed containing the sulphate of the amino-acid, and a thioxanthone, separated by dissolving the former out in alkali. The residue was 4-amino-1-methylthioxanthone, yellow needles from alcohol, m. p. 183° not depressed by admixture of a specimen prepared by the method of Ullmann and Glenck (*Ber.*, 1916, 49, 2499). The alkaline solution, on acidification with acetic acid, gave a 2-amino-2'-carboxy-5-methyldiphenyl sulphide, which crystallised from butyl alcohol in pale buff needles, m. p. 170° (Found: C, 65.2; H, 5.1. $C_{14}H_{13}O_6NS$ requires C, 64.9; H, 5.1%). The acid was re-converted by boiling in acetic anhydride for $\frac{1}{2}$ hour or by standing overnight in sulphuric acid solution into the lactam, m. p. 271°. The lactam was also formed when the acid was heated for 3 hours in boiling ethyl alcohol containing 2–5% of hydrogen chloride, and the ethyl ester of the acid, m. p. 100°, was also produced. When the acid was heated in boiling xylene for $\frac{1}{2}$ hour with phosphoric oxide it yielded the lactam together with 4-amino-1-methylthioxanthone.

The thiazolone with p-anisidine furnished the lactam of 2-amino-2'-carboxy-5-methoxydiphenyl sulphide, which crystallised from alcohol in white needles, m. p. 235° (Found: C, 64.9; H, 4.1; M, ebullioscopic in alcohol, 250. $C_{14}H_{11}O_2NS$ requires C, 65.3; H, 4.3%; M, 241). The acetyl derivative formed white needles from alcohol, m. p. 165° (Found: C, 63.7; H, 4.6. $C_{16}H_{13}O_3NS$ requires C, 64.2; H, 4.4%). The sulphone separated as a microcrystalline powder from acetic acid, m. p. 246° (Found: C, 58.3; H, 4.2. $C_{14}H_{11}O_4NS$ requires C, 58.1; H, 3.8%), which also yielded an acetyl derivative, m. p. 194° (Found: C, 58.5; H, 4.0. $C_{16}H_{13}O_4NS$ requires C, 58.0; H, 3.9%).

The same lactam was obtained when N-p-toluenesulphonylbenzothiazolone was used in place of the benzenesulphonyl derivative. Hydrolysed by acid it furnished the 2-amino-2'-carboxy-5-methoxydiphenyl sulphide, which crystallised from dilute acetic acid or butyl alcohol in buff needles, m. p. 168° (Found: C, 61.6; H, 4.9. $C_{14}H_{13}O_6NS$ requires C, 61.1; H, 4.8%), and formed a perchlorate, which separated from dilute perchloric acid as a white microcrystalline powder, m. p. 210° (decomp.) (Found: C, 43.3; H, 4.5. $C_{14}H_{14}O_6NCIS \cdot H_2O$ requires C, 42.9; H, 4.1%). As a by-product in the hydrolysis a

substance was isolated which crystallised from glacial acetic acid in red needles, m. p. 238°, and appeared to be 4-amino-1-hydroxythioxanthone (Found : C, 63.0; H, 3.8. $C_{13}H_9O_2NS$ requires C, 63.5; H, 3.8%). The acid kept overnight in sulphuric acid solution yielded 4-amino-1-methoxythioxanthone, yellow plates from alcohol, m. p. 168° (Found : C, 64.9; H, 4.4. $C_{14}H_{11}O_2NS$ requires C, 65.3; H, 4.8%).

The action of *p*-chloroaniline on *N*-benzenesulphonylbenzothiazolone (12 hours' boiling) yielded the lactam of 5-chloro-2-amino-2'-carboxydiphenyl sulphide, which crystallised from glacial acetic acid in colourless plates, m. p. 321° (Found : C, 59.0; H, 3.4. $C_{13}H_9ONClS$ requires C, 59.6; H, 3.1%). Hydrolysis with 65% sulphuric acid gave the acid, which separated from dilute acetic acid as a microcrystalline powder, m. p. 183° (Found : C, 55.1; H, 3.8. $C_{13}H_9O_2NSCl$ requires C, 55.8; H, 3.6%).

Lactam of 2-Amino-2'-carboxydiphenyl Sulphide.—2-Amino-2'-carboxydiphenyl sulphide of m. p. 157° prepared Mayer's method (*loc. cit.*), when heated with phosphoric oxide in boiling xylene for $\frac{1}{2}$ hour, gave the lactam, which crystallised from acetic acid in colourless plates, m. p. 256° (Found : C, 68.4; H, 4.2. $C_{13}H_9ONS$ requires C, 68.7; H, 4.4%). Oxidation with hydrogen peroxide in acetic acid yielded the lactam sulphone, which separated from dilute acetic acid in colourless needles, m. p. 290° (Found : C, 60.4; H, 3.8. $C_{13}H_9O_2NS$ requires C, 60.1; H, 3.5%). These lactams are soluble in warm aqueous sodium hydroxide. The same lactam sulphone was also obtained from 2-nitro-2'-carboxydiphenyl sulphone (Mayer, *loc. cit.*) by reduction to the amino-acid sulphone and heating the latter with phosphoric oxide in xylene.

***p*-Toluidide and *p*-Nitroanilide of Dithiobenzoic Acid.**—2 : 2'-Dithiobenzoyl chloride reacted with *p*-toluidine or *p*-nitroaniline in carbon tetrachloride or toluene solution, yielding the *p*-toluidide, m. p. 233° (Found : C, 69.2; H, 5.1. $C_{23}H_{24}O_2N_2S_2$ requires C, 69.4; H, 5.0%), and the *p*-nitroanilide, which crystallised from aqueous pyridine in light brown needles, m. p. 263° (Found : C, 57.0; H, 3.5. $C_{24}H_{18}O_6N_4S_2$ requires C, 57.1; H, 3.3%).

***N*-Arylbisothiazolones.**—Chlorine was passed into 2 : 2'-dithiobenzoyl chloride (10 g.) covered with carbon tetrachloride (60 c.c.) until it had dissolved, the excess of chlorine removed by a current of nitrogen, and the resulting solution added to an ice-cooled solution of *p*-toluidine (20 g.) in carbon tetrachloride (200 c.c.). The dark solution was filtered and evaporated, and the product crystallised from methyl alcohol (charcoal). *N*-*p*-Tolylbenzothiazolone was thus obtained as colourless needles, m. p. 135° (Found : C, 69.3; H, 4.3. $C_{14}H_{11}ONS$ requires C, 69.7; H, 4.5%). A similar condensation with *p*-nitroaniline using pyridine as solvent yielded *N*-*p*-nitrophenylbenzothiazolone, a microcrystalline powder from acetic acid, m. p. 238° (Found : C, 57.1; H, 3.2. $C_{13}H_9O_2N_2S$ requires C, 57.3; H, 3.0%). This substance was also obtained by adding to the *p*-toluidide of dithiobenzoic acid (3 g.) covered with carbon tetrachloride (50 c.c.) a solution of bromine (2 g.) in carbon tetrachloride (10 c.c.). The dirty red precipitate of bromo-thiol was removed by filtration and boiled with acetic acid (100 c.c.). The thiazolone crystallised on cooling, m. p. 238°. Oxidation by hydrogen peroxide in hot acetic acid converted it into *N*-*p*-nitrophenylsaccharin, pale yellow plates from acetic acid, m. p. 229° (Found : C, 50.8; H, 2.4. $C_{13}H_9O_4N_2S$ requires C, 51.3; H, 2.6%).

The authors wish to thank Dr. A. W. H. Barton for his help with the earlier experiments.

KING'S COLLEGE, STRAND, W.C. 2.

[Received, November 29th, 1946.]

232. A Method of Synthesis of Trinitromethane Derivatives.

By W. S. REICH and (in part) G. G. ROSE and W. WILSON.

The present investigations have shown that aromatic halogenomethyl derivatives react with the silver salt of *aci*-trinitromethane yielding trinitromethane derivatives. They are stable, crystalline, colourless compounds, most probably of the true nitro-type. The reaction also yields varying amounts of unstable, deeply coloured derivatives, probably of the *aci*-trinitromethane type.

A number of trinitromethyl and polytrinitromethyl derivatives were prepared by this method, all of which contained the trinitromethyl group in the side chain of the benzene nucleus. The benzene nucleus itself was in many cases either nitrated or polynitrated.

Improved or new methods for the preparation of a number of intermediary products are also described.

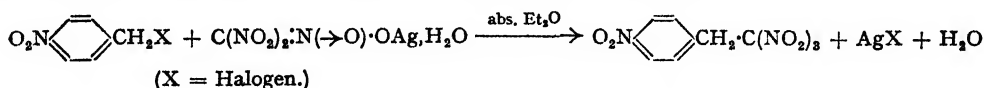

TRINITROMETHANE (nitroform) was first prepared by Schischkoff (*Annalen*, 1857, 101, 216) by the action of water or alcohol on trinitromethyl cyanide, and later several methods for its preparation from tetranitromethane were described (Hantzsch and Rinkenberger, *Ber.*, 1899, 32, 635; Chattaway and Harrison, *J.*, 1916, 109, 171; Macbeth and Orr, *J.*, 1932, 534). A number of addition compounds of trinitromethane, such as its salts with pyridine, piperidine, and dibenzylamine, have also been prepared (Schmidt and Fischer, *Ber.*, 1920, 53, 1529); they are very unstable and soon decompose on keeping.

Two aliphatic trinitromethane derivatives, *viz.*, 1 : 1 : 1-trinitroethane and hexanitroethane, have been described. Franchimont (*Rec. Trav. chim.*, 1886, 5, 282) obtained the former by the action of concentrated nitric acid on methylmalonic acid, and it was later prepared (Hantzsch and Rinkenberger, *loc. cit.*) by reaction between silver trinitromethane and methyl iodide, but

this silver salt and iodotrininitromethane failed to give hexanitroethane. All attempts to use higher halogeno-paraffins, such as ethyl or butyl iodide, instead of methyl iodide, with a view to obtain other trinitromethane derivatives failed to yield any pure or stable compound. Will (*Ber.*, 1914, 47, 963) obtained hexanitroethane by the action of concentrated nitric and sulphuric acids on the potassium salt of 1 : 1 : 2 : 2-tetranitroethane.

Ponzio (*Gazzetta*, 1932, 62, 503) obtained aromatic azo-derivatives of trinitromethane [e.g., $p\text{-Cl}\cdot\text{C}_6\text{H}_4\cdot\text{N}\cdot\text{N}\cdot\text{C}(\text{NO}_2)_3$] by the reaction of ammonium trinitromethane with aromatic diazonium salts. They form yellow or orange crystalline compounds, which rapidly decompose on standing or in solution.

The present investigation has shown that it is possible to prepare stable, crystalline, aromatic trinitromethane derivatives. The synthesis was carried out by reaction of the silver salt of trinitromethane with halogenomethyl derivatives of the aromatic series :

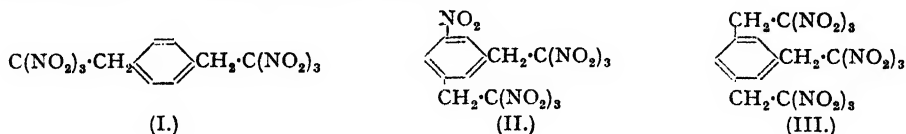

It is noteworthy that the *aci*-trinitromethane group of the silver salt is rearranged to the true nitro-type very probably contained in the stable, colourless trinitromethane derivative. The reaction also yields an unstable, deeply coloured, trinitromethane derivative, probably of the *aci*-trinitro-type, which slowly decomposes with elimination of nitrous fumes. The yield of this unstable compound depends on the working conditions and on the nature of the aromatic group. Substitution of negative groups in the benzene nucleus, especially in the *p*-position, increases the yield of the stable compound.

All the trinitromethane derivatives described in this investigation are very stable : after 3 years' standing in stoppered bottles at room temperature, they showed no change.

(With G. G. ROSE.) The preparation of the 2 : 4 : 6-trinitrobenzyl derivative by the same method proceeds easily, and the yield of the stable compound (presumably of the true nitro-type) is greater (64%) than that of the *p*-nitrobenzyl derivative (45%). In both cases, there was also formed a small amount of an unstable deeply coloured oil, presumably a mono-*aci*-compound or a mixture derived from it by decomposition and secondary reactions.

Attempts to cause reaction between 2 : 4 : 6-trinitrobenzyl bromide and the silver salt of *aci*-trinitromethane were unsuccessful, but the iodide afforded 2 : 4 : 6-trinitro-2' : 2' : 2'-trinitroethylbenzene.

(With W. WILSON.) The same reaction was utilised for the synthesis of some polytrinitromethyl derivatives : *p*-xylylene di-iodide, $\omega\omega'$ -di-iodo-5-nitro-*m*-xylene, and $\omega\omega'\omega'$ -tri-iodo-mesitylene reacted with an ethereal solution of silver *aci*-trinitromethane to yield, respectively, 1 : 4-bis-2' : 2' : 2'-trinitroethylbenzene (I), 5-nitro-1 : 3-bis-2' : 2' : 2'-trinitroethylbenzene (II), and 1 : 3 : 5-tris-2' : 2' : 2'-trinitroethylbenzene (III).

EXPERIMENTAL.

Silver Salt of Trinitromethane.—This preparation has been described by Hantzsch and Rinkenberger (*loc. cit.*), but for the preparation of larger quantities of pure material the following method is better. Silver oxide (freshly prepared, still slightly damp, 265 g.) was cautiously and gradually added to a solution of trinitromethane (180 g.) in ether (1000 c.c.); after each addition the mixture was shaken for a short while, and when the addition was complete the mixture was vigorously shaken over-night. The solution was separated by filtration, and the low-boiling material removed under reduced pressure, the ether at room temperature, and the remaining liquid at 42° (bath temp.)/12 mm. The residue was kept at 42°/12 mm. for an hour after it had crystallised and was then pressed on porous plates. A typical yield was 260 g. (ca. 70%).

***p*-Nitrobenzyltrinitromethane.**—*p*-Nitrobenzyl bromide (85 g.) was dissolved in dry ether (1800 c.c.), the solution stirred in a water-bath at 20°, and a solution of the silver salt of trinitromethane (109 g.) in ether (800 c.c.) gradually added. After the addition was complete, the stirring was continued for about 2 hours and the mixture was left in the water-bath for 48 hours. The precipitated silver bromide was then filtered off, washed with ether, and dried in a desiccator (76 g. Calc. : 75 g.). The filtrate was concentrated in a high-speed evaporation apparatus at 25° (bath temp.)/12 mm., and the residue, consisting of a red liquid and a solid, was left on the vacuum pump at 30° (bath temp.) for about 15 minutes, and then for 2 hours in a refrigerator. The pale pink crystals were separated by filtration and

pressed on a porous plate (51 g., 45%), m. p. 129° (decomp.). The substance was dissolved in 250 c.c. of boiling absolute alcohol, the solution filtered while hot, and the filtrate kept overnight at 0°. The crystals were separated by filtration, washed with a small amount of cold absolute alcohol, and dried in a desiccator (34 g.). The substance was recrystallised from 200 c.c. of hot absolute alcohol-carbon tetrachloride (25:75) (yield 28 g.) and three further similar recrystallisations afforded 17 g. of pure 4-nitro-2':2':2'-trinitroethylbenzene; white crystals, m. p. 135° (Found: C, 33.7; H, 2.3; N, 19.5. $C_8H_6O_6N_3$ requires C, 33.6; H, 2.1; N, 19.6%).

2:4:6-Trinitrobenzyl Bromide.—Ganguly's method (Ber., 1925, 58, 708) was used with some modifications. Repeated crystallisation gave a substance, m. p. 71°, which was almost analytically pure (Found: Br, 26.85. Calc. for $C_7H_4O_6N_3Br$: Br, 26.14%). Ganguly gives m. p. 65° but no analysis.

2:4:6-Trinitrobenzyl Iodide.—Reich, Wetter, and Widmer's method (Ber., 1912, 45, 3056) was used. The brown solid was twice recrystallised from hot methyl alcohol, yielding needles, m. p. 87°; yield 47%. In general, the brominated derivative was only once crystallised before being converted into the iodo-compound, as the latter was then considerably easier to purify.

2:4:6-Trinitro-2':2':2'-trinitroethylbenzene.—Trinitrobenzyl iodide (105.9 g.) and ether (150 c.c.) were stirred whilst a solution of the silver salt of *aci*-trinitromethane (87 g.) in ether (280 c.c.) was added. The stirring was continued for 18 hours and the mixture filtered. The filtrate on evaporation yielded an unstable red oil which was ignored. The residue, a yellow-brown powder (140 g.), was extracted in portions with chloroform (Soxhlet), and the residues from the extraction were powdered and re-extracted with chloroform. On cooling, the chloroform extracts yielded a light brown, crystalline solid (72 g., 64%), m. p. 151.5–152.5° (decomp.). [The residue insoluble in chloroform was silver iodide (65 g. Calc.: 70 g.).] The brown crystals (72 g.) were dissolved in hot ethyl acetate (220 c.c.), the solution filtered from traces of silver iodide, chloroform (500 c.c.) added to the fairly warm filtrate, and the mixture cooled to 0°; the yellow crystals obtained (62 g.), m. p. 152.5–153.5° (decomp.), were four times recrystallised from hot ethyl nitrate-chloroform (1:1 by vol.), and the pure *hexanitro*-compound isolated as faintly coloured, large crystals (38 g.), m. p. 153–154° (decomp.) (Found: C, 25.8; H, 1.3; N, 22.4. $C_8H_4O_{12}N_6$ requires C, 25.5; H, 1.1; N, 22.35%).

Before each crystallisation the substance was finely powdered with an agate pestle and mortar and then dissolved with stirring in the requisite quantity of hot ethyl nitrate (about 150 c.c. to 55 g. of substance); when solution was complete an equal volume of chloroform was added, and the mixture cooled to 0° until crystallisation was complete. By this means prolonged heating, which caused extensive discolouration, was avoided.

ω-Bromo-5-nitro-*m*-xylene.—5-Nitro-*m*-xylene (2 g.) in boiling ethylene dibromide (40 c.c.) was irradiated by a 100-watt tungsten-filament lamp whilst a solution of bromine (4.3 g.) in ethylene dibromide (15 c.c.) was dropped in. After an hour the bromination was complete. Removal of the ethylene dibromide at 75°/20 mm. yielded a dark semi-solid substance, which was recrystallised from petroleum (b. p. 40–60°); yield, 500 mg. of *ω*-bromo-5-nitro-*m*-xylene, m. p. 59.5–60° (Found: C, 9.4; H, 3.4. $C_8H_8O_2NBr$ requires C, 41.7; H, 3.5%).

ωω'-Dibromo-5-nitro-*m*-xylene.—5-Nitro-*m*-xylene (m. p. 71–72.5°; 120 g.), dissolved in boiling ethylene dibromide (450 c.c.), was heated under reflux and irradiated with a 500-watt tungsten-filament lamp whilst a solution of dry bromine (100 c.c.) in ethylene dibromide (100 c.c.) was added fairly rapidly. After the bromine had almost disappeared, the ethylene dibromide was removed in a vacuum, the residue allowed to crystallise, and the crystals separated and washed with ether. Recrystallisation from petrol (b. p. 80–100°) yielded pure *ωω'*-dibromo-5-nitro-*m*-xylene (46 g.), m. p. 105–106.5° (Found: Br, 51.4. $C_8H_6O_2NBr_2$ requires Br, 51.8%).

Both the mono- and the di-bromo-compound were lachrymatory and had skin-irritant properties, and both afforded silver bromide quantitatively on treatment with warm aqueous-alcoholic silver nitrate.

ωω'-Di-iodo-5-nitro-*m*-xylene.—The crude dibromo-compound (above) (62 g.) was added to a solution of sodium iodide (85 g.) in acetone (400 c.c.); after 1 hour's heating under reflux the acetone was distilled off, and the residue washed with water. The product, crystallised from benzene-petroleum (b. p. 40–60°), yielded 53 g. of pure *ωω'*-di-iodo-5-nitro-*m*-xylene, m. p. 136–137° (Found: N, 3.6. $C_8H_6O_2NI_2$ requires N, 3.5%).

5-Nitro-1:3-bis-2':2':2'-trinitroethylbenzene.—(i) *ωω'*-Dibromo-5-nitro-*m*-xylene (m. p. 102–105°; 8 g.) was suspended in ether (100 c.c.) and 48.8 c.c. of a solution of the silver salt of trinitromethane (containing 297.4 g. per l. of ether) were added slowly. After 3 days, the silver bromide (10 g.) was filtered off, the filtrate washed with water, and then desolvated at 30°/20 mm.; the semi-solid residue was triturated with chloroform at 0°, yielding crystals (0.9 g.), m. p. 158–160°. Recrystallisation from chloroform yielded the pure *heptanitro*-compound, m. p. 170–171.5° (slight decomp.) (Found: C, 26.6; H, 1.8; N, 21.8. $C_{10}H_2O_{14}N_7$ requires C, 26.7; H, 1.6; N, 21.8%).

(ii) *ωω'*-Di-iodo-5-nitro-*m*-xylene (50 g.) was suspended in dry ether (500 c.c.), and 280 c.c. of an ethereal solution of the silver salt of trinitromethane (containing 248 g. per l.) were added fairly rapidly at 18–25° with vigorous stirring. After the stirring had continued for 4 hours, the silver iodide (61 g.) was filtered off, and the filtrate washed with water and dried (Na_2SO_4). The ether was removed in a vacuum, and the residue triturated with a little chloroform at 0° and the solution filtered after 15 minutes. The product was separated by filtration and washed on the filter with chloroform, yielding a pale pink solid (29 g.), m. p. 160–165° (decomp.). Recrystallisation from chloroform (charcoal) yielded the *heptanitro*-compound (22 g.), m. p. 171–172° (decomp.) (Found: C, 26.5; H, 1.65; N, 21.7%).

p-Xylylene Di-iodide.—This was prepared from the dichloride by double exchange with sodium iodide in acetone solution, the dichloride having been made by chloromethylation of benzyl chloride (Stephen, Short, and Gladding, *J.*, 1920, 117, 510; Quelet, *Bull. Soc. chim.*, 1933, 53, 222). Recrystallised from benzene-ethanol, the di-iodide had m. p. 179.5–180° (Found: C, 26.9; H, 2.0. Calc. for $C_8H_6I_2$: C, 26.8; H, 2.2%). Grimaux (*Compt. rend.*, 1870, 70, 1365; *Annalen*, 1870, 155, 341) gives m. p. 170°; Finkelstein (Ber., 1910, 43, 1532), m. p. 174°.

1:4-Bis-2':2':2'-trinitroethylbenzene.—*p*-Xylylene di-iodide (5 g.) was suspended in dry ether

(100 c.c.) and 27 c.c. of a solution of the silver salt of trinitromethane (containing 303.5 g. per l., in ether) were added slowly. After 2 hours' stirring and a further 15 hours' standing, the silver iodide (7 g. Calc. : 6.6 g.) was filtered off, the filtrate washed with water, dried, and desolvated at 30°/20 mm.; the pale yellow semi-solid product was triturated with a little chloroform on a sintered-glass filter, yielding a solid (0.6 g.), m. p. ca. 165° (decomp.). Recrystallisation from chloroform yielded white needles of the *hexanitro*-compound, m. p. 190° (decomp.) (Found : C, 29.7; H, 2.3; N, 20.6. $C_{10}H_2O_{12}N_6$ requires C, 29.7; H, 2.0; N, 20.8%).

ωω'ω''-Tri-iodomesitylene.—*ωω'ω''-Tribromomesitylene* (m. p. 98–99°; 1.5 g.) was added to a solution of sodium iodide (3.0 g.) in acetone (30 c.c.); after 30 mins.' heating under reflux, most of the acetone was distilled off, and the residue washed with water and dried, yielding *ωω'ω''-tri-iodomesitylene* (2.1 g.), m. p. 131–133°; crystallised from benzene, needles, m. p. 133° (Found : C, 22.6; H, 1.9. $C_9H_3I_3$ requires C, 22.1; H, 1.9%).

1 : 3 : 5-*Tris*-2' : 2' : 2'-*trinitroethylbenzene*.—*ωω'ω''-Tri-iodomesitylene* (5.5 g.) was suspended in ether (100 c.c.) and 34 c.c. of a solution containing 287 g. of the silver salt of trinitromethane per l. of ether were added fairly rapidly. After 2 hours' stirring, the product was allowed to stand overnight. The silver iodide (7.3 g. Calc. : 7.8 g.) was filtered off, and the solution washed with water to remove unchanged silver nitroform [the amount of which was determined by conversion into silver chloride (1.3 g.), showing that the reaction was probably about 80% complete]. The ethereal solution was dried and desolvated at 30° in a vacuum, yielding a brown oil mixed with crystals. Trituration with chloroform yielded a white solid (550 mg.), m. p. 198–200° (decomp.). Two crystallisations from chloroform yielded the required *nitro*-compound (250 mg.), m. p. 205–206° (decomp.) (Found : C, 25.4; H, 1.72; N, 22.23. $C_{12}H_9O_{15}N_9$ requires C, 25.4; H, 1.59; N, 22.22%).

This work was carried out during 1941–1944 in the Department of Scientific Research, Inter-Services Research Bureau, The War Office. The authors wish to express their thanks to the Director of the Department, Professor D. M. Newitt, F.R.S., for his interest and invaluable support. Their thanks are also due to the Director General of Scientific Research (Defence) for the permission to publish these investigations.

233. The Reaction of Benzoic Anhydride with Aromatic Compounds Catalysed by Boron Trifluoride.

By P. H. GIVEN and D. LL. HAMMICK.

Boron trifluoride catalyses the interaction in nitrobenzene solution of benzoic anhydride with aromatic compounds to give ketones. Phenyl 1-naphthyl ketone, phenyl 2-hydroxy-1-naphthyl ketone, and phenyl 2-thienyl ketone are formed by reaction of the acid anhydride with naphthalene, 2-naphthyl methyl ether, and thiophen respectively. The same catalyst is effective in the Fries rearrangement of 2-naphthyl benzoate.

IN 1939–1940 we initiated a programme of work on the acylation of aromatic compounds with benzoic and other anhydrides in the presence of boron trifluoride, but were unable to complete it. We therefore record here the results of the work as far as we were able to carry it.

Meerwein and Vossen have reported (*J. pr. Chem.*, 1934, **141**, 149) the interaction of acetic anhydride with benzene and other aromatic compounds in the presence of boron trifluoride to give aryl methyl ketones, but do not mention the use of any other acid anhydrides. Their experimental procedure involved the saturation of the mixed reactants at 0° with the catalyst, followed by warming till all the fluoride was given off again. The yield of some ketones was decreased by intermolecular condensations of the acetic anhydride to give β-diketones. Bowlus and Nieuwland (*J. Amer. Chem. Soc.*, 1931, **53**, 3835) state that benzoic and phthalic anhydrides (in an unspecified solvent) do not absorb boron trifluoride, but that benzoic acid in chloroform takes up the gas, forming an insoluble complex.

We have found that benzoic and phthalic anhydrides in nitrobenzene, and the former in carbon tetrachloride and in tetrachloroethane, react with boron trifluoride, depositing solid complexes. The weight of gas taken up, after allowing for its solubility in the solvent, was approximately equivalent to 2 moles of BF_3 per mole of anhydride.

For our acylation experiments we chose nitrobenzene as solvent, on the grounds that the reaction presumably resembles the Friedel–Crafts reaction in being ionic in nature (see Linstead, *Ann. Reports*, 1937, 251; Price and Ciskowski, *J. Amer. Chem. Soc.*, 1938, **60**, 2499), and therefore should proceed most readily in a solvent of high dielectric constant.

By reaction of benzoic anhydride with thiophen we obtained a 40% yield of phenyl 2-thienyl ketone; a dirty residue, non-volatile in steam, was also formed. 2-Naphthyl methyl ether gave 55% of phenyl 2-hydroxy-1-naphthyl ketone; complete demethylation occurred.

Phenyl naphthyl ketone (77% crude product) was obtained by reaction of benzoic anhydride with naphthalene; after three crystallisations, substantially pure phenyl 1-naphthyl ketone was obtained (about 60%). Price and Ciskowski (*loc. cit.*) in the reaction of benzyl alcohol with naphthalene in the presence of boron trifluoride, also found the 1-isomer to predominate.

It was found that (under the conditions used in the benzoylations) boron trifluoride catalysed the Fries rearrangement of 2-naphthyl benzoate; a 34% yield of pure phenyl 2-hydroxy-1-naphthyl ketone was obtained.

In order to confirm the reasoning which led to the choice of nitrobenzene as solvent for the reaction mixture, an attempt was made to acylate naphthalene with benzoic anhydride in carbon tetrachloride solution. Under the same conditions as were used in the reaction in nitrobenzene only 4% of crude phenyl naphthyl ketone was obtained. Benzoic acid in reaction with naphthalene and boron trifluoride in nitrobenzene solution gave no phenyl naphthyl ketone.

The procedure used here appears to be unnecessarily vigorous for the benzoylation of reactive substances such as thiophen, as is shown by the formation of tarry by-products. The benzoylation of naphthalene by this method gives a rather higher yield of phenyl 1-naphthyl ketone, and the product is less contaminated with the 2-isomer than that of the Friedel-Crafts reaction of benzoyl chloride with naphthalene, catalysed by aluminium chloride (see, for example, Caille, *Compt. rend.*, 1911, 153, 393); the necessary time of reaction is less (24 hours as against 3 days).

EXPERIMENTAL.

(Melting points are corrected.)

Materials.—Naphthalene, benzoic acid, and benzoic anhydride were dried in a vacuum desiccator before use. Solvents were dried with calcium chloride and redistilled. Boron trifluoride was prepared by the method of Krause and Nitsche (*Ber.*, 1921, 54, 2786). A mixture of boric oxide, potassium borofluoride, and concentrated sulphuric acid was heated slowly from 135° to 250°. The gas was passed through a spray trap, but was not purified in any other way.

Absorption of Boron Trifluoride by the Reactants.—Experiments were carried out in test tubes fitted with side tubes. These, with inlet tube, rubber connections and clips were weighed empty and with the liquid before and after absorption. The liquid was cooled in ice during absorption. Absorption was allowed to proceed to constant weight. These experiments were made primarily to determine whether the acid anhydrides did or did not absorb boron trifluoride, and high accuracy is not claimed.

The data are presented in the Table. In column 4 the solubility of the gas in the solvent or solution is given in g. per 100 g. of solvent. In column 5 the molar ratio, boron trifluoride to benzoic acid or anhydride, is given.

Absorption of Boron Trifluoride.

Solute.	Solvent.	Wt. of solute per 100 g. of solvent.	Solubility, g./100 g.	Ratio, moles BF ₃ / moles acid or anhydride.
None.....	Nitrobenzene	—	17.6	—
None.....	Tetrachloroethane	—	9.8	—
Benzoic anhydride	Nitrobenzene	12.6	24.4	1.8
Benzoic anhydride	Tetrachloroethane	7.87	15.0	2.2
Phthalic anhydride	Nitrobenzene	10	26.3	1.9

Benzoylation Experiments.—The reactants and solvent were placed in a three-necked flask, which was fitted with an inlet tube, mechanical stirrer, and calcium chloride tube. The stirrer was of the glass link type, and was run very fast so as to break up the surface of the liquid. A mercury-sealed stirrer was used in some experiments, but a simple well-fitting glass sleeve was found quite satisfactory. The inlet tube was bent so that the gas was delivered in the liquid, directly under the stirrer. An excess of boron trifluoride (3–5 moles per mole of benzoic anhydride) was passed in the course of 1–2 hours according to the scale of experiment. During absorption of boron trifluoride the flask was cooled in ice. After absorption, the reaction mixture was stirred and kept at 0° for 3–4 hours, and then left, while slowly warming to room temperature, for a further 18 hours. It was then shaken with dilute sodium hydroxide solution, and the solvent and any excess reactants were removed in steam. The product was obtained either from the steam distillate or from the residue by extraction.

Phenyl 2-thienyl ketone. Benzoic anhydride (2 g.) and thiophen (1 c.c.) in nitrobenzene (12 g.) were treated with excess of boron trifluoride, and the product was worked up as above. The ketone distilled in steam after the solvent had been removed; it was extracted from the distillate with ether and dried, and the ether was removed; 0.7 g. of brownish crystals was obtained. After 2 crystallisations from light petroleum (b. p. 60–80°) the compound had m. p. 52°.

Phenyl 2-hydroxy-1-naphthyl ketone from 2-naphthyl methyl ether. Benzoic anhydride (4 g.) and 2-naphthyl methyl ether (2.5 g.) in nitrobenzene (18 g.) were treated with excess of boron trifluoride as above. From the residue of the steam distillation, 2.5 g. (70%) of crude ketone were obtained, completely soluble in warm sodium hydroxide solution. Crystallised from ligroin and twice from 60% alcohol, it gave fine yellow needles, m. p. 140–140.5°.

Phenyl 1-naphthyl ketone. (a) Benzoic anhydride (22.6 g.), naphthalene (12.8 g.), and nitrobenzene (140 c.c.) were treated with about 23 g. of boron trifluoride (*i.e.*, about 3 moles per mole of benzoic anhydride). From an ether extract of the residue from the steam distillation, 19 g. (77%) of crude

phenyl naphthyl ketone were obtained. A solution of 0.3 g. in 1 c.c. of benzene gave no precipitate after being boiled for 2 minutes and kept for 15 hours with 0.2 g. of picric acid in 1 c.c. of benzene (the 2-isomer gives an insoluble picrate in benzene, the 1-isomer none, and a mixture can be separated by virtue of this fact; see Perrier and Caille, *Compt. rend.*, 1908, **146**, 769). The remainder of the crude product was crystallised 3 times from dilute alcohol, with charcoal; m. p. 73—74° (Perrier and Caille, *loc. cit.*, give 76°).

(b) Naphthalene (4.3 g.) and benzoic anhydride (7.5 g.) in carbon tetrachloride (75 c.c.) were treated with excess of boron trifluoride; a copious white precipitate was thrown down. About 2.8 g. of unchanged naphthalene were found in the steam distillate. From the residue 0.3 g. (about 4%) of crude phenyl naphthyl ketone was obtained.

Attempted reaction of benzoic acid with naphthalene. Benzoic acid (5 g.) and naphthalene (5 g.) in nitrobenzene (65 c.c.) were treated with boron trifluoride as above. The materials were recovered substantially unchanged, and no phenyl naphthyl ketone was detected.

Fries Rearrangement of 2-Naphthyl Benzoate.—Naphthyl benzoate (7 g.) in nitrobenzene (65 c.c.) was treated with a large excess (about 15 g.) of boron trifluoride as above. The residue from the steam distillate was made strongly alkaline, and filtered hot from some black solid. The filtrate was made acid and filtered again. The residue on the filter was crystallised twice from dilute alcohol with the addition of charcoal. The product was phenyl 2-hydroxy-1-naphthyl ketone (2.4 g., 34%), m. p. 140.5—141°.

234. *The Reduction of Oxides by Hydrogen and Carbon Monoxide.*

By W. E. GARNER.

The previous investigations on the heats of adsorption of hydrogen, carbon monoxide, oxygen, and carbon dioxide on ZnO , $\text{MnO}_{1.4}$, Cr_2O_3 and their mixtures have been summarised. These oxides are semi-conductors and there is considerable mobility of ions in the oxide lattice at the temperature of reduction. The adsorption at room temperature takes place on a surface which may be the result of an equilibrium set up in a lattice defect structure at higher temperatures.

Reversible chemisorption of carbon monoxide occurs on metal-rich oxides with negative holes, and irreversible chemisorption on oxides with positive holes. The two types of chemisorption are not readily interconvertible. The reversible adsorption of carbon monoxide on zinc oxide, and the adsorption of carbon dioxide on the oxides of the transition elements occur without appreciable activation energy. It is suggested that when carbon monoxide is adsorbed irreversibly, there is set up a resonating system involving the *S* and *D* shells of the transition element. This system is moved in the direction of the carbonate ion, when the stoichiometric quantity of oxygen is adsorbed on the surface. The ease with which the carbonate ion is dissociated is thus determined by the number of unpaired electrons in the *D* and *S* shells of the transition element.

INVESTIGATIONS on the reduction of metallic oxides by hydrogen and carbon monoxide have shown that the reaction proceeds through a number of intermediate stages to yield hydroxides and carbonates which decompose to produce the lower oxide or metal (Garner and Kingman, *Trans. Faraday Soc.*, 1931, **27**, 322; Garner and Veal, *J.*, 1935, 1436, 1487; Dowden and Garner, *J.*, 1939, 894; Garner and Ward, *J.*, 1939, 858; Ward, following paper). The processes which precede the evolution of water or carbon dioxide include (a) van der Waals adsorption, which is specially predominant at low temperatures, and also (b) several types of chemisorption. The rate of chemisorption on oxides increases rapidly with increase of temperature, which led Taylor (*J. Amer. Chem. Soc.*, 1931, **53**, 578) to designate this type of process as "activated" adsorption. The heats of chemisorption of carbon monoxide and hydrogen on a number of oxides range from 15 to 70 k.-cals./mol., according to the oxide. It is found that if the heat of adsorption is below 20 k.-cals./mol., the gas can be desorbed unchanged on raising the temperature, but when the heat is greater than this value, the adsorption is usually irreversible, in the sense that, on warming, carbon dioxide or water is evolved. The results have been obtained on oxides which are reducible with difficulty. They may, however, be capable of application to easily reduced oxides, where the various stages in the reaction may proceed too quickly for them to be readily isolated from one another.

Chemisorption of Carbon Monoxide and Hydrogen.—In Table I are summarised the heats of adsorption of the two gases on a number of oxides at room temperature. On zinc oxide, carbon monoxide is adsorbed reversibly and carbonates are not formed, the activation energies and heats of reaction being unfavourable for the formation of carbonates in this case. For a mixture of zinc and chromium oxides, the adsorption of hydrogen or carbon monoxide is partly reversible and partly irreversible, the proportion of the two types of chemisorption depending on the state

TABLE I.

Heats of adsorption (in k.-cals./mol.) of CO and H₂ on oxidised and on reduced surfaces.

Substance.	H ₂ .		CO.		Remarks.
	Reduced.	Oxidised.	Reduced.	Oxidised.	
ZnO	No appreciable adsorption		20	18 → 13	Reversible desorption of CO at room temp.
Cr ₂ O ₃	36	72	29 → 22	28 → 12	Hydrogen very difficult to remove, even by long treatment at 450°; CO evolved as CO ₂ at 70—400°.
MnO _{1.5}	44	30	67	62	
ZnO, Cr ₂ O ₃	13 → 10	48 → 13	15 → 11	44 → 16	Partial desorption of CO and H ₂ at room temp.

of reduction of the oxide. On heating the oxide on which hydrogen or carbon monoxide is reversibly chemisorbed to 100—200°, the gas is evolved unchanged. The pressure rises to a maximum and then falls to zero. On further heating to 400° the gas is evolved as water or carbon dioxide respectively. It is clear that the direct conversion from reversible to irreversible chemisorption does not occur, since the surface reaction is hindered by a high potential energy barrier which is greater than the heat of desorption of the gas (see Fig.). This may be due to the two states of adsorption taking place on different centres. For the other oxides quoted in Table I, the adsorption is, for the most part, irreversible.

Formation of Carbonates.—Information relevant to the formation of carbonates on the surface of the oxides is given in Table II. The oxides were treated with oxygen at 450°, then evacuated and cooled to room temperature. Measurements were made of the heats of adsorption of carbon monoxide, oxygen, and carbon dioxide, and of mixtures of carbon monoxide and oxygen.

When the carbon monoxide is adsorbed irreversibly, carbon dioxide can be liberated on raising the temperature, but it is difficult to desorb this gas at room temperature. On the other hand, if carbon dioxide is adsorbed on the oxide, the heat of formation of the carbonate is of the order of 20 k.-cals., and the gas can be usually desorbed at room temperature, at a rate given by the Polanyi-Wigner equation, $r = \nu \cdot N e^{-Q/RT}$, where Q is the heat of adsorption, N is the number of molecules adsorbed on 1 cm.² of the surface, and $\nu = 10^{13}$ sec. The absence of appreciable activation energy in the formation and dissociation of carbonates is in agreement with the conclusions of Zawadzki and Bretsznajder (*Z. Elektrochem.*, 1935, 41, 215) and Spencer and Topley (*J.*, 1929, 2633). It is, however, clear that when carbon monoxide is adsorbed on an oxide, the product differs in some way from the carbonate formed from carbon dioxide.

* Oxide containing hydrogen as hydroxide.

† Calculated.

The surface after adsorption of carbon monoxide (col. 2) is, however, unsaturated with respect to oxygen, and a quantity of oxygen can be taken up with the liberation of the heats shown in col. 3. These heats are quite large and depend on the previous history of the oxide as well as on its nature. For Cr₂O₃ the heats are lower if hydrogen is present in the oxide. The observations made with MnO_{1.5}, Cr₂O₃ are instructive. The adsorbed carbon monoxide cannot be removed by evacuation at room temperature, but after the adsorption of oxygen or after the adsorption of CO + $\frac{1}{2}$ O₂ (col. 4), carbon dioxide is liberated on evacuation with a heat of desorption equal to the heat of adsorption of carbon dioxide (col. 5). In order to produce a carbonate from carbon monoxide with the same properties as that formed from carbon dioxide,

it is necessary to reoxidise the surface with the stoichiometric quantity of oxygen. It will be noted that the total heats given in col. 6 correspond in most cases with the heat of the reaction, $\text{CO} + \frac{1}{2}\text{O}_2 \longrightarrow \text{CO}_2$, which provides a good check on the accuracy of the measurements.

Formation of Hydroxides.—The position with regard to the formation of hydroxides is not so clear, since the results at room temperature were not sufficiently complete. "Activated" adsorption of hydrogen does not readily occur on some of the oxides at room temperature. It was shown, however, in a number of cases that the surface reduced with hydrogen was not unsaturated to the same extent as with carbon monoxide. Also, the hydrogen adsorbed irreversibly is so tightly held that it is difficult to remove it completely without sintering the oxide. Thus no information could be obtained with regard to the heat of desorption of water. For Cr_2O_3 , the hydrogen cannot be completely removed, even at 450° . It can, however, be removed in the course of the reduction by carbon monoxide, which mobilises the adsorbed hydrogen. The residual hydrogen in the case of Cr_2O_3 is found to increase materially the heat of adsorption of carbon monoxide.

The reduction of oxides by carbon monoxide.

Energy Levels.—The energy levels formed during the reduction of the oxides are set out schematically in the figure. This only gives a very approximate representation of the results of Table II, since the position of the levels varies with the oxide. The levels from left to right are: I, $\text{CO} + \frac{1}{2}\text{O}_2$; II, van der Waals adsorption of CO; III, reversible chemisorption of CO; IV, irreversible adsorption of CO, leading to an unsaturated surface; V, adsorption of $\text{CO} + \frac{1}{2}\text{O}_2$; and VI, carbon dioxide. There is an activation energy between II and III and carbon monoxide may be desorbed unchanged on raising the temperature if this activation energy is greater than the heat of desorption. This is the case for the adsorption of carbon monoxide on $\text{ZnO}, \text{Cr}_2\text{O}_3$. The overall change from I to VI is the conversion of carbon monoxide and oxygen into carbon dioxide.

Lattice Irregularities.—These oxides belong to the class of semiconductors, the electrical conductivity being due to a defect or excess of some ion in the lattice. Zinc oxide dissolves zinc, giving negative holes in the lattice. Oxides of manganese give a series of partially miscible solid solutions of MnO , Mn_2O_3 , and Mn_3O_4 , which can only be produced at the expense of some lattice irregularity. In this case, oxygen is in excess, which probably gives rise to positive holes in the lattice. It is thus similar to the cuprous oxide, which has been thoroughly investigated by Wagner (cf. Mott and Gurney, "Electronic Processes in Ionic Crystals", 1940), who shows that there is considerable mobility of the ions at high temperatures. On removal of oxygen by

reduction, negative holes will be produced on the surface, and if the temperature is sufficiently high, these negative holes will migrate into the interior of the lattice, their place on the surface being taken by oxygen ions. The surface reduction of oxides might therefore at sufficiently high temperature lead to a movement of oxygen from the interior of the lattice to the surface.

A phenomenon of this type possibly occurs at 450°, when the oxides are undergoing reduction. The extent to which the reduction occurs at this temperature and the quantities of gas which can be absorbed on the reduced surface are shown in Table III.

TABLE III.
Reduction of surfaces of oxides.

Substance.	Wt., g.	Gas used in reduction.	Vol. of gas used up at 400—450°.	Gases adsorbed on reduced surface at saturation, in c.c. at room temp.			Remarks.
				H ₂ .	CO.	O ₂ .	
ZnO, Cr ₂ O ₃	14.8	H ₂	200	3.0	1.4	9.0	Zn volatilises on reduction
ZnO	6.0	H ₂	3 c.c./hr.	V. small	0.35	—	
MnO _{1.5}	11.2	{ CO H ₂	64 243	— 0.17	2.0 —	— —	
Cr ₂ O ₃	16.1	CO	57	V. small	32.3	30.0	
MnO _{1.5} , Cr ₂ O ₃ ...	19.7	CO	28	V. small	1.0	0.10	

If the surfaces are reduced stepwise, only a relatively slow change in the character of the surface occurs as the reduction proceeds. Thus with ZnO, Cr₂O₃ the reduction by 50 c.c. of hydrogen out of a total possible of 200 c.c. made no significant difference to the volume of hydrogen adsorbed or to its heat of adsorption at room temperature. A similar result also was obtained with MnO_{1.5}; the adsorption and heat of adsorption of carbon monoxide was not appreciably affected by the partial reduction of the oxide. Also, the amount of oxygen adsorbed and the heat of adsorption of oxygen on Cr₂O₃ only increases slowly as the surface is reduced. The amount of oxygen adsorbed by manganous-chromic oxide is only slightly affected by the reduction process. As oxygen is removed from the surface during the reduction, there is evidently some compensating factor which keeps the properties of the surface unchanged. This may well be the diffusion of oxygen ions from the lattice to the surface.

At room temperature the mobility of the oxygen ions within the lattice is probably very low, so that the oxide under these conditions would be expected to be a frozen form of the equilibrium set up at higher temperatures. The adsorption of hydrogen and carbon monoxide at room temperature may therefore take place on lattice irregularities caused by the establishment of equilibrium in a lattice defect structure at higher temperatures. The bearing of lattice defects on the reduction of oxides and for catalysis generally has not yet received much attention, and no researches appear to have been directed specifically to clear up this point.

Activation Energy during the Reduction of Oxides.—Carbon monoxide is adsorbed on oxide surfaces in two ways, (1) reversibly and (2) irreversibly. The first type occurs on ZnO, on ZnO, Cr₂O₃, and only to a small extent on the other oxides. On zinc oxide the heat of adsorption is 18 k.-cals. and the gas can be completely desorbed at room temperature within 20 minutes. The rate of desorption is given by $Nve^{-E/RT}$, where N = number of adsorbed molecules per cm.², v = 10^{13} as a maximum value, and E = the energy required to evaporate the molecule from the surface. Calculation shows that E is approximately the same as the heat of adsorption within a few calories. The reversible adsorption is thus not appreciably activated.

On ZnO, Cr₂O₃, both types of adsorption occur, but the passage from reversible to irreversible adsorption does not readily occur on the surface. On heating, carbon monoxide first evaporates and then condenses to give an adsorption complex from which carbon dioxide can be liberated. It is very probable, therefore, that different centres are involved in the two types of adsorption process.

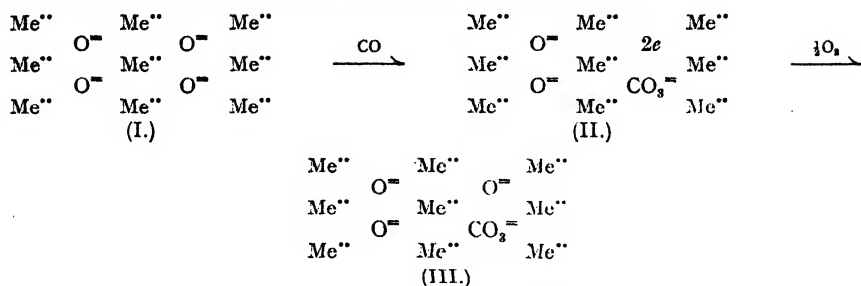

On oxides of the transition elements and their mixtures, carbon monoxide reacts with two oxygen ions or atoms on the surface to give CO₃²⁻ ions, liberating two electrons:

The surface has become unsaturated with respect to oxygen, which can be added in stoichiometric quantities, viz., $\frac{1}{2}\text{O}_2$ to each CO:

The process is shown schematically below for a bivalent metal ion.

The following qualitative picture can be given in explanation of the experimental results. The electrons set free in (II) will be held in the neighbourhood of the carbonate ion. They will possibly be accommodated in the *S* or *D* shells of the transition element,* which, together with the CO_3^{2-} ion, can form a resonating system :

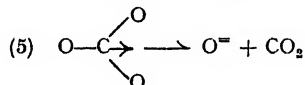

The addition of $\frac{1}{2}\text{O}_2$ in (III),

will have the effect of moving the resonating system in (3) to the right, *i.e.*, in the direction of the formation of CO_3^{2-} ion, which would explain the observation that CO_2 is evolved more readily from state (III) than from state (II).

The carbonate ion can be dissociated to give carbon dioxide. Measurements of the rates of desorption show that within a few calories the activation energy is the same as the heat of adsorption. The process of dissociation involves the displacement of the carbon atom as in (5), and the transference of the two electrons to an oxygen atom and the metal ions associated

with it in the lattice. An activation energy might be expected for this step, but it may be small,† especially if there is some choice among the levels of the *D* and *S* shells of the transition element, in the formation of the bond between the oxygen ion and the surrounding metal ions. If there is a broad band of electronic levels in the shells of the transition element, which are suitably placed with respect to the levels of the oxygen and carbonate ions, then the electron transfer reactions (3)–(5) would be facilitated. The effectiveness of the transition metals for catalysis generally may depend on a suitable distribution of the electron levels in the catalyst.

When carbon monoxide is adsorbed reversibly on zinc oxide, the surface does not become unsaturated with respect to oxygen, and no additional oxygen can be adsorbed after carbon monoxide. This is in accord with the view that reversible and irreversible adsorption of carbon monoxide occur on different centres.

Conclusions on the Reaction of Carbon Monoxide with Oxides.—It has been demonstrated that reversible adsorption of carbon monoxide occurs on metal-rich oxides with negative holes in the lattice, and irreversible adsorption on oxides defective in metal ion with positive holes. The two types of adsorption are not readily inter-convertible and probably occur on different types of centre. Reversible chemisorption may take place on sites where electrons can be donated to the adsorbed molecule, and irreversible adsorption on sites which can abstract electrons from the molecule. The reversible adsorption is not appreciably "activated".

It is suggested that the resonating system $\text{CO} + 2\text{O}^- + 2\text{Me}'' \rightleftharpoons \text{CO}_3^{2-} + 2\text{Me}''$ may play an important part in the irreversible adsorption. The carbon monoxide is held in an intermediate state on the way to a CO_3^{2-} ion. This system will move to the right if the number of unpaired electrons in the shells of the metal ion is increased, so that the extent to which the

* The transition elements are most effective as catalysts when their magnetic susceptibility is highest, indicating that the unpaired electrons in the *D* shell play an important part in heterogeneous catalysis (Hüttig, *J. Amer. Chem. Soc.*, 1935, **57**, 2470; Hofer, Peebles, and Dieter, *ibid.*, 1946, **68**, 1953; Selwood, Hill, and Boardman, *ibid.*, p. 2055).

† I am indebted to Dr. F. C. Frank for this suggestion.

carbonate ion is formed can be increased by the adsorption of oxygen simultaneously with carbon monoxide, $\frac{1}{2}\text{O}_2 + 2\text{Me}^+ \longrightarrow \text{O}^{2-} + 2\text{Me}^+$. This is in accord with the fact that the carbonate ion is more readily dissociated when the surface is saturated with oxygen.

The dissociation of the carbonate ion has been shown to possess an activation energy approximately equal to the heat of adsorption of carbon dioxide, so that the formation of carbonate ions from carbon dioxide requires no appreciable activation energy. In explanation of this fact, it is suggested that the activation energy for the dissociation may be small if the electronic levels of the shells of the metal ions lie in a broad band which is suitably placed with respect to the electronic levels of the oxygen and carbonate ions.

I am indebted to Imperial Chemical Industries Ltd. for a grant for the purchase of apparatus used in these researches.

235. Heat of Adsorption of Gases on Manganous-Chromic Oxide at Room Temperature.

By T. WARD.

Measurements have been made of the heats of adsorption of carbon monoxide, carbon dioxide, and oxygen. Carbon monoxide is irreversibly adsorbed, giving carbon dioxide on rise of temperature. The surface, after the addition of carbon monoxide, is unsaturated with respect to oxygen. The evolution of carbon dioxide is facilitated after the unsaturation has been removed, and carbon dioxide can be desorbed with a heat of desorption equal to the heat of adsorption of carbon dioxide. The adsorption of carbon dioxide is not "activated".

This investigation is a continuation of a series of experiments on the heats of adsorption of carbon monoxide, carbon dioxide, oxygen, and hydrogen on the metallic oxides, ZnO , $\text{MnO}_{1.5}$, and Cr_2O_3 , and the changes in adsorptive properties that occur on mixing two of the oxides (Garner and Veal, *J.*, 1935, 1436, 1487; Garner and Kingman, *Trans. Faraday Soc.*, 1931, 27, 322; Dowden and Garner, *J.*, 1939, 894; Garner and Ward, *ibid.*, p. 858). In the present work, a study has been made of the heats of adsorption of the above gases on the fully oxidised, reduced, and partly reduced surfaces of manganous-chromic oxide. Particular attention has been paid to the formation of carbonates from carbon monoxide and oxygen, and from carbon dioxide.

Although the properties of Cr_2O_3 and MnO_2 as promoters are well known, little attention appears to have been paid to the study of adsorption on the mixed oxides. Taylor and Williamson (*J. Amer. Chem. Soc.*, 1931, 53, 2168) have shown that over the range -78.5° to 144° there are two forms of adsorption of hydrogen and carbon monoxide. At -78.5° hydrogen was adsorbed molecularly with a heat of 1.9 k.-cals./mol., as calculated from adsorption isotherms. At $300-400^\circ$, the heat of adsorption of hydrogen was ~ 20 k.-cals. Only qualitative results were obtained with carbon monoxide.

EXPERIMENTAL.

Preparation of the Oxide.—Manganous ammonium chromate was prepared by the method of Taylor and Williamson (*loc. cit.*) by the interaction of manganous nitrate and ammonium chromate, the solution being titrated until just neutral with ammonia and then filtered. The precipitate was washed thoroughly with ammonium nitrate solution, then with distilled water, and finally dried. It was now oxidised at 400° in a stream of oxygen for 48 hrs., a black amorphous powder being formed. The powder was unsuitable for use in the type of calorimeter employed; hence, it was pressed into small tablets by means of a pastel press, these tablets being then cut into squares 0.1 mm. in size. It was finally treated *in situ* with oxygen at 400° . No information concerning the X-ray structure of the spinel could be obtained.

Specific Heat of the Oxide.—This was determined by the method employed by Garner and Randall (*J.*, 1924, 125, 881). The average value for the determination was 0.166 cal./deg.

Calorimeter.—This was of the type 1f (Garner and Veal, *loc. cit.*), but with the slight alterations mentioned by Garner and Ward (*loc. cit.*), where the details of the method of measurement are given. The weights of the materials used were, platinum 1.6506 g., Pyrex 2.4023 g., oxide 19.680 g., and the specific heats 0.0314, 0.20, and 0.166 cal./deg. respectively. These values gave a water equivalent of the calorimeter of 3.800 cal./deg.

The calibration of the calorimeter was carried out by noting the change in temperature by a standardised Beckmann thermometer when the temperature of the calorimeter fluid was altered by the addition of either ice or hot water, and at the same time recording photographically the e.m.f. of the thermocouple on a Z.c. Kipp and Zonen galvanometer. The sensitivity was 15 cm. per degree.

A preliminary series of experiments showed that the heat conductance of the catalyst was good; the admission of helium as a diluting gas and the mixing of the oxide with gold wire (Garner and Dowden, *loc. cit.*) were therefore unnecessary. The cooling correction was determined after saturating the oxide with oxygen, carbon dioxide, etc., at pressures of 10^{-4} – 10^{-2} cm., allowing the system to come to equilibrium, and then reducing the temperature of the calorimeter by 1° or 2° . The change in e.m.f. of the thermocouple was recorded, and the loss of temperature per minute for a difference of temperature of 1° between the calorimetric fluid and the thermocouple was obtained for every minute up to the 20th. The values obtained were, 1–8 mins., 0.020° ; 6–10 mins., 0.018° ; 10–15 mins., 0.016° ; 15–20 mins., 0.015° . These values were independent of the gas used, and held over a range of pressures from hard vacuum to 10^{-2} cm. In the following experiments the pressure was not allowed to rise above 10^{-2} cm.

There was no drift with time in the values of the heats of adsorption, except in a few experiments where slow reactions occurred, showing that a uniform distribution of gas was attained throughout the calorimeter.

For most of the work the oxide was reduced by carbon monoxide at 400° . Hydrogen was not employed in the reduction until the end of the experiments, in order to avoid contamination of the solid with hydrogen in the initial experiments.

Adsorption of Oxygen.—28 c.c. of carbon monoxide were required to reduce the surface, and beyond this point the reduction was so slow as to be noticeable only after several days. The extent of the reduction was determined by freezing out and measuring the volume of the carbon dioxide formed. The results for the heats of adsorption on the oxidised, reduced, and partly reduced surface are given below. The last value was obtained on a surface reduced with hydrogen. The partly reduced surface gave lower values for the heat of adsorption than either the fully oxidised or the fully reduced surface.

Reduction of surface (c.c. of CO).	Oxygen adsorbed (c.c.).	Heat of adsorption (k.-cals.).	Reduction of surface (c.c. of CO).	Oxygen adsorbed (c.c.).	Heat of adsorption (k.-cals.).
0	0.2	22 *	18	0.03	— 4.6 †
4	0.045	— 6.6 †	28	0.09	+19.1
8	0.10	— 6.0 †	30 (H ₂)	0.08	+52

* After oxidation at 400° .

† The adsorption on the partially reduced surface was abnormal. The galvanometer showed an immediate absorption of heat, recorded above, followed by a slow positive evolution. The negative values were not due to the presence of temperature gradients in the oxide, since the addition of helium before the experiments gave no change in temperature.

Adsorption of Carbon Dioxide.—The oxidised surface adsorbed 1.8 c.c. of carbon dioxide at a pressure of 10^{-2} cm. For the measurements of heats of adsorption, the gas was admitted 0.6 c.c. at a time and a heat of 20 k.-cals. was obtained for the first admission and 14 k.-cals. for the second. All of the gas could be desorbed on evacuation at room temperature, and the heat of desorption after the first admission gave 19 k.-cals. The rate of desorption was measured, and the Polanyi-Wigner equation, $\text{rate} = N\nu e^{-Q/RT}$, applied, the symbols are as defined in the preceding paper. If Q is calculated from the rate, a value of 22 k.-cals. is obtained for the heat of desorption. On the fully reduced surface the heat of adsorption of carbon dioxide was lower: 0.5 c.c. gave 14 k.-cals. The heat of desorption of this gas was 13 k.-cals. These results show that very little activation energy is needed for the adsorption of carbon dioxide, in agreement with the majority of the results in previous papers.

Adsorption of Hydrogen.—No hydrogen could be adsorbed on the oxidised or reduced surfaces at room temperature, although at 400° the catalyst could be readily reduced. Neither was there any appreciable adsorption of hydrogen when the gas was mixed with oxygen. This is in agreement with the experiments of Taylor and Williamson (*loc. cit.*), who did not obtain appreciable "activated" adsorption of hydrogen below 100° .

Adsorption of Carbon Monoxide, followed by Oxygen.—The carbon monoxide was adsorbed on the oxidised surface, and oxygen admitted subsequently to the same surface. The quantity of oxygen adsorbed was always less than the stoichiometric proportion given by the ratio $\text{CO} : \frac{1}{2}\text{O}_2$. Three series were carried out:

Gas.	C.c. adsorbed.	Heat of adsorption (k.-cals.).	Total (k.-cals.).	Gas.	C.c. adsorbed.	Heat of adsorption (k.-cals.).	Total (k.-cals.).
CO	0.602	46 }	85	CO	0.682	48 }	80
O ₂	0.132	78 }		O ₂	0.168	64 }	
CO	0.546	45 }	83				
O ₂	0.113	76 }					

Carbon monoxide could not be desorbed from the oxide at room temperature until the oxygen had been adsorbed, whereupon it could be completely desorbed as carbon dioxide with a heat of 22 k.-cals. This is the same as the heat of adsorption of carbon dioxide on the oxide surface, so that it is clear that the same adsorption state has been reached from carbon monoxide and oxygen as was obtained with carbon dioxide.

If the surface was saturated previously with 1.81 c.c. of carbon monoxide, only about 0.19 c.c. of oxygen was adsorbed, with a heat of 76 k.-cals., which was the same as that given in the above table, but in this case the heat was liberated slowly and was not completely evolved until 20 mins. had elapsed. This indicates that adsorbed oxygen is undergoing a slow reaction with the surface. On desorption, the carbon dioxide was evolved at room temperature with a heat of 20 k.-cals.

A mixture of $\text{CO} + \frac{1}{2}\text{O}_2$ was admitted to the oxidised surface (0.4 and 0.8 c.c. respectively) and completely adsorbed. A heat of 85 k.-cals. was liberated, which is in agreement with the total heat

1246 *Heat of Adsorption of Gases on Manganous-Chromic Oxide, etc.*

in the above table. The heat of desorption of carbon dioxide in this case was 18 k.-cals., which is within a few calories the same as the heat of adsorption of carbon dioxide.

On the surface reduced with 28 c.c. of carbon monoxide, carbon monoxide was adsorbed with a heat of 33 k.-cals. (0.7 c.c. adsorbed).

DISCUSSION.

The measurements of the heats of adsorption on the mixed oxide, $\text{MnO}_{1.5}\text{Cr}_2\text{O}_3$, and the two oxides separately do not bring to light any phenomena which might be said to characterise promoter action. The research has only been concerned with measurements at one temperature. For the study of promoter action, measurements need to be made over a range of temperatures, in order to cover adequately the range at which chemisorption occurs. At room temperature, the slight adsorption of hydrogen on the separate oxides, and negligible adsorption on the mixed oxides, make it impossible to obtain much information about promoter action in so far as the adsorption of hydrogen is concerned.

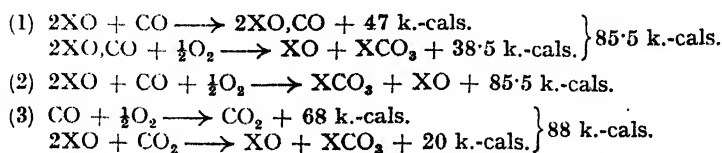

It has become evident as the work proceeded that measurements were giving information on the reduction of oxides by hydrogen and carbon monoxide. This aspect of the results will be dealt with in a separate communication. This discussion will be limited to aspects more specifically derived from the results in the present paper.

It is a striking fact that, for both manganous oxide and manganous-chromic oxide, the reduction of the surface at 400° does not materially increase the quantities of oxygen which can be taken up at room temperature. This is in marked contrast with the behaviour of ZnO , Cr_2O_3 and Cr_2O_3 , where there is an increase on reduction of the quantities of oxygen adsorbed. These differences in behaviour are very probably due to differences in the mobility of the constituents of the lattice at the temperature at which the reduction is carried out. Too little is known about these movements in the case of these oxides to warrant an attempt at a very precise interpretation. The oxides belong to the semi-conductor class for which there is an appreciable electrical conductivity due to lattice defects. A possible interpretation of the results with manganous oxide and manganous-chromic oxide is that the oxygen ions are mobile at the temperature of reduction and that the effects of reduction of these oxides are made good by the diffusion of oxygen from the lattice to the surface at which reduction occurs.

When an oxide is reduced with hydrogen, it is difficult to remove the last traces of water. These materially affect the heats of adsorption, as was pointed out previously in the paper on Cr_2O_3 . A hydrogen-reduced surface of manganous-chromic oxide gives a greater heat of adsorption of oxygen than a carbon monoxide-reduced surface. The heat obtained approaches that given when oxygen is adsorbed on a surface containing carbon monoxide. The high heat may thus be due to lattice defects caused by the presence of hydroxyl ions in the lattice.

The results obtained with carbon monoxide and carbon dioxide are perhaps of the greatest interest, since they can be interpreted unequivocally. Carbon dioxide is adsorbed on manganous oxide, manganous-chromic oxide, and chromic oxide to give carbonates without the necessity for activation energy. The heat of desorption is the same as the heat of adsorption, and the rate of desorption can be calculated from the Polanyi-Wigner equation.

When carbon monoxide is adsorbed on the oxidised surface, the product formed cannot be dissociated at room temperature, and carbon dioxide is evolved only after the temperature is raised. The surface is, however, unsaturated after the adsorption of carbon monoxide, and can take up oxygen. When the unsaturation has been removed, carbon dioxide can be desorbed by evacuation at room temperature. The same final state is produced, whether starting from carbon dioxide or from carbon monoxide, provided in the latter case that oxygen be added at the same time. This is made clear by the following data derived from the heats of adsorption:

The agreement between the heats for the three processes shows that a carbonate is produced in the reaction of carbon monoxide and oxygen with the oxide.

236. The Constitution of a By-product from the Preparation of Trichloropyrimidine from Barbituric Acid.

By F. E. KING, T. J. KING, and P. C. SPENSLEY.

The constitution of a high-boiling crystalline by-product from the reaction between barbituric acid, phosphoryl chloride, and dimethylaniline is shown by synthesis to be 4 : 6-dichloro-2-*N*-methylanilinopyrimidine and not the expected 2 : 6-dichloro-4-*N*-methyl compound.

WHEN preparing 2 : 4 : 6-trichloropyrimidine from barbituric acid by the improved method of Baddiley and Topham (*J.*, 1944, 679), using phosphoryl chloride and dimethylaniline, a crystalline by-product was isolated from the residue, after distillation of the trichloro-compound, as a fraction of b. p. 240—300°. The yield of recrystallised product averaged 5%, and it was at first believed to be a partly chlorinated barbituric acid. However, analyses indicated the structure to be that of a dichloropyrimidine containing a monomethylaniline residue, thus suggesting either 4 : 6-dichloro-2- or 2 : 6-dichloro-4-*N*-methylanilinopyrimidine as the correct constitution. The by-product was still obtained even when dimethylaniline carefully freed

from traces of the monomethyl compound was employed, and its formation is therefore similar to that of 2 : 4 : 6-tri-*N*-methylanilinopyrimidine (I) from trichloropyrimidine and dimethylaniline (Kawai and Miyoski, *Sci. Papers Inst. Phys. Chem. Res. Tokyo*, 1931, 16, 20), in which the loss of methyl chloride from an intermediate quaternary salt is involved.

Since the action of aniline on trichloropyrimidine is presumed to give 2 : 6-dichloro-4-anilinopyrimidine (Winkelmann, *J. pr. Chem.*, 1927, 115, 305), the constitution of the new pyrimidine was thought to be analogous. This supposition was, however, disproved when the condensation of monomethylaniline and trichloropyrimidine in ethanol gave the non-identical 2 : 6-dichloro-4-*N*-methylanilinopyrimidine (II). Its 2-methylanilino-isomer (III, R = Cl) was therefore synthesised from α -phenyl- α -methylguanidine and ethyl malonate in alcoholic sodium ethoxide solution, the intermediate *N*-methylanilinodihydroxypyrimidine (III, R = OH) giving on treatment with phosphoryl chloride a product indistinguishable from the substance under investigation.

By means of the phosphoryl chloride-dimethylaniline method, 4 : 6-dichloro-5-*p*-chlorobenzeneazo-2-methylpyrimidine has been prepared from the corresponding dihydroxypyrimidine (Lythgoe, Todd, and Topham, *J.*, 1944, 3151), but under similar conditions the 2 : 4 : 6-trihydroxy-5-*p*-chlorobenzeneazo-compound gave only tarry products.

EXPERIMENTAL.

2 : 6-Dichloro-4-*N*-methylanilinopyrimidine.—Methylaniline (11 g., 2 mol.) was added to a solution of trichloropyrimidine (9.2 g., 1 mol.) in ethanol (40 c.c.) at room temperature. After 3 hours the colourless product was collected and crystallised from alcohol. The *dichloromethylanilinopyrimidine* (II) separated in tiny prisms, m. p. 106—107° (Found : C, 51.7; H, 3.8; Cl, 27.8. $C_{11}H_{11}N_3Cl_2$ requires C, 52.0; H, 3.5; Cl, 27.9%).

2-*N*-Methylanilino-4 : 6-dihydroxypyrimidine.— α -Phenyl- α -methylguanidine hydrochloride (8 g.) dissolved in ethanol (20 c.c.) was added to a solution of sodium (2 g.) in ethanol (40 c.c.), and, with the addition of ethyl malonate (6.3 g.), the mixture was heated under reflux on a steam-bath for 8 hours. After standing overnight, the precipitated sodium salt was collected and treated with dilute acetic acid. Crystallisation of the product from boiling water gave the *pyrimidine* (III, R = OH) (2.5 g.) as nearly colourless flat prisms, m. p. 219° (Found : C, 60.8; H, 4.9; N, 19.5. $C_{11}H_{11}O_2N_3$ requires C, 60.8; H, 5.0; N, 19.4%).

4 : 6-Dichloro-2-*N*-methylanilinopyrimidine.—(a) The colourless distillate obtained from the residue of the trichloropyrimidine preparation was crystallised from alcohol, and the *pyrimidine* (III, R = Cl) obtained in thick rhombic plates, m. p. 92—93° (Found : C, 52.0; H, 3.6; Cl, 27.6. $C_{11}H_9O_2Cl_2$ requires C, 52.0; H, 3.5; Cl, 27.9%).

(b) The dihydroxypyrimidine (III, R = OH) (2 g.) was heated under reflux with phosphoryl chloride (6 c.c.) for 15 minutes. The liquid was then poured on ice, and the precipitated solid collected and crystallised from ethanol (Found : C, 53.4; H, 3.8%). Admixture of the product with a specimen from the trichloropyrimidine preparation did not depress its m. p. of 92°.

4 : 6-Dichloro-5-*p*-chlorobenzeneazo-2-methylpyrimidine.—A mixture of 4 : 6-dihydroxy-5-*p*-chlorobenzeneazopyrimidine (5 g.), phosphoryl chloride (6 c.c.), and dimethylaniline (3 c.c.) was warmed until the solid dissolved. The black liquid was poured on ice, and after 1 hour the resinous product was separated by decantation and triturated with alcohol. Crystallisation of the orange solid (2.9 g.,

47%) from ethanol afforded the *azopyrimidine hemi-alcoholate* as clusters of bright red needles, m. p. 104° (Found: C, 44.7; H, 3.1. $C_{11}H_7N_4Cl_2 \cdot \frac{1}{2}EtOH$ requires C, 44.3; H, 3.1%).

2:4:6-Trihydroxy-5-p-chlorobenzeneazopyrimidine (cf. Lythgoe, Todd, and Topham, *loc. cit.*).—A cold aqueous solution of barbituric acid (15 g.) was treated with a solution of *p*-chlorobenzenediazonium chloride (from 15 g. of *p*-chloroaniline) in excess of concentrated hydrochloric acid. The solid which separated on basification with sodium hydrogen carbonate was collected, washed, and dried at 100° ; the very sparingly soluble *azopyrimidine* crystallised from cyclohexanone in minute yellow needles, m. p. 300° (Found: C, 45.0; H, 2.7. $C_{10}H_7O_3N_4Cl$ requires C, 44.9; H, 2.6%). The action of phosphoryl chloride-dimethylaniline on the azo-derivative gave an uncrystallisable resin.

237. Spectroscopic Studies of the Amide Linkage.

By R. E. RICHARDS and H. W. THOMPSON.

The infra-red absorption spectra of a number of simple and substituted amides have been measured between 2 and 15μ . The regions of particular interest are $5-7\mu$ and 3μ , where absorption bands characteristic of the amide grouping occur. There are significant alterations in the spectra according to the state of aggregation in which the substance is measured, and these have an important bearing upon the interpretation of the results. A satisfactory explanation of the positions and shifts of the bands has been given. It is concluded that the amides exist predominantly in the ketonic form, which associates in the solid state through N-H...O bridges. The results provide a basis for more detailed studies on complex amides, amino-acids, and peptides.

THE correlation of the infra-red absorption spectra of simple molecules with the presence of particular structural groups has recently made it possible to apply the method successfully in studying polymers and macro-molecules. It is natural to enquire whether information can be obtained in this way about the structure of proteins, and other compounds in which the amide linkage forms an essential part. We have already obtained some promising results with nylon 66 and its derivatives, and new experimental methods suggest fresh possibilities for the infra-red examination of proteins. Other workers have also explored the subject (Wright, *J. Biol. Chem.*, 1939, 127, 137; Buswell and Gore, *J. Physical Chem.*, 1942, 46, 575). It remains certain, however, that before any detailed understanding of these more complicated molecules is achieved, much must first be explained about the spectra of simple amides and amino-acids.

The conventional plausible structures for an amide are the keto- (I; R = H) and the enol (II; R = H) form. Each of these structures would probably be stabilized by resonance with

a dipolar form, such as (III; R = H) or (IV; R = H). Hantzsch (*Ber.*, 1931, 64, 661) measured the ultra-violet absorption spectra of amides in various solvents, and concluded that in the cases studied—trichloroacetamide and benzamide—the enolic form predominates. On the other hand, more recent X-ray measurements by Senti and Harker (*J. Amer. Chem. Soc.*, 1940, 62, 2008) show that in the solid state these molecules are associated into ring polymers, and that the occurrence of the enolic form is very unlikely. Some infra-red measurements by Buswell, Rodebush, and Roy (*ibid.*, 1938, 60, 2444), by Buswell, Downing, and Rodebush (*ibid.*, 1940, 62, 2759), and by Buswell and Gore (*J. Physical Chem.*, 1942, 46, 575) have been described, but the results are not conclusive.

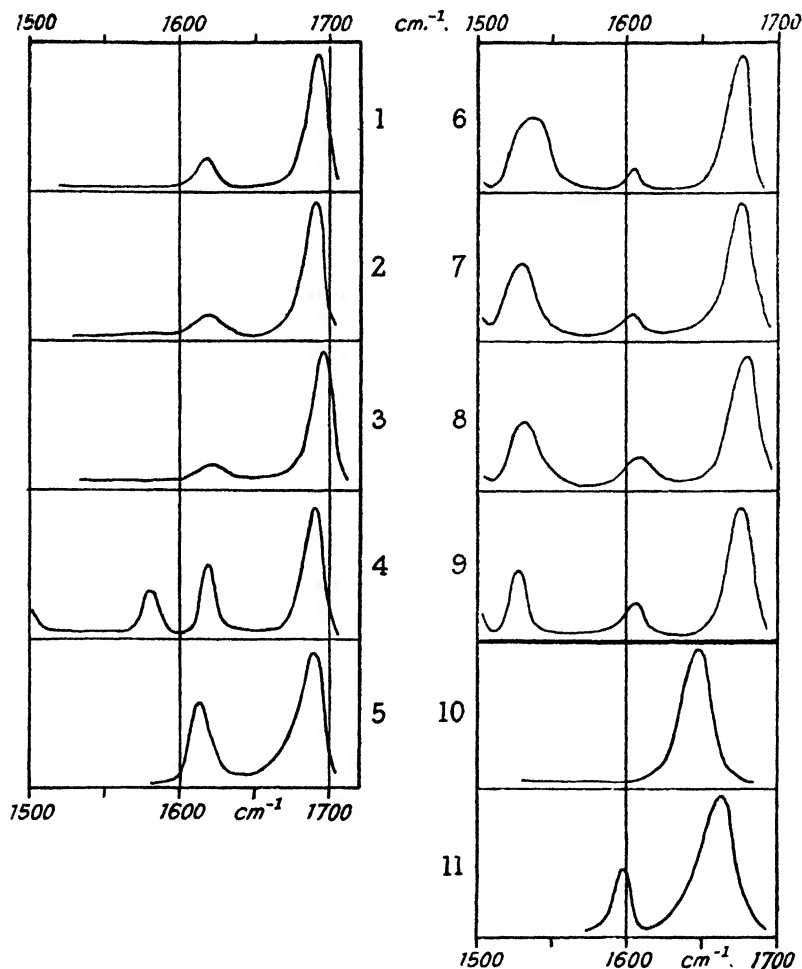

The amide grouping may be expected to have vibrational frequencies corresponding to the stretching of C=O, N-H, C-N, or O-H bonds, and also the associated bending oscillations. These several frequencies will be expected to give rise to absorption bands in the regions $5-7\mu$ and near 3μ . Absorption bands due to less localized vibrations of the molecular skeleton as a whole will for the most part lie at wave-lengths longer than 7μ , and between 7 and 14μ at least are not usually very significant for our present purpose. Results are summarised below of measurements on the spectra of a number of amides in the solid state and in solution, and interpretations are suggested in terms of the possible molecular structure.

EXPERIMENTAL.

Between 7 and 15μ the spectra were measured with a single-beam recording spectrometer using a rock-salt prism (Whiffen and Thompson, *J.*, 1945, 268). Most of the measurements considered here,

however, are for the regions $5-7\ \mu$ and $3\ \mu$, for which a large double-beam recording spectrometer with calcium fluoride prism was used (Sutherland and Thompson, *Trans. Faraday Soc.*, 1945, **41**, 174; Thompson, Whiffen, Richards, and Temple, to be published shortly). This instrument not only has the marked advantage that there is no disturbance in the region $5-7\ \mu$ from the atmospheric water vapour band, but also use is made of the greater dispersion of fluorite compared with rock-salt. Calibration of wave-lengths was obtained with the absorption lines of water, ammonia, carbon dioxide (Oetjen, Kao, and Randall, *Rev. Sci. Instr.*, 1942, **13**, 515), nitrous oxide, and other substances. At about 1700 cm^{-1} the position of bands could be measured to within $\pm 3\text{ cm}^{-1}$, and at 3000 cm^{-1} to within $\pm 8\text{ cm}^{-1}$,

depending upon the breadth of the bands concerned. In many cases where comparisons were being made to discover a general trend, the relative positions of bands of different substances were probably more accurately determined than their absolute values, since several spectra could be measured on the same chart. As indication of the resolving power of the instrument, it was possible when using it as a single-beam spectrometer to resolve clearly lines 2—3 cm^{-1} apart at 1700 cm^{-1} , and about 15 cm^{-1} apart at 3000 cm^{-1} ; with the double-beam arrangement, which necessitated somewhat wider slits, the corresponding figures were about 5 cm^{-1} and 20 cm^{-1} .

Solutions were measured in cells 0.01 and 0.2 cm. in thickness, according to the dilution used. The choice of solvent is limited by the solubilities of these compounds, and by the absorption of the solvent.

Dioxan, chloroform, methyl cyanide, and methanol were normally used, being purified in the standard manner. Amides were measured in the solid state by grinding to a fine paste with medicinal paraffin and pressing between a pair of rock-salt plates. By suitable adjustment of the size of the particles, specimens prepared in this way produce little scattering and a satisfactory spectrum can be obtained with only a few mg. of the solid.

The compounds examined were either prepared in this laboratory or obtained commercially. In all cases they were purified by recrystallisation or other appropriate methods.

Results.—Solutions in dioxan. Fig. 1 shows the spectra (1—5) of five simple unsubstituted amides in dioxan near 6μ . Any effect of this solvent on C=O or C=N groups by association or similar interactions must be negligibly small. Two bands occur in this region, a strong one near 1690 cm^{-1} and a weaker one of somewhat variable intensity at $1615\text{--}1620\text{ cm}^{-1}$. Fig. 1 also shows (6—9) some *N*-alkyl mono-substituted amides, which exhibit two bands at $1675\text{--}1680\text{ cm}^{-1}$ and $1530\text{--}1540\text{ cm}^{-1}$. In these cases the latter band is more marked in intensity than the band of the unsubstituted amides at $1615\text{--}1620$. With the two *NN*-disubstituted amides there is only one band, near 1650 cm^{-1} unless a phenyl group is one of the substituents, in which case the band lies at slightly higher frequencies. All the compounds containing a phenyl group show the well-known sharp, even if weak, bands near 1500 and 1600 cm^{-1} . These results are summarised broadly in Table I. The band at the higher frequencies will be called the A band, and that at the lower frequency the B band.

The results suggest that the band B only appears when there is at least one hydrogen atom in the amide group, and that both the bands A and B are lowered in frequency by substitution of alkyl groups on the nitrogen atom.

Fig. 2 shows the spectra of some derivatives of acetanilide in dioxan. The main feature with these compounds is that the band A lies at about 1700 cm^{-1} , distinctly higher than with the *N*-alkyl-substituted amides. It should be noted that when the group attached to the nitrogen atom is strongly electrophilic, the frequency of this band is further raised, and although such increases of $10\text{--}15\text{ cm}^{-1}$

may be regarded as small, they are nevertheless real and regular. Conversely, we should expect electrophobic substituents to lower the frequency, and this seems to occur. As regards the band B of the acetanilides, although there is some interference in the region $1500\text{--}1550\text{ cm}^{-1}$ from bands due to the aromatic ring and other substituent groupings, there seems to be a less definite influence of the *N*-substituents upon its position.

Solutions in other solvents. Many of the amides have also been measured in chloroform and methanol, with particular reference to the position of the band A. The general behaviour found with all amides is that the frequency of this band falls in passing along the series dioxan, chloroform, methanol, and is illustrated by the examples listed in Table II.

Solids. The spectra of a number of solid amides measured as a paste in "Nujol" in the region of 6μ are shown in Fig. 3. In Fig. 4, further examples are given of *N*-monosubstituted amides in which the substituent group has either electron-attracting or electron-repelling character. The simple unsubstituted amides show two fairly close bands in the region 1620 – 1670 cm^{-1} . The *N*-alkylamides show bands at about 1580 and 1640 cm^{-1} , whereas the amides with electrophilic *N*-substituents have the second band—the band A mentioned above—at higher frequencies than 1640 cm^{-1} . The position of the band B is variable, as found with the solutions in dioxan. One solid *NN*-disubstituted amide, namely aceto-*N*-methylanilide, was examined and the position of the band A was hardly affected in

passing from solution in dioxan to the solid state. The above results are summarised broadly in Table III.

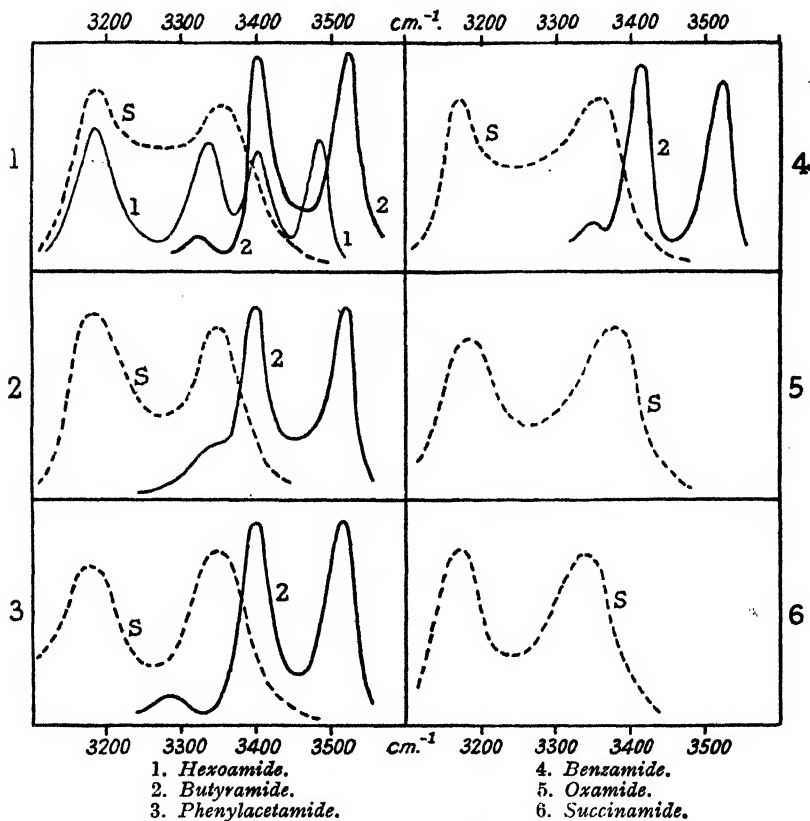

TABLE III.

Solids (R = alkyl, R_e = electrophilic group).

Approximate position (cm.⁻¹) of bands:

	A.	B.

FIG. 6.

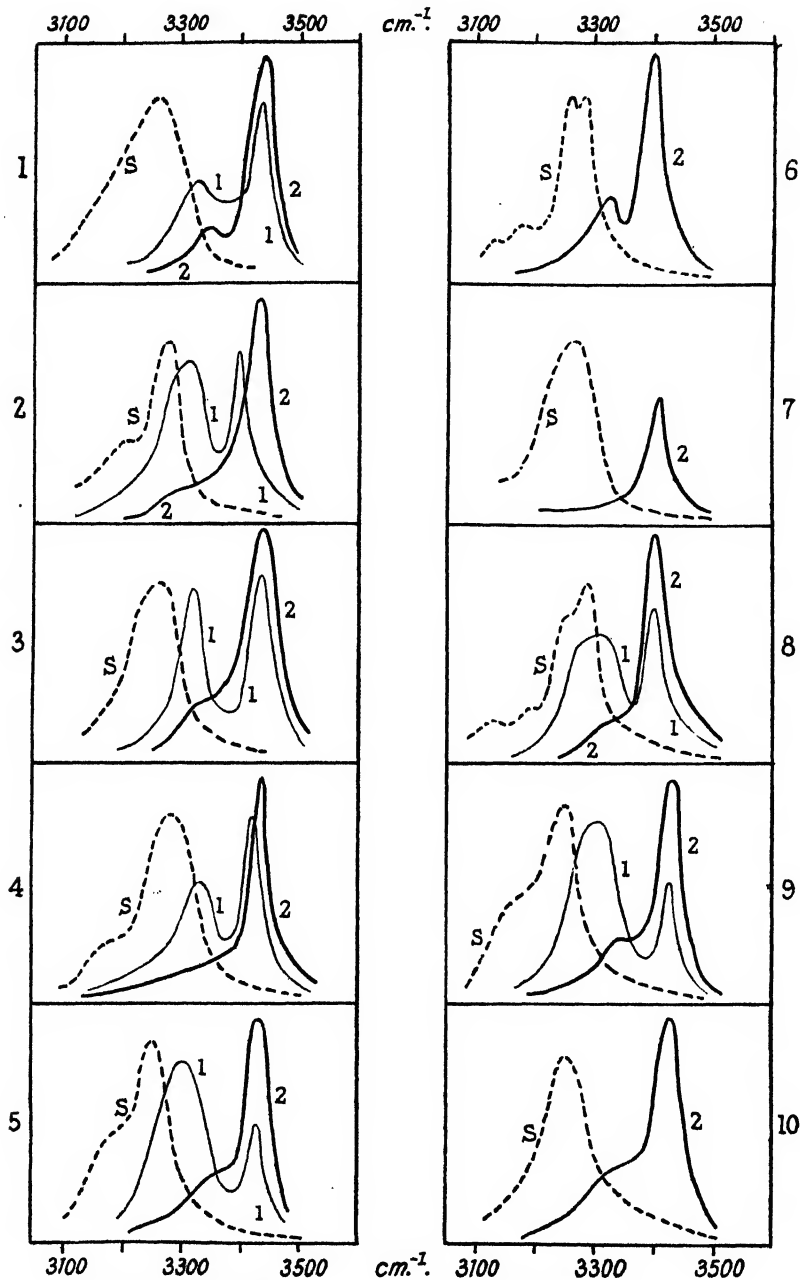

s. Solid. 1. Conc. soln. in CHCl₃. 2. Dil. soln. in CHCl₃.

It can be seen that in the solid state the unsubstituted amides show the A band at about 1655 cm.⁻¹, and the *N*-alkyl-substituted amides at about 1640 cm.⁻¹, in both cases a noticeable decrease from the values found (Table I) for the solutions in dioxan. With the *NN*-disubstituted amides, either liquid or solid, there is little change in the frequency of this band on passing from the liquid or solid to the solution, although the band may broaden. With the solid *N*-alkylamides a fairly strong band appears at about 1560 cm.⁻¹, corresponding to that at 1530 cm.⁻¹ with solutions in dioxan.

The increase in frequency of the A band of the solids when the *N*-substituent is electrophilic is parallel to the change found with the solutions. It may also be noted that when this band is raised in frequency by the electrophilic substituent, the band normally at 1560 cm.⁻¹ is generally lowered. Finally, the relative intensity of the bands A and B appears to alter with the change of state, the latter usually becoming stronger with the solid.

Gradual Transitions from Solid or Liquid to Dilute Solution.—Several examples have been examined of the changes associated with the transition from the solid or liquid amide to a very dilute solution, through intermediate concentrations of the solute. Some of the results are shown in Fig. 5 for *n*-hexoamide, phenylacetomethylamide, and methyl phenylacetamidoacetate in chloroform. Some of bands shown are connected with groups with which we are not immediately concerned; for example, that at 1750 cm.⁻¹ due to the carbonyl group of the ester. The main point to notice is that in every case the passage from the solid (or liquid) to the dilute solution brings about an increase in the frequency of the band A and a simultaneous decrease in the frequency of the band B. Thus with hexoamide, the

solid has the bands at 1655 and 1635 cm^{-1} , in concentrated solution they lie at 1668 and 1615 cm^{-1} , and in dilute solution at 1680 and 1595 cm^{-1} . With methyl phenylacetamidoacetate the solid has bands at 1642 and 1557 cm^{-1} , the liquid (at 100°) at 1660 and 1535 cm^{-1} , and the solution in chloroform at 1672 and 1517 cm^{-1} . (The band at about 1750 is due to the carbonyl link in the ester group.)

The region of 3 μ . The spectra of many unsubstituted and *N*-substituted amides have been measured between 3000 and 3600 cm^{-1} , as solids and also as solutions in chloroform. The curves are shown in Figs. 6 and 7. With substances containing phenyl radicals, there is usually a band near 3070 cm^{-1} connected with a vibration of the aromatic C-H linkages, but this is not significant for our present purpose. Dilute solutions of the unsubstituted amides appear to have two sharp bands at about 3400 and 3520 cm^{-1} , which give place in the solids to two others at about 3180 and 3350 cm^{-1} . In concentrated solutions all four bands may appear simultaneously.

In dilute solutions, the *N*-monosubstituted amides have one sharp band at about 3430 cm^{-1} which gives place in the solid to a broader band at about 3270 cm^{-1} . In concentrated solutions the latter band seems to appear at frequencies rather higher than 3270 cm^{-1} , and can be found concurrently with the sharp band near 3430 cm^{-1} .

In connexion with the possible interpretation of these bands and shifts, we have examined the spectra of diphenylamine in dilute solution in carbon tetrachloride and as a solid, and also of solutions of diphenylamine to which acetodiethylamide had been added. This experiment is a variant on that

FIG. 8.

previously described by Buswell, Downing, and Rodebush (*loc. cit.*). The results are depicted in Fig. 8. It can be seen that the dilute solution of diphenylamine has the N-H stretching vibration band at 3430 cm^{-1} , but in the solid state this is replaced by the broader association band at 3380 cm^{-1} . Similar N-H---N association has been recorded with ethyleneimine (Thompson and Harris, *J.*, 1944, 301). When the acetodiethylamide is added to the solution of diphenylamine, the band at 3430 cm^{-1} is diminished in intensity and a new band appears at 3320 cm^{-1} . This change corresponds to the formation of N-H---O bridges. As the mixture of diphenylamine and acetodiethylamide is diluted, the association band at 3320 cm^{-1} is much diminished whilst the normal N-H frequency at 3430 cm^{-1} is strengthened. This phenomenon is markedly parallel to that seen in Fig. 7 for the *N*-substituted amides.

DISCUSSION.

The results described above show that the vibration frequencies exhibited by amides are much affected by the change of state from solid to solution. It will be convenient first to consider the spectra of solutions before discussing the shifts which occur on passing to the solids.

As already stated, a simple *N*-monosubstituted amide could exist as either the ketonic (I) or the enolic (II) form, each of these being capable of hybridisation with its corresponding dipolar structure, (III) and (IV), respectively. The band A of *NN*-disubstituted amides which occurs at about 1650 cm^{-1} must be attributed to the stretching vibration of the C=O bond, since

no enolisation of the conventional type can occur. The lower value as compared with that in ketones—about 1710 cm^{-1} —will result from the resonance with the ionic form. In the case of the simple or *N*-monosubstituted amides the band A could be interpreted in the same way. In this case, however, enolisation would lead to some form of $\text{C}=\text{N}$ link, and it is well known from the Raman spectra of ketoximes that this can give rise to a band in the region $1650\text{--}1660\text{ cm}^{-1}$ (Hibben, "The Raman Effect," p. 280). Now the above measurements with the amides having a strongly electrophilic *N*-substituent provide an argument against this correlation of the band A with the vibration of a $\text{C}=\text{N}$ bond, as follows. If the amide has the ketonic form, the presence of strongly electrophilic groups on the nitrogen atom should cause the dipolar form (III) to be less stable relative to the non-polar form (I). Alternatively, the electron-attracting groups can be regarded as opposing the conjugation from the nitrogen atom to the carbonyl group, as in

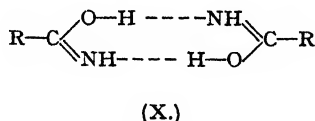

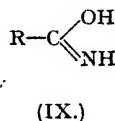

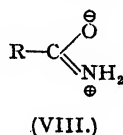

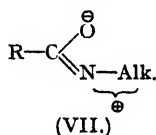

(V). In these circumstances the carbonyl group will be expected to have greater double-bond character, and a rather higher stretching-vibration frequency, which is in fact found. If the molecule existed in the enolic form, however, the converse would apply. An electrophilic substituent on the nitrogen atom would then favour the dipolar form, shown by (VI), and the double-bond character of the $\text{C}=\text{N}$ bond would be lowered.

It therefore seems satisfactory to attribute the band A in the amides as a whole to the stretching vibration of the essentially ketonic carbonyl group. In connexion with these arguments it is interesting to consider the effect of *N*-alkyl substituents upon the frequency of the band A. The results of Table I and Fig. 1 suggest that these groups have an opposite effect to those groups which are known to be electron-attracting. Now, alkyl groups are known to be readily polarisable (Ingold, *Chem. Reviews*, 1934, 15, 238), that is, they can provide or accept electrons according to the particular group to which they are attached. This is well illustrated by the values for the dipole moments of some simple compounds quoted by Watson ("Modern Theories of Organic Chemistry," 2nd edition, p. 93), and listed in Table IV. It is possible,

TABLE IV.
Dipole moments of compounds RX.

R/X =	Cl.	Br.	I.	CN.	NO ₂ .	OH.
H	1.03	0.78	0.38	2.93	—	1.84
CH ₃	1.87	1.80	1.64	3.94	3.54	1.69
C ₂ H ₅	2.05	2.01	1.87	4.04	3.68	1.69

therefore, that in the alkyl-substituted amides the fractional positive charge on the nitrogen atom is shared by the alkyl group. In other words, the energy of the charge separation in (VII)

is lower than in (VIII). In that case, the relative contribution of (VII) to the hybrid will be greater than that of (VIII), so that the carbonyl group will have less double-bond character and a lower vibration frequency in the alkyl derivatives.

The interpretation of the band B found between 1520 and 1630 cm^{-1} with the unsubstituted and *N*-monosubstituted amides is more difficult. It might be explained in four ways, namely, (i) as the stretching vibration of the C-N link in a ketonic form, if this bond has acquired considerable double-bond character due to resonance with the dipolar form; (ii) as the stretching vibration of the $\text{C}=\text{N}$ link in an enolic form, reduced in frequency by resonance with its dipolar structure; (iii) as a bending frequency of the N-H link; or (iv) as an overtone or combination band. As already explained, the band is not observed with disubstituted amides where there will certainly be contributions from the dipolar form. Also, the degree of double-bond character required to produce such a high frequency seems much greater than is plausible from the molecular bond lengths found in some solid amides such as acetamide (Senti and Harker, *loc. cit.*). These arguments make the first interpretation improbable.

The assignment of the band B to the $C=N$ link of an enolic form would imply the simultaneous existence of both ketonic and enolic forms both in solution and in the solid state. The X -ray measurements have shown, however, that in the solid state only the ketonic form is present. Further, in no case is the shift produced by the substitution of an electron-attracting group by an alkyl group consistent with this interpretation. Also, the band B increases in frequency on passing from the solution to the solid. This is contrary to what would be expected if this change were accompanied by the formation of bridged links in passing from (IX) to (X).

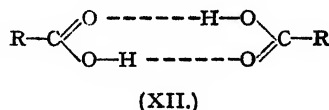

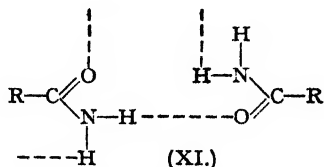

Finally, if an amide were to exist as a mixture of the ketonic and the enolic form, samples from different sources and recrystallised from different solvents would be expected to show different proportions of the two forms. In no case have such variations been detected.

The possibility that the band B is due to an overtone cannot be ruled out, but it is improbable. The band varies in intensity in different compounds, but with the N -monosubstituted derivatives it is usually stronger than might be expected for anything but a fundamental. Experiments with deuterated compounds might help to settle this question.

The third possibility seems to us the most reasonable. It explains the absence of the band in the disubstituted amides, and the shift of the band B in passing from the solid to solution—namely, a decrease in frequency—agrees with that expected of a bending mode of the $N-H$ link if the latter takes part in hydrogen bridges in the solid state. The difference between the band B in unsubstituted amides on the one hand, and N -monosubstituted amides on the other, can be explained by interaction between the two $N-H$ bonds in the former case. Hence, it seems that in dilute solution in dioxan, the amides exist predominantly in the ketonic form.

The results of Table II illustrate the effect of solvent on the stretching frequency of the carbonyl group. This may be due to two causes, namely, the difference in dielectric constant of the medium, or the effect of hydrogen bonding from the solvent to the carbonyl group of the amide. The energy of the charge separation in (VII) or (VIII) might be lowered by an increase in the dielectric constant of the medium, and the stretching frequency of the carbonyl group would then be expected to lie at lower values than in a medium of low dielectric constant. In methyl cyanide, however ($\epsilon = 37.5$), the frequency of the carbonyl group is substantially the same as in dioxan ($\epsilon = 2.2$), so this influence of dielectric constant cannot be very significant. On the other hand, solvation by hydrogen bonding to a carbonyl group lowers the frequency of the latter. With acetone in carbon tetrachloride solution, it lies at 1710 cm^{-1} , but in methyl alcohol at 1701 cm^{-1} . It is therefore possible that the changes shown in Table II are caused by a change in hydrogen bonding from the solvent to the carbonyl group.

In the solid state, the stretching frequency of the carbonyl group in an unsubstituted or N -monosubstituted amide lies at a much lower value than in dilute solution in dioxan, whilst the band B lies at higher values. Our own measurements, and those of Gordy (*J. Chem. Physics*, 1939, 7, 163) show, as just outlined, that the frequency of the carbonyl group is reduced by hydrogen bonding. Since the X -ray measurements indicate that acetamide exists in a

polymeric form (XI), it is evident that the bonding will lower the frequency of the carbonyl group. Moreover, in such polymers, the strength of the hydrogen bridges will be increased by the presence of a greater positive charge on the nitrogen atom, or a greater negative charge on the oxygen atom, and therefore by an increase in the contribution of the dipolar structure to the hybrid. It follows that in the associated form of the amides the carbonyl link will have a smaller double-bond character than in the unassociated form, and hence a lower frequency of vibration. The NN -disubstituted amides, which cannot undergo such association, show no such shifts of the frequency with change of state.

That this association has a powerful effect on the stretching vibration frequency of the carbonyl group is further borne out by our measurements on acetic acid and phenylacetic acid in the liquid and in the solid state, where the substances are known to exist as dimers of the type (XII). With liquid acetic acid the band lies at 1712 cm^{-1} , and with solid phenylacetic acid there is a double band at 1704 — 1692 cm^{-1} . A dilute solution of acetic acid in dioxan, however, shows bands at 1730 and 1753 cm^{-1} , which may correspond to the dimeric and the monomeric

form. Herman and Hofstadter (*J. Chem. Physics*, 1939, 7, 460) have similarly shown that in the vapour state the frequencies of the carbonyl group in dimeric and monomeric aliphatic acids lie at about 1740 and 1770 cm^{-1} , so the shift is about 30 cm^{-1} . In dioxan, phenylacetic acid shows one sharp band at 1735 cm^{-1} , and the shift in passing from the dimer to the monomer is therefore closely parallel to that found with amides in passing from solutions in dioxan to the solid state.

If this interpretation of the shift is correct, we might expect that in concentrated solutions of the amides, the co-existence of both unassociated and associated forms might give rise to two frequencies of the carbonyl group, and there is some evidence to support this. The curves of Fig. 5 show that the band due to the carbonyl group is broad with concentrated solutions of hexoamide and phenylaceto-*tert*.-butylamide, and there are signs of a double band. Dilute solutions of hexoamide in chloroform show three bands at 1595 (strong), 1615 (weak), and 1678 (strong and sharp), whereas with concentrated solutions the bands are at 1595 (weak), 1615 (strong), and 1668 (strong and broad). This suggests that in concentrated solutions the dimers giving rise to 1615, 1668 predominate, whilst in dilute solutions the monomer (1595, 1678) is in excess. Two amides were examined as liquids at temperatures above their melting point, and the bands A and B were displaced to positions intermediate between those found for the solids and for the solutions, and were also broad suggesting the presence of more than one species.

To sum up, therefore, the bands in the region 5–7 μ suggest that amides have the ketonic structure, resonating with its corresponding dipolar form. In dilute solution in dioxan and chloroform the amides appear to be monomeric, but in more concentrated solutions in chloroform, and in the liquid state, association occurs. In the solid state this association is complete.

In the region of 3 μ we should expect to find absorption bands due to the stretching vibration of N–H links, and of O–H links if present. In dilute solutions, the unsubstituted amides show sharp bands at about 3400 cm^{-1} and 3520 cm^{-1} , which might at once be correlated with the symmetrical and antisymmetrical vibrations of the NH_2 group in an unassociated form. On the other hand, the band at 3520 cm^{-1} might be assigned to the O–H link of an enolic form. However, the frequency due to the unassociated hydroxyl link in a large number of alcohols and phenols lies between 3610 and 3680 cm^{-1} , and with fatty acids at about 3550 cm^{-1} . We might therefore expect the unassociated hydroxyl band in an enolized amide to lie at about 3600 cm^{-1} . Only in the case of trichloroacetic acid (Buswell, Rodebush, and Roy, *J. Amer. Chem. Soc.*, 1938, 60, 2239) does this band lie at a frequency as low as 3520 cm^{-1} , and in this case the O–H link must certainly be weaker than in the amide. Hence it is unlikely that the amide band at 3520 cm^{-1} could be due to the hydroxyl group, and the explanation given at the start is to be preferred.

In very dilute solution, the *N*-monosubstituted amides show one band at 3420–3440 cm^{-1} . This low value cannot possibly be due to an enolic O–H group, and lies as expected between the two frequencies of the unsubstituted amides. *NN*-Disubstituted amides show no absorption in this region.

In the solid state, the unsubstituted amides have strong bands at about 3180 and 3350 cm^{-1} , which are plausibly interpreted as being due to two bonded N–H groups of a polymeric complex such as was indicated above. In the concentrated solutions, illustrated for hexoamide in Fig. 6, both the association bands at 3180, 3350 cm^{-1} , and the unassociated N–H bands at 3400, 3520 cm^{-1} appear simultaneously.

N-Monosubstituted amides have one band only in the solid state, at 3270 cm^{-1} , which again corresponds to a bonded N–H group. Here too, in concentrated solutions, both the association band and the "normal" band at 3430 cm^{-1} are simultaneously present. In these cases the association band appears to shift gradually towards higher frequencies and has a diminishing intensity as the dilution is increased, which would imply some gradual weakening of the bonding strength.

This interpretation of the bands of *N*-monosubstituted amides near 3 μ is supported by the measurements already described with diphenylamine and acetodiethylamide. These showed that the unbonded N–H link in diphenylamine has a frequency of 3430 cm^{-1} , and the strongly bonded N–H --- O group has a frequency of 3320 cm^{-1} . These values fall exactly into line with those for the unsubstituted amides.

It seems, therefore, that the spectroscopic data in both the regions, 3 μ and 6 μ , indicate the existence of the amides in the ketonic form, which associates through N–H --- O bonds in concentrated solutions, in the liquids and in the solids. This preliminary survey will be useful in our later consideration of the more complex amides, amino-acids, and peptides.

We thank the Government Grant Committee of the Royal Society for a grant in aid of equipment, and the Department of Scientific and Industrial Research for a Maintenance Grant to one of us. We are also pleased to record appreciation of some valuable discussions which one of us had with workers at the University of Michigan, and at the Shell Development Company, Emeryville, during 1945, on the above and related problems.

238. Vibrational Spectra of Phenolic Derivatives and Phenolic Resins.

By R. E. RICHARDS and H. W. THOMPSON.

The vibrational spectra of some substituted phenols and related compounds, and of some resins formed from phenols and aldehydes, have been examined. The possibility of formulating correlation rules for use in determining structural features of the resins has been explored. From the bands observed in the region $700\text{--}900\text{ cm}^{-1}$ it may be possible to infer the type of substitution around the aromatic nuclei in these complex molecules. The absorption of hydroxyl groups in the region $3200\text{--}3650\text{ cm}^{-1}$ reveals differences in the types of hydrogen bonds in the different compounds and suggests that differences between resins made from the same materials may be related to this particular structural feature. Some of the compounds have been measured both as solids and as liquids and spectral differences in the two states of aggregation have been found.

INFRA-RED spectroscopy has recently been used in examining compounds of high molecular weight, and some results have emerged which might not have been derivable by other methods (Thompson and Torkington, *Trans. Faraday Soc.*, 1945, **41**, 246; *Proc. Roy. Soc.*, 1945, **184**, A, 3, 21). Among other classes of compound we have studied the resins formed by condensation of phenols with aldehydes, the aim being to discover more about the mechanism of condensation and the nature of cross linkage in these structures. Whilst some empirical spectral differences between different resins were of immediate practical interest, it became clear that the only satisfactory way of understanding the spectra would be to collect results for a large number of structurally related simpler molecules from which closer correlations with molecular structure could be made. In the course of this investigation some interesting facts have emerged about the association which occurs with these hydroxylic compounds, and the nature of the hydrogen bridges which arise. Some of the results are given in the present paper.

EXPERIMENTAL.

The spectra between 6 and $15\text{ }\mu$ were measured on a single-beam recording spectrometer with rock-salt prism (Whiffen and Thompson, *J.*, 1945, 268). The measured frequencies were accurate to $\pm 5\text{ cm}^{-1}$ at $7\text{ }\mu$, and to $\pm 2\text{ cm}^{-1}$ at $15\text{ }\mu$. Between 2.5 and $6\text{ }\mu$ a double-beam recording spectrometer was used (see preceding paper). With this spectrometer, the frequencies of bands near $7\text{ }\mu$ could be determined to $\pm 3\text{ cm}^{-1}$, and at $3\text{ }\mu$ to $\pm 8\text{ cm}^{-1}$ depending upon their breadth. At $3\text{ }\mu$ it was possible to resolve bands 20 cm^{-1} apart, although when the instrument was used as a single-beam spectrometer rather better resolution was possible.

Solutions in carbon disulphide were measured in rock-salt cells about 0.1 mm. thick. Solutions in carbon tetrachloride were studied at $3\text{ }\mu$ in rock-salt cells of thickness 2 mm. , 3.5 cm. , and 7.8 cm. , according to the dilution being used. Solids were examined either by melting them and allowing them to crystallise between a pair of rock-salt plates, or by the method of a paste in paraffin used in the preceding paper. Measurements at higher temperatures were made with an electrically heated cell (Richards and Thompson, *Trans. Faraday Soc.*, 1945, **41**, 183).

Many of the phenolic derivatives were kindly supplied by Messrs. Bakelite Ltd. or by the Chemical Laboratory, Teddington. Others were commercial samples purified in this laboratory in the appropriate manner. The resins were supplied by Messrs. Bakelite Ltd. and by other firms.

RESULTS AND DISCUSSION.

Figs. 1 and 2 show the spectra between 700 and 1500 cm^{-1} ($14\text{--}6.5\text{ }\mu$) of some phenols, aromatic alcohols, and other compounds likely to have a bearing on the structure of the resins themselves. Each of the spectra is complex, and few correlations are immediately obvious. All the compounds show one or more intense bands in the region $700\text{--}870\text{ cm}^{-1}$, and these are of particular interest since it has previously been found that substituted benzenes have more or less characteristic frequencies in this range, according to the number and position of the substituents and in great measure independent of their exact nature (Thompson and Torkington, *loc. cit.*; Whiffen and Thompson, *loc. cit.*). The normal vibration of benzene in which the group of six carbon atoms moves in a rigid plane perpendicularly to the plane containing the six

hydrogen atoms has a frequency of 671 cm^{-1} . Previous results have shown that when the substituent is attached to the ring, this type of vibration, which is essentially a deformation of the remaining C-H bonds, is displaced to 740–760 cm^{-1} . With disubstituted benzenes, the corresponding vibration has a frequency which depends on the relative position of the substituents; with *o*-derivatives it usually lies at 740–760 cm^{-1} , with *m*-compounds at 770–790 cm^{-1} , and with *p*-compounds at 810–830 cm^{-1} . With tri- and tetra-substituted benzenes the corresponding deformations of the residual C-H bonds also appear to have fairly definite frequencies. The earlier work suggested for the 1:2:3-derivatives a band at 760–770 cm^{-1} , for 1:2:4-compounds a band at 800–820 cm^{-1} , and for 1:3:5-compounds at 825–860 cm^{-1} . With the 1:2:3:5- or 1:2:4:5-compounds the band lies in the region 850–880 cm^{-1} .

The present results appear in most cases to conform with these correlations. Thus, mono-substituted benzenes include:

Benzyl alcohol	745 cm^{-1}	Diphenyl ether	752 cm^{-1}
β -Phenylethyl alcohol	748 „	Diphenylmethane	735 „
Dibenzyl ether	746 „		

Typical disubstituted benzenes include the following:

<i>ortho</i> -		<i>para</i> -	
Fluorene	741 cm^{-1}	4:4'-Dihydroxydiphenylmethane ...	816 cm^{-1}
Diphenylene oxide	750 „	2:4'-Dihydroxydiphenylmethane ...	810 „
2:4'-Dihydroxydiphenylmethane	752 „	4:4'-Dihydroxydiphenylmethane ...	827 „
2:2'-Dihydroxydiphenylmethane	754 „		

Some compounds show simultaneously the mono- and di-substituted type, such as

	Mono.	<i>o</i> -Di.	<i>p</i> -Di.
<i>p</i> -Hydroxydiphenyl	755	—	830
<i>o</i> - „ „	730	754	—

Polysubstituted benzenes include the following:

3-Hydroxymethyl- <i>p</i> -cresol (1:2:4)	815 cm^{-1}
3:5-Bishydroxymethyl- <i>p</i> -cresol (1:2:3:5)	864 „
5-Hydroxymethyl- <i>o</i> -4-xyleneol (1:2:4:5) ...	856 „

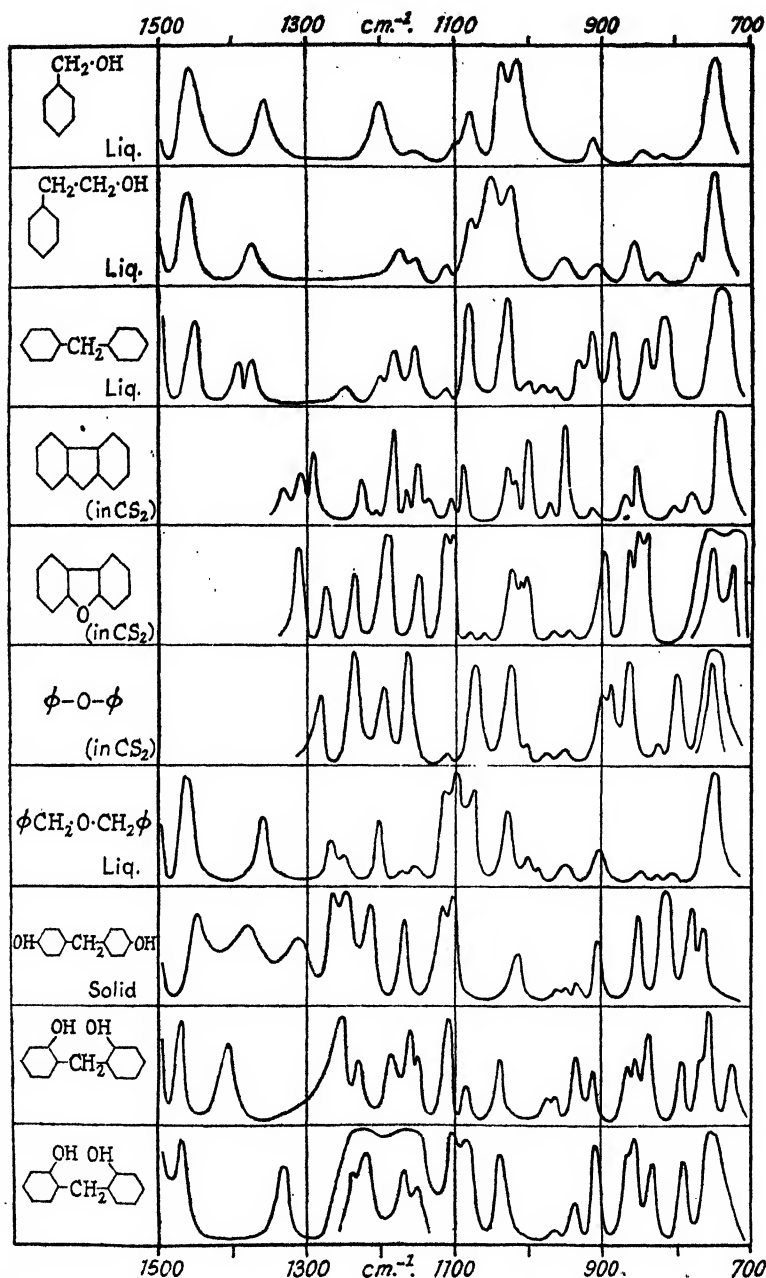

It is clear, therefore, that these correlation rules are fairly widely applicable, although it is obvious that since there are small variations within a given class there may in some cases be ambiguity and the rules must be used with caution. Also, whilst the correlations do not seem to be seriously affected by a change of state of the substance being measured, this possibility must not be excluded.

It is impossible to assign the bands between 1000 and 1500 cm^{-1} to particular normal modes, although this region will include vibrations of the groups C-O-C, C-O-H, CH₂, and CH₃, as well as of the skeleton of the aromatic rings. It is, however, apparent that in these cases the exact position of a particular band depends upon the environment of the group within the molecule. It is hoped shortly to explore this region in greater detail under higher resolving power.

Some of the substances given in Figs. 1 and 2 were measured in the solid and in the liquid state, or in solution. In some cases there are striking changes of spectrum with change of state, which have been noted already in other connexions (Thompson and Torkington, *Trans. Faraday Soc.*, 1945, 41, 260; Thompson, *Nature*, 1946, 158, 234). In order to eliminate the possibility of decomposition on melting, the procedure was to measure the spectrum of the liquid first, then to allow it to crystallise between the rock-salt plates, and then to measure the solid film again. The spectrum of this solid film was also compared with that obtained by measuring the paste formed by grinding with paraffin. The spectrum of the monoalcohol of *m*-4-xyleneol was measured at 100° and 250°, but showed no appreciable change, and other liquids showed no change of spectrum with temperature. It seems certain, therefore, that the marked changes of spectrum at the melting point must be connected with fresh influences which come into play in the arrangement of the molecules in the solid. The spectra of the solids usually show sharper bands than those of the liquids, and new bands appear which are absent with the latter. This whole problem is being examined more systematically, and a detailed consideration of the physical principles involved will therefore be deferred.

In Fig. 3 (Nos. 1, 2, 3, 4, 5) the spectra around 3 μ are shown of some simple *p*-substituted phenols in the solid state, and of dilute solutions in carbon tetrachloride. In the dilute solutions the normal sharp band of the hydroxyl group occurs at 3615 cm^{-1} . With the solids, this band

is replaced by a broader band with centre at $3200\text{--}3250\text{ cm}^{-1}$, corresponding to the "bonded" hydroxyl group. With concentrated solutions, both the normal and the "association" band may appear simultaneously. These relationships correspond to those already examined by Fox and Martin, and others.

When there is a substituent in the *o*-position to the hydroxyl group (Fig. 4, Nos. 1, 2, 3, 4) the position of the "normal" hydroxyl group band in dilute solution is again at about 3615 cm^{-1} , but the association band with the solids lies at rather higher frequencies than in the above cases of the simple *p*-substituted phenols. This implies that the screening of the hydroxyl

group by the neighbouring groups decreases the strength of the hydrogen bridges which may be formed. With diphenylcarbinol and triphenylcarbinol (Fig. 4, Nos. 7, 8) this steric influence is well marked. In these connexions *o*-hydroxydiphenyl appears to be an exception, and will be discussed below.

When there are two hydroxyl groups in the molecule (Fig. 3, Nos. 6—10; Fig. 4, Nos. 6, 9—16) the dilute solutions again show the "normal" hydroxyl band at about 3615 cm^{-1} , but in the solid state a given compound may simultaneously show several "association" bands. When there are two neighbouring hydroxyl groups (Fig. 4, Nos. 9—16) the dilute solutions

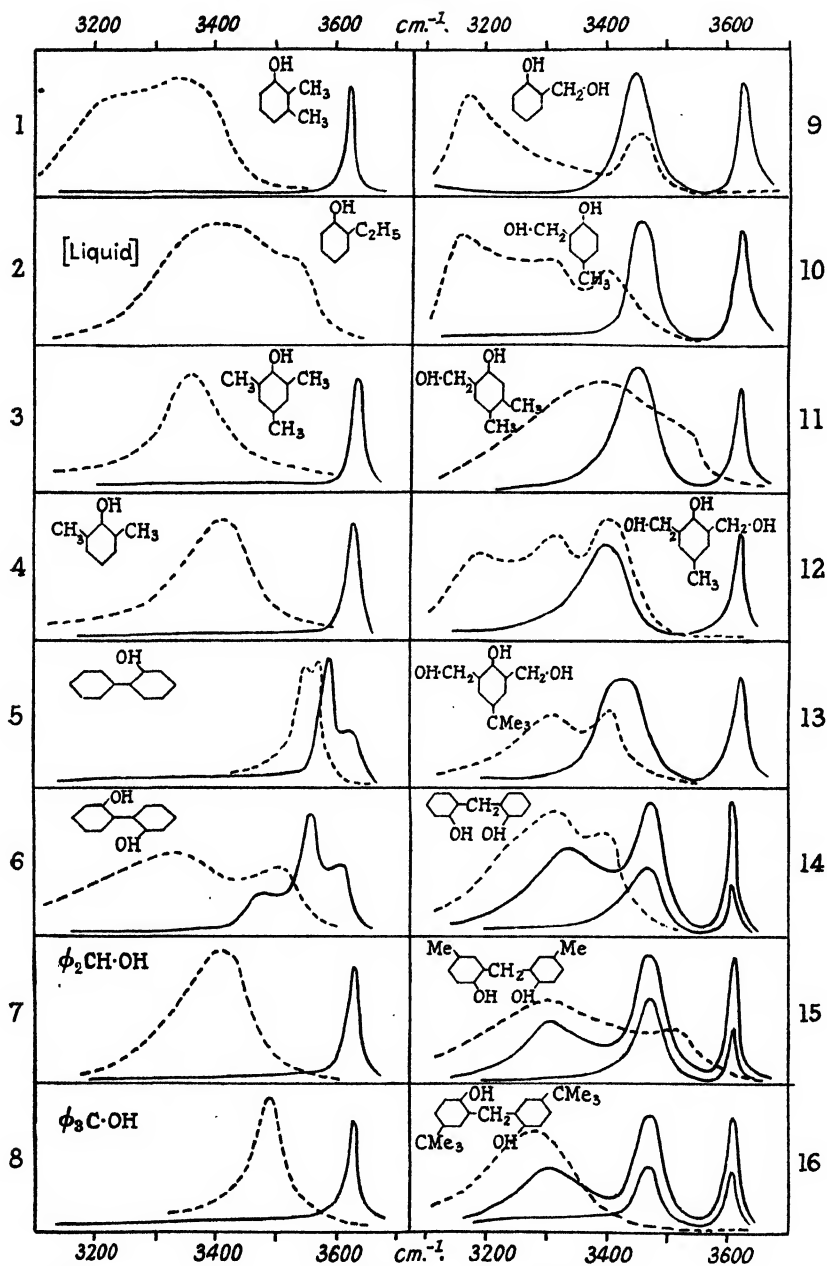

FIG. 3.

show, in addition to the normal hydroxyl band, another fairly sharp band at about 3450 cm^{-1} , which generally persists in the solid state. This band is sharper than the customary "association" bands, but behaves as if it were due to internal hydrogen bonding not markedly affected by dilution. Just as with *o*-hydroxydiphenyl already mentioned, so, too, 2,2'-dihydroxydiphenyl appears to be anomalous.

In the case of *o*-hydroxydiphenyl, a dilute solution shows the main hydroxyl band at 3590 cm^{-1} , although there is a weak shoulder in the usual position at about 3610 cm^{-1} . In the solid a close doublet appears at 3560 cm^{-1} . Reference to a scale model of the molecule suggests that the size of the OH group is such that the planes of the two aromatic rings may be slightly oblique to each other. In any case, however, the distance between the oxygen atom and the 2'-carbon atom is within the value which would allow of a hydrogen bond being formed of the

 ——— solution in CCl_4 .

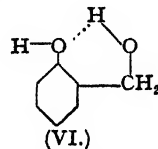

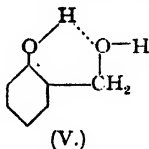

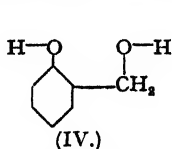

type $\text{O-H} \cdots \text{C}$. In this particular case the formation of such a bond might be assisted by the fractional charge which the 2'-carbon atoms may acquire owing to electronic displacements depicted in (I). The formation of $\text{C-H} \cdots \text{O}$ bridges has been established by infra-red and

other methods (e.g., Gordy, *J. Chem. Physics*, 1940, 8, 170; 1941, 9, 204, 215; *J. Amer. Chem. Soc.*, 1938, 60, 605; 1941, 63, 1094; Buswell, Rodebush and Roy, *ibid.*, 1938, 60, 252), and it is not unreasonable to expect $\text{O-H} \cdots \text{C}$ bonds in favourable circumstances. If there is internal bonding of this kind, it is not surprising to find only a small shift of the absorption band on passing from the solution to the solid. In this connexion, too, it is worth noting that *o*-hydroxydiphenyl melts at a much lower temperature than its *p*-isomer.

2:2'-Dihydroxydiphenyl in dilute solutions shows some similarities to *o*-hydroxydiphenyl. It may be noted that the strong band at 3560 cm^{-1} is due to internal bonding of the type $\text{O-H} \cdots \text{C}$, as in (II), the broad band at 3610 cm^{-1} to some unassociated hydroxyl groups, and the weak band at 3470 cm^{-1} to bonded hydroxyl group of the type shown in (III).

With dilute solutions of compounds containing two close hydroxyl groups, two sharp bands were found at about 3610 and 3450 cm^{-1} . The former must be due to free hydroxyl groups as in (IV). Internal bonding as in (V) or (VI) may give rise to the sharp band at 3450 cm^{-1} which is sometimes hardly affected, or only slightly displaced, on passing to the solid. In the solid state there is indication of intermolecular bonding giving broader bands at lower frequencies ($3200\text{--}3350 \text{ cm}^{-1}$), as well as the intra-molecular bonding.

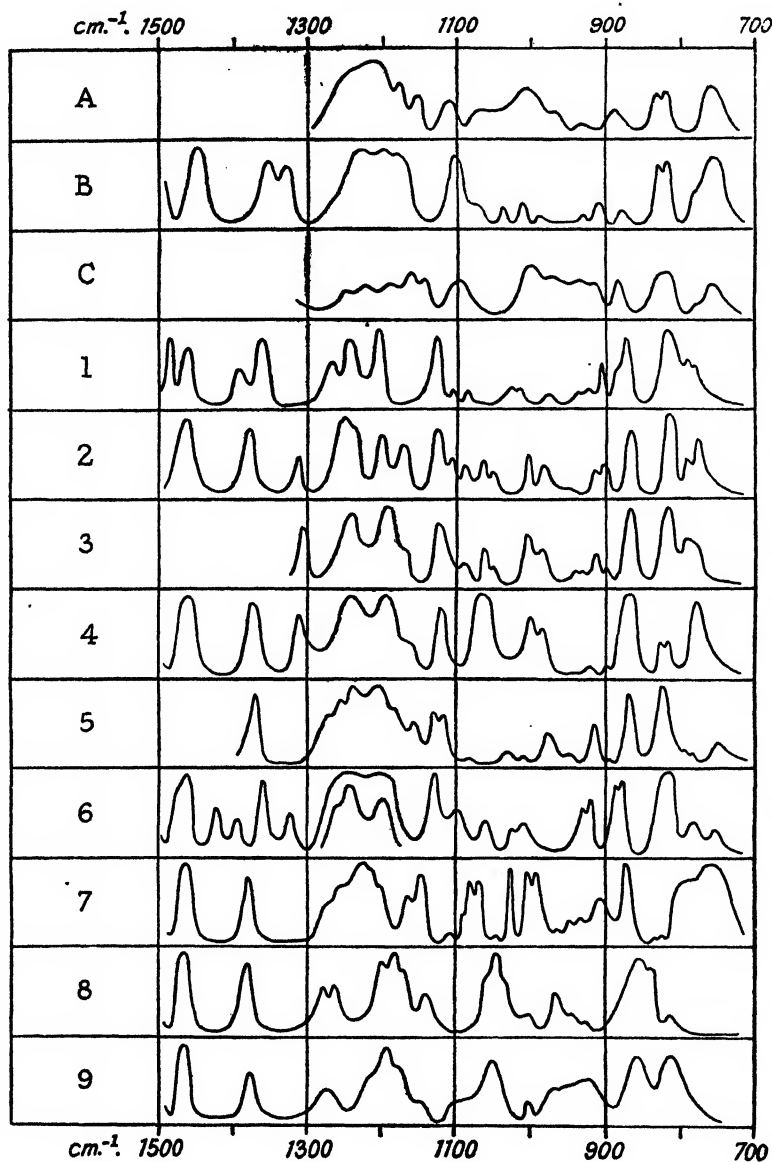

Some exploratory attempts have been made to measure the relative intensities of the bands due to the free and the bonded hydroxyl groups at different temperatures, since this should lead to a quantitative estimate of the strengths of the hydrogen bonds. The low boiling point of carbon tetrachloride makes it an unsuitable solvent, but carbon tetrabromide has been used in thickness up to 5 cm . at 3μ . The spectra of *o*-hydroxybenzyl alcohol in carbon tetrachloride at 20° , and in carbon tetrabromide at 100° , show a profound change in the relative intensities of the free and the bonded hydroxyl group bands. It is hoped shortly to extend these measurements by an improved method.

Fig. 5 shows the spectra between 700 and 1500 cm^{-1} of some resins formed by the condensation of phenols with formaldehyde or acetaldehyde at various stages of the condensation, and there are examples of pairs of resins made from the same starting materials but having different physical properties, e.g. (2) and (3) from *p*-tert.-amylphenol and formaldehyde. The samples were measured either as solid films made by melting and allowing to solidify between rock salt plates, or by grinding to a paste with "Nujol." Undoubtedly a little free phenol must have been present in some of the starting materials, and there are signs that small amounts were present in the final resins. This must be taken into account in drawing conclusions from the measurements.

Clear differences exist between the spectra of the phenol-formaldehyde resins at different stages of condensation. In particular, the two-stage fusible resin differs from the one-stage resin in having a stronger band at about 1105 cm^{-1} , and weaker absorption between 950 and 1050 cm^{-1} . The two-stage infusible resin shows the band at 880 cm^{-1} relatively more strongly, and has intense absorption between 900 and 1000 cm^{-1} . All the other resins show significant differences in the region $900\text{--}1500 \text{ cm}^{-1}$. For example, (2) and (3), novolacs of different melting point made from *p*-tert.-amylphenol and formaldehyde, differ in the region $1100\text{--}1300 \text{ cm}^{-1}$, and the resol (4) has a strong band near 1070 cm^{-1} which is probably connected with the CH_2OH group. The differences between the spectra of (8) and (9) reflect the different nature of the xylenols used in their preparation.

The spectral differences in the range 700—900 cm^{-1} are especially important, since as already explained the intense bands in this region may be associated with C-H deformations of different kinds of substituted benzene nucleus. In the one-stage phenol-formaldehyde resin the band

at 750—760 cm^{-1} will be due to *o*-substituted nuclei, and to any residual free phenol. Such *o*-substituted groups will presumably be as in (VII), the end groups of a chain, and the intensity of the band suggests that such groups are relatively so numerous that the chain length must be

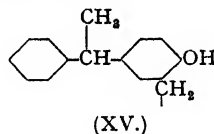

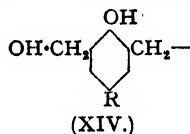

fairly short, say 4—8 aromatic nuclei. The weaker band at about 780 cm^{-1} in the two-stage resins is probably due to 1 : 2 : 3-substituted rings of the type (VIII). The bands at 815—

830 cm^{-1} probably arise from *p*-substituted rings such as (IX), or 1 : 2 : 4-substituted rings such as (X). The band at about 880 cm^{-1} may be due to tetra-substituted rings such as (XI), and it may be noted that in the two-stage infusible resin this band is strengthened, as would arise from further cross linking.

Resins (1), (2), (3), (5), and (6) all show strong bands at about 820 and 870 cm^{-1} . The latter can be correlated with tetra-substituted nuclei as in (XII), and the former with 1 : 2 : 4-substituted nuclei such as (XIII). With the resol from *p*-*tert*-amyphenol (4), the weak band at 820 cm^{-1} may arise because the end groups are of the type (XIV), rather than (XIII). The

resol from *p*- α -phenylethylphenol is peculiar in having no appreciable band near 820 cm^{-1} , and has intense absorption near 750 cm^{-1} and 790 cm^{-1} . The latter can be interpreted as arising from the monosubstituted phenyl group in (XV), and the strong shoulder at about 790 cm^{-1} from the 1 : 2 : 4-substituted rings. The xylenol resins also differ from the others in this region, as might be expected since the nuclei must in this case be either tetra- or penta-substituted.

These examples serve to illustrate how useful structural correlations can be made, but it would be premature to discuss them in greater detail until resins can be examined which have been made from purer starting materials and by controlled methods of condensation.

The resins differ, however, in one other important feature, namely, the position of the band near 3μ due to the stretching vibration of the hydroxyl group. All the solid resins show a more or less broad band due to the hydrogen-bonded hydroxyl group, but its exact position varies in the different resins between 3200 and 3550 cm^{-1} . Dilute solutions in carbon tetrachloride show a weak sharp band at about 3615 cm^{-1} due to unassociated hydroxyl groups, together with the association band found with the solids and lying in about the same position as in the latter case. The results are shown in Fig. 6. It is noteworthy that (10) and (11), both novolac resins made from *p*-*tert*-octylphenol and formaldehyde, have their bonded hydroxyl group bands at noticeably different frequencies.

The results show that in the resins there are hydrogen bridges of varying strengths. In some cases, more than one association band appears [*e.g.*, Fig. 6, Nos. (7), (1), and (2)]. This might arise from impurities in the starting materials, but is more probably due to different types of hydrogen bond within the same resin. With the exception of the weak band at 3615 cm^{-1} in dilute solutions there is a close similarity between the spectra of a solid resin and of its solution. This suggests that the majority of the hydrogen bonds may be intramolecular, which would agree with the comparatively low melting points of these particular resins, and also with the inactivity of their hydroxyl groups towards diazomethane. If this is so, one factor in the "curing" of the resins might be a change from intra- to inter-molecular association. In the final heating intramolecular bonds may be opened, and larger complexes formed by inter-molecular association. Whilst such changes may only be one factor in the "curing" process, it might cause a considerable rise of melting point and hardness quite apart from that caused by further chemical condensations. The differences in the strengths of the hydrogen bonds in the solid novolacs are to some extent paralleled by differences in their physical properties.

This was well marked in the resins (10) and (11) shown in Fig. 6. A more exhaustive and controlled survey of this question is desirable.

NOTE.

2-cycloHexenones from 2-Methylpyridines. By ARTHUR J. BIRCH.

DERIVATIVES of several methyl-2-cyclohexenones were required for comparison with those obtained from the reduction products of methylanisoles and methyldimethylanilines (J., 1944, 430; 1946, 593). Ketones of type (I; R' = alkyl) have been obtained by the cyclisation of 1:5-diketones, but for the formation of type (I, R' = H) the more difficultly accessible 1:5-keto-aldehydes are necessary (cf. Koetz and Steinhorst, *Annalen*, 1911, 379, 20). Derivatives of both kinds of dicarbonyl compound have been obtained from 1:4-dihydropyridines (Shaw, J., 1937, 300), and it has now been found that reduction

of 2-methylpyridines with sodium and alcohol in liquid ammonia followed by refluxing with acid leads to hydrolysis of the dihydropyridine and cyclisation with direct formation of the cyclohexenone.

The 2-methylpyridine (10 g.) was reduced with sodium (5 g.) and alcohol (20 c.c.) in ammonia (150 c.c.) (see Birch, J., 1946, 595), water (150 c.c.) added, the product isolated by ether extraction, and refluxed for 6 hours with sulphuric acid (*d* 1.84, 15 c.c.) and water (50 c.c.), and the solution saturated with ammonium sulphate and extracted with ether. The ether solution was dried (K₂CO₃) and the product distilled.

The yields of cyclohexenones are poor, and the method has no advantage over the standard ones for their preparation in quantity, except where the alkylpyridine is readily available and other methods are difficult, *e.g.*, 5-methyl-2-cyclohexenone from 2: 4-dimethylpyridine (cf. Koetz and Steinhorst, *loc. cit.*). For the preparation of small amounts of derivatives the method is rapid and convenient.

This work was carried out during the tenure of an I.C.I. Research Fellowship.—THE DYSON PERRINS LABORATORY, OXFORD UNIVERSITY. [Received, November 19th, 1946.]

*Address on the Occasion of the Centenary Celebration of the
Chemical Society.*

By THE PRESIDENT, PROFESSOR C. N. HINSHELWOOD, M.A., Sc.D., D.Sc., F.R.S.

THE observance of anniversaries and centenaries is dictated by a deep-seated instinct. How far this in its turn is inspired by a feeling for the magic of numbers and awe at the vast cyclical processes of Nature, I do not know, but, however that may be, these recurrent occasions for retrospect and prospect are assuredly felt to be significant and moving.

The character of the thoughts and emotions which they arouse will in some measure depend upon the attitude towards history adopted by the participants. To some, history is as a play that is ended: to others, as a chart on which they hope to read the future from the past. But to everyone, I suppose, the centenary of a scientific society must bring a message of some kind.

There are few dramas as enthralling as the struggle for the secrets of reluctant Nature, and few fields in which the future beckons so insistently as in that of scientific thought.

We are celebrating the centenary, not of a discovery, not of a person, but of a Society, and this circumstance reminds us that thoughts and inventions are in a considerable measure the products of particular historical settings. For our purpose, therefore, we cannot reflect upon the history of chemistry in the past century in England, or speculate upon its probable future, except in relation to the people who made it and are making it, and to the general conditions of their lives.

Not only does the pious memory of our Founders, benefactors, and predecessors (both the recognised and the unrecognised great men) bid us consider the human as well as the purely intellectual story, but it is doubtful whether any other approach would be more than an abstraction with the limited validity which abstractions have.

You see what deep philosophical questions are raised by the major theme: the relation of the scientific and the humane; the nature of history and the possibility of extrapolation and prediction; piety towards the past, expectations from and duties toward the future. I feel called upon to remind you of these themes, even though I cannot possibly do justice to them.

The Chemical Society was founded in the year 1841. The England in which it came into being stood on the threshold of one of its greatest eras of expansion, but no one at the time could know of this, and to many the prospect must have appeared sombre and even fuller of uncertainties than that which confronts us today. The dislocations caused by the Industrial Revolution were all too obvious, but the fruits of progress were still to be gathered. The lot of the impoverished manual workers was wretched in the extreme, the scandals of child labour in coal mines, potteries, and other industries were coming to light, but the Factory Acts were not yet passed, the agitation and distress connected with the Corn Laws coloured the political scene, and the demand of workers for a better mode of life expressed itself in the Chartist movement and broke forth into riots which to many people suggested that society was on the verge of revolution and disruption.

Queen Victoria was on the throne, but the splendours of her era were yet to be, and the great movements of her time would only have been discernible to those of unusual penetration. The worst social conditions depicted in the writings of Dickens still prevailed.

There was nothing in the obvious character of the time to announce a period of intellectual flowering, and yet it was just then that many learned societies, including our own, came into being. Scientific studies in England were hardly in any clear way the product of their age, and sprang more from the learned curiosity of amateurs than from the conscious needs of society. There were practically no laboratories for chemical research, and little or no University instruction in chemistry.

The chemical stage was set as follows. In 1841, the time which had elapsed since the "chemical revolution" of Lavoisier was almost exactly equal to that from the discovery of radioactivity to the present day. Chemistry as a science was then as old as is now the new nuclear alchemy upon which we believe the future so largely to depend. It is difficult today for a scientifically educated person to realise how profound was the change of thought which followed the publication of the Lavoisier treatise. It represented a complete philosophical re-orientation of ideas on the nature of substance. Two Englishmen in very different ways had played parts of the first magnitude. Priestley, whose house was wrecked by a mob, had made the discovery which opened the way for Lavoisier, and Dalton, living in an obscurity which astonished his foreign visitors, had formulated the theory upon which all future development was to depend.

Between the time of Dalton and the foundation of the Chemical Society the great forward sweep of organic chemistry had begun, but in this the English school had played little part, as was explicable in a country which tended to produce a few of the finest flowers of science, art, and literature without any very vigorous general growth of leaf and root. At the moment of our foundation Dalton was still alive, but Liebig, who visited England at about this time, found little in the world of chemistry to inspire him. Yet Faraday was at the height of his powers and his great work on the laws of electrolytic action was already accomplished. Its full implications were far from obvious to his contemporaries, and indeed the confusions which Avogadro's paper of 1811 might have cleared away still clouded chemistry. On the Continent the great battle between the rival interpretations of the structure of organic compounds was at its height.

At about this time much was being done in England to lay the foundations of physical chemistry, not only by Faraday with his work on the liquefaction of gases and on electro-chemistry, but also by the original and versatile Thomas Graham, first President of the Chemical Society.

Such was the chemical scene at the time of our foundation.

Let us now, after the manner of the dramatist, raise the curtain at successive intervals of a generation and see what transformations have been brought about.

1861, twenty years after the foundation, was, as it happens, the year of Prince Albert's death and of the outbreak of the American Civil War. The early dislocations caused by the Industrial Revolution were now largely righted, the conditions of labour had improved, steamships and railways were in rapid development, the era of prosperity symbolised by the Great Exhibition of 1851 was well launched, and the great intellectual movements of the Victorian age were under way. Herbert Spencer's advocacy of scientific education sought to justify in theory what the foundation of the College of Chemistry in 1847, Owens College, Manchester, in 1851, and the Oxford laboratories in 1861 were gradually implementing in practice. "The Origin of Species" had appeared in 1859, and the materialist trend of thought was evident. Chemistry had seen two decades of steady progress but had been on the whole unshaken by revolutionary changes. Cannizzaro's paper of 1858 had removed one of the major obscurities, and Frankland and Kekulé had placed structural chemistry on a firm foundation. In this country Hofmann, Mansfield, Williamson, and Frankland are seen among the outstanding figures of the period. Chemistry in England was still mainly the affair of the amateur. Indeed, in 1867 the only technical education in Leeds with its quarter of a million inhabitants was provided by one teacher who worked in a cellar and held a class in chemistry, receiving a grant of £11 a year for the purpose. Nevertheless the *Journal of the Chemical Society* from its early years had attracted contributions from the eminent chemists of the Continent, and the names of Liebig and Bunsen are in evidence.

Another twenty years pass and many momentous changes have occurred. The historical background shows political democracy in England in full stride with widened franchise and a sweeping increase in general literacy: it shows the decline of agriculture in its most disastrous phase, and the British primacy in the manufacturing export trade just about to decline from its height. The early signs of major world troubles are already discernible: the rank weeds of bureaucracy are breaking through the soil, and since 1870 the world has learnt from Prussia that war on the national scale has possibilities hitherto unexploited. The curse of conscription already lies on Europe. Disraeli has died, and Karl Marx lives in London. In some respects the Victorian age has passed its zenith, and some of the brightest stars have set: Dickens, Mill, and Clark Maxwell are gone, and Darwin's work is over. Although there have been important events such as the founding of the Cavendish laboratory in 1871, the position of scientific studies in the Universities is still feeble, and even now the great discoveries and inventions continue to come from men who are self-taught and have received little formal training.

Some of the great trends of chemistry are reflected in our *Journal*. One of the most splendid phenomena had been the flowering of the great tree of organic chemistry. To this science the contribution of England was honourable but limited. At the time in question the great name of Perkin appears currently, first the father, then the son. The science of physical chemistry is well launched, and perhaps the papers of Harcourt and Esson on the "Course of Chemical Change" are among the most characteristic of the contributions from this country. We must note the immense clarification which chemistry had by now received from the Periodic Law, observing with satisfaction that Newlands had done so much to initiate this by a paper read to the Chemical Society in 1866, but with regret that this paper was never published.

The *Journal* of the year 1881 is interesting. Boron hydride is described, while experiments on the synthesis of ammonia and discussions of absorption spectra show the approach of modern

times. But one publication above all shines like a beacon. This is the great Faraday lecture of Helmholtz, where for the first time the full implications of Faraday's laws are revealed and the way is opened for the whole modern electronic theory.

As an example of the delay which may attend the exploitation of valuable discoveries a passage in the Presidential Address of Roscoe in this year speaks for itself. "The researches of Captain Abney have been continued with conspicuous success, and have given birth to a discovery of the highest interest and of the greatest possible promise. This is no less than a distinct physical test of the existence in organic compounds of the organic radicals, and a means of recognising the chemical structure of an organic compound by means of the spectroscope. This result, which naturally opens out an entirely new field for investigation, and effects for the organic metals that which ordinary high temperature spectrum analysis does for the inorganic metals, is accomplished by photographing the absorption spectra of organic compounds in the infra-red part of the spectrum. In these invisible portions, characteristic and distinct absorption lines and bands occur for each organic radical. . . . This investigation is still in its infancy, but one of greater importance to chemists has seldom, if ever, been communicated to the Society."

The next scene presents a mottled picture of sun and shade. In 1901 the death of Queen Victoria symbolised the end of an epoch. It was a time of intellectual and social unrest and uncertainty: agriculture had collapsed, industrial struggles had acquired a new bitterness, the tide of the new popular journalism was rising in a strong flood, and the administrative machinery of the country was elaborated beyond what had ever been known. Some trade prosperity and the residues of a romantic imperialism imparted their diverse glammers, and a brilliant Court was about to lend an appearance of solidity to an age which the first German War was destined to bring to a catastrophic end.

By this time the health of chemistry in Britain was much more robust, and schools of research were gradually coming into being in many of the Universities. Tilden in 1904 told the Chemical Society that he considered the science to be flourishing. A glance at the *Journal* of 1901 certainly shows a great variety of activities, which range over investigations on alkaloids, bacterial actions, optically active nitrogen compounds, absorption spectra, and the synthesis of methane. A paper by Lapworth marks the beginning of that detailed interpretation of the inner mechanism of reactions which has been one of the great British contributions to organic chemistry in the present century. It is indeed appropriate that the Faraday lecture to be given during the present celebrations is devoted to the exposition of this powerful theme.

Radioactivity had been discovered in 1896 by Becquerel, and in 1902 the first of Rutherford's great contributions makes its appearance in the *Journal*. A measure of the excitement of the times is conveyed by the words at the end of the second contribution of Rutherford and Soddy:

"Nothing can yet be stated of the mechanism of the changes involved, but whatever view is ultimately adopted it seems not unreasonable to hope that radioactivity affords the means of obtaining information of processes occurring within the chemical atom."

The transformation by 1921 was colossal indeed in every aspect of life: profound political changes, an unprecedented degree of mechanism, and all the febrile aftermath of what then counted as the greatest war in history. People were more conscious than ever before of international and economic problems. The scene shifts from a national stage to a world stage.

The war of 1914—1918 had brought profound changes to British chemistry. It has often been called the chemist's war. Unprecedented needs of explosives, chemical warfare agents, and other products of industry had forced an improvised expansion, which, by a fortunate dispensation of providence, gradually merged into an orderly and continued evolution. In the following decade there is a history, which may be followed with a degree of sober satisfaction, of the creation of a new chemical industry, of the expansion of University research, of the founding of research institutes, and, not least, of the establishment of the most excellent relations between industrial and academic chemistry. These are one of the happiest auguries for our uncertain future.

Taking a glance at some of the subjects represented in the *Journal* of 1921, we find, in the first place, papers belonging to the aftermath of the chemist's war: on explosives and mustard gas, and on the sorption of gases: we are reminded of a major revolution in science by Aston's lecture on mass spectra. On the physical side, colloidal electrolytes, heterogeneous catalysis, and photochemistry are coming into prominence, and Brönsted's paper on salt effects typifies not only the transition from the older to the newer theories of solution, but also the abiding international character of our chemical literature. On the organic side, Perkin's papers on the

alkaloids, harmine and harmaline, belong to the culmination of one great tradition in organic chemistry, while a newer tradition, that of studying function as well as structure and of bringing physical ideas into intimate relation with the study of organic substances, is illustrated by papers on the influence of substituents on the character of benzene compounds and by a series of Ingold's early papers on questions of reactivity. Vernon's work on tellurium derivatives reminds us of the contributions which this country has made to stereochemical problems, especially through the researches of Mills, past President of the Chemical Society.

If we pursue our theatrical fancy to the end and raise the curtain for a last time on the actual centenary date of 1941, it discloses a scene of chaos and destruction. Two decades of fruitful progress seem to have been brought to a tragic end. In some ways the two decades had been among the most productive that chemistry had known. The constitution of natural products had been brilliantly revealed, and in this connexion the names of two Presidents of the Society—Haworth and Robinson—are outstanding. Modern theories of valency had brought an immense clarification into the whole system of inorganic chemistry: the subtleties of organic behaviour had been penetrated, and the intimate mechanism of chemical changes in general stood largely revealed. There had been a powerful cross-fertilisation of chemistry with physics and mathematics. And on the human side the developments were no less vigorous: vastly increased support of research in the Universities, a flood tide of advance in the chemical industry, and, not least, the growth of co-operation between the centres of pure science on the one hand and the great industries on the other, which was of incalculable significance.

As I have remarked, the way in which all this is assessed depends upon a philosophical attitude. One view of history sees the course of human affairs as a chaotic sequence of accidents, the results of unpredictable and indeed often unknowable contingencies: the other sees an orderly and inevitable flow of events in well-marked channels. In that great work "War and Peace" Tolstoy defends and illustrates the second thesis, discounting the influence of great men, and maintaining passionately that the fate of nations evolves naturally out of their essential nature.

All men of science are familiar with those controversies in which the arguments on both sides seem unanswerable: and they know that in the end the contending parties are realised to have seen not truth and falsehood but two aspects of a larger whole. A scientific analogy helps to resolve the conflict about the nature of history.

The evolution of material systems is governed both by those thermodynamic factors which determine equilibria and define the extent and direction of possible changes, and, differently but equally powerfully, by the kinetic factors which determine when and where the changes are initiated and with what speed they progress. The former depend upon average conditions such as temperature and pressure, the latter upon chance fluctuations of energy, highly localised and intense departures from the average. Without these exceptional events the system remains inert. But on the other hand, no fluctuation, however violent, causes its evolution in a direction different from that required by the thermodynamic state. So it may well be in affairs: the exceptional event, the rise of the great man of thought or action, determines time and location, but, for the exceptional to take effect, the average must be in a condition to respond.

In the survey of the century, therefore, one may try to discern the essential trends, to which great events and personalities are related more as occasions than as causes.

As far as chemistry is concerned the history of at any rate the first half of the century has been very much the affair of the individual. The great names—Davy, Faraday, Dalton, Graham, Newlands, Frankland, Perkin—do not seem to bear any special relation to their environment, and might seem to support the purely sporadic view of history. And yet certain general currents are discernible in the contribution from this country. Perhaps one of the deepest and strongest has been the evolution based upon an intuitive sense of the electrical nature of matter. By much more than a play of fancy a genealogy can be traced, through Davy who found the key to the phenomena of polar combination, Faraday, Crookes whose instinct guided him to the study of "radiant matter", Townsend and J. J. Thomson who infuse new blood from physics, to the modern schools of Lapworth, Robinson, and Ingold, who have carried the electrical conception into the subtlest regions of organic chemistry. Nor should I omit in this connexion to mention the scholarly studies of Sidgwick, another past President of the Society, which have done so much to clarify the vast field of inorganic chemistry. This line will almost certainly continue, but how, or where, is as indeterminate as the position of a single electron in an atom.

A collateral line is formed by those who, speculating on the nature of matter, were vouchsafed a glimpse of a promised land into which they did not enter fully—Prout, Newlands, Crookes.

The final conquest of that land came only when the armies of physics and of chemistry joined forces in the victorious advance of Rutherford and Soddy, Rayleigh and Ramsay, J. J. Thomson, Aston and Moseley.

In contrast with the imaginative quality of these men, another of our strongest traditions has been that of empirical observation, unguided by much in the way of theory. This has expressed and illustrated both a national strength and a national weakness. From the days of Priestley onwards, it has led to factual discoveries of the first importance, and produced experimenters second to none in such men as Dewar, Dixon, and Bone, but it has not created schools, and its positive achievements have occasionally been lessened by a mistrust of theory so healthy as almost to discourage understanding. But the impact of the two opposing schools has been unquestionably fruitful, and has sometimes added to the gaiety of nations.

Other recurrent themes can be traced throughout the century: on the one hand a sense of the mystery and wonder of chemical change, and on the other a joy in precise measurement for its own sake—two contrasted but equally important motives in the development of physical chemistry, which reflect the blend of the romantic and the practical in the make-up of so many Englishmen. Affinities could be traced throughout the period, as between the work of Graham and that of Berkeley and Hartley, or between the spirit of Harcourt and Esson and that of various modern schools. And yet, the purely personal character of much of the great work could equally well be illustrated by innumerable examples, such as Perkin's famous discovery of mauve, Dewar's observations on specific heats at low temperatures, or Crookes's studies of the rare earths.

The truth is, I think, that the more easily distinguishable threads have been woven more by what is common in the intellectual make-up of the people, than by a direct and conscious tradition. There are men who, placed in almost any circumstances, will mould them to something great, and it is such men predominantly whom we have to commemorate, at any rate in all but the last two decades of the century. The breeding of such men is not likely to change in any rapid way, but the nature of the society into which they are born is changing before our eyes.

One of the unmistakable trends of the past century has been the successive decline of different aspects of individualism: the independent craftsman, the aristocratic politician, the empire-building explorer all departed from the scene. In science a similar trend has been visible though at a lag of several decades. At the time of our foundation the stage is dominated by the amateur, whether a Cavendish or a Faraday: later the individual is more and more frequently dependent upon the University or technical college, small and independent but none the less a community. Then the great research associations appear and the State subsidy becomes indispensable. Two great wars intensified and accelerated the collective process in the world of science until today we are faced with the problems presented by vast industrial research laboratories and by state enterprises undertaking work which is inconceivable without the co-ordinated efforts of hundreds of men of science. The great question is: what is to be the fate of the individual in the world which has emerged?

In this matter something of an ideological battle has been engaged, and since the question is one of moment for the future of an independent scientific society, I propose to say a little about it, in as objective a manner as possible.

May I, for this purpose, introduce an analogy between human affairs and certain scientific laws? The particles composing matter are endowed with individual motions which would lead to complete chaos but for attractive forces constraining them at times into orderly configurations. The two conflicting tendencies are, of course, what men of science know as the entropy factor and the energy factor. It is the balance between the two which governs all the rich complexity of chemistry and physics, and determines that measure of effective action called free energy. Were there maximum entropy and complete chaos the world of phenomena would be much the poorer, but were there the rigid constraint which the energy factor alone would impose things would be as bad or worse. Nobody who has thought about science can fail to admire the art with which Nature interweaves her two great themes. When molecular chaos is set in order it is only at a price, but price and value are astutely bargained. So it must be in human affairs.

Complete individualism means chaos, which is only given form by something analogous to an energy factor—by State compulsion, or by powerful emotional forces. If any of these controls are applied too vigorously the result is order indeed but the order of utter stagnation. Just as Nature strikes her subtle balance, so it must be here. Nothing is less fruitful than doctrinaire argument about freedom and planning. The vast achievements of military regimentation in

wartime have been cited as examples for peace, but in this it is forgotten that results in limited spheres have had to be bought with an utter disregard of cost, whether of money, happiness, or life.

The problem is not to propound facile doctrines, but by hard and detailed thinking in every possible sphere to find those mechanisms and those techniques which in combination lead to the greatest measure of effective action.

A hundred years ago we saw an individualist society faced with the task of controlling the industrial revolution: at the beginning of a new century we face a task which seems even greater, that of preventing an organised society from turning individuals into slaves. The problem involves the relation of the State to science, of the industries to the Universities, the organisation of research laboratories, and indeed the relation of every man of science to the laboratory in which he works and to the science as a whole.

Those who call themselves planners are often, I think, not conscious enough of the art and effort involved in large-scale action. Even with the most admirable motives and goals, operative complexity often brings frustration. There is need for a complete new science, a kind of biological and psychological statistical mechanics to clarify these matters. The beginnings of it exist. Indeed we have seen one gigantic manifestation of directed human activity in the evil arts of the late rulers of Germany, whose ingenious mechanisms were applied in opposition to truth and justice but might have been used to better ends.

This thesis will be accepted readily enough by the exponents of what are now called social studies, but we may be told that the organisation of affairs must be placed in the hands of specially trained humanists, and that the scientific man should be confined to the rôle of an advisory expert. Such a tradition has of course tended to grow up in some of the public services. But one can say with conviction that its persistence will be unfortunate and its extension disastrous. It is like a separation of the heart from the brain and of the mind from the body. The man of science must himself handle the human problems, and, in scientific affairs, nobody but the man of science can do it. On the whole the Universities and the great chemical industries are aware of this, and the excellent relations which have been growing up between them will exert a powerful influence for good, and are of happy augury. But eternal vigilance is the price of these things. At every level in every organisation where men are engaged in scientific pursuits those in charge must continue to wrestle with the problems of combining liberty with order to the end of finding that course which is humanly as well as technically the most effective.

One very welcome sign of the past few years has been the increasing number of scientific papers published from the chemical industry. These are clear and welcome evidence that the leaders of that industry are showing understanding of the intellectual needs of the men who serve it. One can only hope that the whips of commercial secrecy will not be succeeded by the scorpions of military security.

Looking to the future of chemical research, one can confidently foresee an era of great technical progress. The powerful organisations which will ensure this are already in operation. The relevant problems of pure science will also be explored on a scale which has hitherto been undreamt of. Such matters as thermodynamic and kinetic studies on polymers, biological studies on chemotherapeutic agents, and scores of others could be cited to show how the approach is changing from the sporadic and the amateur to the thorough and the professional. All this leads to new knowledge of inestimable value, and in this field also progress seems assured.

But of that most important kind of new knowledge, that which does not seem to relate to any existing field, it is harder to speak on the basis of anything but faith. And yet in this knowledge lies the true seed of the future. It will come only from the least conforming of minds, and the discoveries of the greatest ultimate moment are the least likely to have been favoured by official encouragement or support. They must be like the flowers of the poet

"daffodils,
That come before the swallow dares, and take
The winds of March with beauty."

We may well ask whether the winds of future Marches may not be more intolerant than those of the past.

There is no royal road to be followed into the future. In the scientific and social history of the past century the picture has been one of light and shade, ebb and flow, and enormous uncertainties crowned by miraculous progress. On this scene men of all kinds have laboured for the science of chemistry. Today we honour them. There is no reason to suppose that

their qualities have not been inherited. The stage is changed and the parts are different, but the actors are very much the same.

It is still the individual who really counts, but his problems are different. Faraday's genius overcame lack of education and lack of facilities. These are handicaps from which he would be very unlikely to suffer today. The Faraday of tomorrow will have by his own methods to break through the trammels of an over-organised society : and for this it may well be that he will need something more of the quality of a Nelson.

Nothing has ever yet contained the great river of knowledge. Though Archimedes was slain, Galileo persecuted, and Lavoisier condemned, it has flowed over or around every obstacle which stupidity, indifference, or malevolence have created.

In the old eastern story a debate arises as to what is the strongest thing in the world, and in the end this is recognised to be the truth. "As for the truth it endureth and is always strong : it liveth and conquereth for evermore. . . . Great is truth and mighty above all things." Whatever clouds may seem to lower over the new century, this is the great light which shines on it.

But this faith does not obviate the necessity for continuous detailed effort. If it is based upon an extrapolation from the past, that past is one in which people were ready to struggle and endure. It is incumbent on us to consider what stands before our Society and what policies that Society should pursue.

There is one which stands in the centre of and indeed includes all other policies, and that is to maintain the prestige of chemistry as a pure science. It is right that the Chemical Society should occupy a central position in the world of chemistry. I have referred to the increasing complexity of this world, with its multiplicity of organisations. But by common consent new knowledge is the life blood of it all, and the heart should be the Chemical Society itself. Of the relations between the great chemical industry and the Universities I have already spoken, and gratitude must be expressed for the humane policy of so many leaders of that industry. But it remains for the younger chemists in it to take an ever more active part in the publication and discussion of new knowledge. Provision for this is one of those problems where the scientific and the humane are inseparable.

Relations between chemistry and its neighbour sciences—physics, mathematics, and biology—are now so close that the frontiers are practically abolished and the joint discussion of common problems will be of increasing importance.

All this raises a practical question of the first magnitude, that of adequate facilities for meeting. I feel a little ashamed that on this great occasion we should receive our guests in alien halls, however hospitable they may be. I should like to hope that before long a statesmanlike solution to this problem will have been found.

Important as buildings may be, our publications are still more so, and in the eyes of posterity the Society of today will be judged more by the quality of the work which it publishes than by any other criterion. As Shakespeare tells us, the immortality conferred by black ink is greater than that of gates of steel or rocks impregnable. It has been a sad economy which has lavished money upon so many objects while neglecting the means of scientific publication. We must continue to struggle against this unhappy policy and hope that it will pass, never to return.

Among the traditions upon which we look back with pride is that of the international character of the Society. I am happy to say that as the result of a special Centenary Appeal for the purpose this valuable element in our activity will be strengthened, and that we now have the means of bringing foreign men of science to take part more often and more fully in our doings. There can be no question of the great benefit which chemists in this country will derive from the arrangement.

And now to the conclusion of the whole matter. What the Society is and must continue above all else to be is a fellowship of those who share the love of chemistry, that most splendid child of intellect and art. Chemistry provides not only a mental discipline, but an adventure and an æsthetic experience. Its followers seek to know the hidden causes which underlie the transformations of our changing world, to learn the essence of the rose's colour, the lilac's fragrance, and the oak's tenacity, and to understand the secret paths by which the sunlight and the air create these wonders.

And to this knowledge they attach an absolute value, that of truth and beauty. The vision of Nature yields the secret of power and wealth, and for this it may be sought by many. But it is revealed only to those who seek it for itself. Its pursuit has united the predecessors whom we commemorate : it will unite our successors for as long as the spirit of man endures.

*A Century of Chemistry.**

A LECTURE DELIVERED ON FEBRUARY 19TH, 1947, AT A JOINT MEETING OF THE ROYAL SOCIETY OF ARTS AND THE CHEMICAL SOCIETY TO COMMEMORATE THE CENTENARY OF THE FOUNDATION OF THE CHEMICAL SOCIETY.

By Sir HAROLD HARTLEY, K.C.V.O., M.C., F.R.S.

THIS evening Fellows of the Chemical Society have made a pilgrimage, not, it is true, a very long or hazardous one, although in this year of grace 1947 we shall return by torchlight, to John Street, Adelphi, to the Royal Society of Arts, the birthplace of our Society. We have come like the pilgrims of old, who made much longer journeys, in a spirit of piety to the place that holds such a high place in our memories, to pay our homage to the Society that gave us hospitality for our first meetings. It was on February 23rd, 1841, thanks to the initiative of Robert Warington and the kindness of his friend Arthur Aikin, formerly the Secretary of the Society of Arts, that twenty-five chemists, including Aikin, met in this building to consider founding a Chemical Society, and here its first regular meeting took place on March 30th, 1841.

The Society of Arts had been established for nearly a century, and its Secretary Aikin was a very remarkable man. He had been one of the founders of the Geological Society, but his abiding enthusiasm was for chemistry, thanks to his early friendship with Priestley, and he became the first Treasurer of the Chemical Society and its second President. So we started life with a close personal link between us.

However, the fledgling Society soon wanted to try its wings, and in six months it left the nest to go to the Westminster Literary and Scientific Institution in Leicester Square. There was some fear too that chemical experiments might not be welcomed in these august precincts. But migration was found to have its drawbacks; oddly enough there were difficulties about heating; they missed this warm nest, and in 1842 the Society was back in John Street, where it enjoyed the hospitality of the Society of Arts at the modest rent of £25 a year until 1849. The Annual Reports reveal the general satisfaction of the members with this arrangement, and indeed in 1844 the Council reported "that the arrangement . . . continues to be satisfactory to both parties, and especially to ourselves, as we have not only acquired a convenient habitation, but have avoided the expenses included in the word establishment so often ruinous to young Societies". Happy indeed is the institution that has no overheads!

But by 1849, when the Society got its Charter, it had outgrown the limits of your kind hospitality, and needed rooms for its library and collections, which it found in the Strand. And so ended this happy connection between us, for which the Chemical Society will always be most grateful.

This year in July the Chemical Society is celebrating, somewhat belatedly, its centenary, and tonight we come here to commemorate its first meeting in the building where it took place. It is my privilege, in this joint meeting, to try and sketch the achievements not of the Chemical Society, for that is the task of the President, but the achievements of our science since 1841—what it has done, with the help of its sister sciences, to give man control over the materials on which his well-being depends, and to throw light on the complexities of living matter.

Chemistry in 1790—1840.

1841—just over half a century since Lavoisier had given chemistry its modern form in his great Treatise of 1789, his autobiography of one of the simplest and most decisive revolutions science has known. Lavoisier applied to chemistry not only the balance but, being skilled in affairs, the method of the balance sheet. The idea of the chemical equation dominated his mind, and his first chemical equation dealt, as the Bible tells us, with one of the earliest and one of the most significant chemical reactions known to man. It runs:

Le moût de raisin = acide carbonique + alkool.

We owe to Lavoisier the first clear distinction between physical and chemical change. With Laplace he laid the foundations of thermochemistry. We owe to him the idea of organic combustions by which he was the first to determine the quantitative composition of the products of living processes. When he was guillotined in 1794 he was setting his course towards the Atlantis of biochemistry.

* Reprinted by permission from the *Journal of the Royal Society of Arts*, 1947, 95, 454.

After Lavoisier in 1808 came Dalton with his Atomic Theory. It was one of those flashes of genius that crystallises an idea that had been floating in men's minds for centuries, and gives it the simple concrete form that makes it a powerful instrument in the hands of mankind. Lavoisier's analyses and his nomenclature could then be translated into atomic formulæ, the chemist's shorthand.

The next landmark was Davy's verification of Lavoisier's prediction of the existence of the alkali metals; their isolation by electrolysis laid the foundation of electrochemistry and of the association of chemical affinity with electrical charges. Davy also redressed the balance of Lavoisier's over-estimate of the central position of oxygen by showing that the essential element in an acid is hydrogen and not oxygen.

And then, just as chemistry was attracting more and more attention and new chemical facts were being discovered so rapidly, came the Swede, Berzelius—the most massive figure in the whole of its history. In a few years he determined single-handed with amazing skill and sagacity the atomic weight of every known element and the composition of many compounds, thus giving added reality to Dalton's theory. He too substituted for Dalton's geometrical symbols the initial letters of the names of the elements, which we use to-day. Berzelius had an encyclopædic mind, and he embodied in ten volumes the whole compass of chemical knowledge enriched by many of his own discoveries. Conservative as to the ideas which had served him well, he had the intuition to see where there was a common pattern in diverse chemical phenomena, and we owe to him the generalisations of isomerism and catalysis and their names.

For twenty years Berzelius was the accepted authority and the influence he exerted through his Annual Reports on current literature and through his friendships with the younger generation of chemists was immense. Meanwhile the younger men like Liebig, Wöhler, and Dumas were laying the foundations of organic chemistry by making series of derivatives from natural products with inorganic reagents. The new facts they discovered were difficult to reconcile both with the dualism and the theory of radicals which Berzelius had inherited from Lavoisier, and with his own view of the dependence of chemical affinity on electrically charged atoms. By 1841 his authority was seriously challenged. His formulæ were discredited, even his atomic weights were largely replaced by equivalents, and there was a drift from theory towards empiricism.

Founding of the Chemical Society.

So the Chemical Society was founded at a most opportune moment, when the number of young men doing research was rapidly increasing and the opportunity for discussion and publishing their results was badly needed. For the next twenty years chemistry was to be in a state of flux, without any generally accepted theory. It was a time of bitter controversy, when the older chemists resented criticism and the younger men like Gerhardt and Laurent suffered persecution for their views. In their heroic battle against authority, which they ultimately won, Pope's lines, often spoken in jest of our profession, came literally true :

" The starving chemist in his golden views
Supremely blest, the poet in his Muse ".

Laurent died as a result of privation.

From 1840 to 1860 the work of most outstanding chemists lay in organic chemistry. It was a period of rapid growth, when experiments were almost bound to lead to discoveries. Each chemist had his own theory of which he was tenacious, as it meant much to him; it was in a sense the scaffolding which enabled him to make his own contribution to the structure of chemistry. And so it is not surprising that by 1859 a whole page of Kekulé's text book was filled by the different formulæ proposed for such a simple substance as acetic acid.

As the technique of organic reactions was gradually developed, each year brought an increasing harvest of new compounds and there was a growing need for some new system of classification to include them all. Laurent and Gerhardt, with their logical French minds, had each been seeking a new basis of classification along rather different lines, and their partnership led eventually to Gerhardt's type theory in which all organic compounds were derived by substitution from four simple inorganic substances, hydrogen, water, hydrochloric acid, and ammonia. Gerhardt's theory was an unconscious recognition of the different combining powers of the atoms and groups, and led inevitably to Kekulé's theory of atom linkage. It had been a long struggle, and Laurent died in 1853, but Gerhardt lived until 1856 to taste success and see his views adopted by the younger chemists.

The early meetings of the Chemical Society during that stormy period must have been lively and stimulating, with men like Lyon Playfair, Graham, Brodie, William Odling

(Gerhardt's *l'ami Odling*), and Williamson, to whose classic paper on ether and alcohol Gerhardt owed so much. And there were in London during those years young German chemists of great ability—Kolbe came in 1845, to infect the young Frankland with his interest in the synthesis of organic compounds from simple molecules. Hofmann came in the same year to teach at the new College of Chemistry in Oxford Street, and Kekulé in 1853 as assistant to Stenhouse, the Chemist to the Mint. Kekulé often said that his theory of the structure of organic compounds started in his dream about atoms on the top of an omnibus one night between Islington and Clapham Road where he lodged. So in those days London and the meetings of the Chemical Society which took place in this building from 1841 to 1849 were a focus of chemical thought.

Cannizzaro and Kekulé.

These two decades of uncertainty and divided opinion ended almost abruptly after 1860, thanks to the constructive thinking of two men. In 1860 the first international conference of chemists was held at Karlsruhe at Kekulé's suggestion, with the object of arriving at some agreement about atomic weights and molecular formulae. Nearly all the active workers in each country were present, but as at other international meetings progress was slow. Committees were appointed which grew larger and larger, there was jockeying for position and eventually the Congress broke up in a chilly mood, having accomplished practically nothing. But copies of a thin paper-covered pamphlet on atomic and molecular weights by Cannizzaro, the Professor of Chemistry at Palermo, were given to some of the delegates. His exposition of the existing difficulties and their solution by the consistent use of the laws of Avogadro and Dulong and Petit was so clear and convincing that as Lothar Meyer said when he read it "the scales fell from my eyes, doubts disappeared and were replaced by a feeling of certainty". It was not long before there was a general agreement among chemists about the weights of the atoms and the number of atoms in a molecule, which, as Kekulé had foreseen, was a necessary preliminary to a general theory of the constitution of molecules.

The other decisive factor was Kekulé's theory of atomic linkages, each atom having a definite combining power—hydrogen one, oxygen two, nitrogen three, and carbon four. On this basis, recognising that atoms of carbon, unlike other elements, could unite to form stable chains, or rings like the six-membered benzene molecule, Kekulé was able to assign definite structures to organic compounds, and this gave an immense impulse to the advance of organic chemistry.

When these major controversies were over, chemistry advanced rapidly on a wide front in the years from 1860 to 1900 which form the next epoch.

Organic Chemistry, 1860—1900.

Kekulé's theory of atomic linkage had presented chemists with an almost unlimited number of possible arrangements of carbon atoms in straight or branched chains, or in rings with intermediate links of other atoms which could also form part of closed-ring structures. These possibilities chemists were quick to explore, both by building up new molecules by synthesis in the laboratory, and by trying first to ascertain the molecular structure of natural products and then to synthesise them in the laboratory. Outstanding examples of this were the syntheses of alizarin in 1869 and of indigo in 1880. In this way many new compounds were made and described, and the technique of organic reactions was continuously extended. Between 1856 and 1910 the number of known organic compounds increased from 3,000 to 200,000.

In this period of rapid development there was one episode of outstanding importance, the simultaneous recognition by van't Hoff and Le Bel of the need to take into account the arrangement of the atoms in three dimensions. Kekulé had realised this, but he was sceptical about the power of chemistry to reveal the actual structure of the molecule, although he thought physics might do so. Pasteur in 1845 had already proved from the rotation of light passing through them that in certain cases the same atoms could form either a right- or a left-handed molecule. Van't Hoff and Le Bel showed that this was due to the presence of one or more carbon atoms combined with four different groups which could be arranged spatially in right- and left-handed forms. In addition, the arrangement of the atoms in space could account for a number of other unexplained phenomena. All their predictions were quickly verified, and since 1874 stereochemistry, the arrangement of the atoms in space, has been a potent factor in the progress of organic chemistry.

During these years it was in Baeyer's laboratory that most of the foremost organic chemists served their apprenticeship. It was there that Emil Fischer, the younger Perkin, Willstätter, and many others learnt the simple technique of the test tube and glass rod with which so many

discoveries were made before the elaborate technique of modern organic chemistry became necessary. The sugars, the terpenes, and the alkaloids yielded the secrets of their structures. Some of the many new compounds that were synthesised were only of scientific interest, while others yielded new dyes or new perfumes or new drugs like eucaine and veronal, so called because Emil Fischer happened to wake up and look out of his carriage window at Verona after a visit to Baeyer to discuss its properties.

Inorganic Chemistry, 1860—1900.

The advance of inorganic chemistry naturally took a different course. In 1860 sixty-four elements were known and many attempts had been made to classify them in families with very limited success. When agreement had been reached as to the relative weight of the atoms a new line of attack was opened, and in 1864 both Newlands and Lothar Meyer pointed out that if the elements are arranged in the order of their atomic weights, elements recur at regular intervals with similar properties, apparently belonging to the same family. Four years later Mendeléeff, using more accurate atomic weights, developed the Periodic System in much greater detail and predicted by means of it the properties of three undiscovered elements which were missing from the system. The accuracy of his predictions was shown by the discovery of gallium in 1875, scandium in 1879, and germanium in 1886. The invention of the spectroscope by Bunsen and Kirchhoff in 1859 had given chemists a powerful new instrument, and the discovery of further new elements, rubidium, caesium, and thallium, soon followed with its aid, to fill other gaps in the Periodic Table of the elements. But even though it provided a basis for the classification of the elements in families, many puzzling problems in the Table remained unsolved.

Physical Chemistry, 1860—1900.

Meanwhile the influence of physics on chemistry was being felt more and more, both in the use of new techniques like the spectroscope and in various applications of physical theory. Here again van't Hoff was the pioneer in a dual attack by applying both molecular theory and the laws of energy to the analysis of chemical phenomena. The laws of energy or thermodynamics are laws of experience like Newton's law of motion, independent of any hypotheses as to the nature of matter, and affording therefore a useful test of the truth of such hypotheses and of classifying and forecasting certain chemical phenomena. Willard Gibbs had been the forerunner in this field in 1876—1878, but van't Hoff was the first to show the wide applications of thermodynamics to chemistry. At the same time he was analysing the kinetics of chemical reactions and the nature of chemical equilibrium in the light of molecular theory, and showed their dependence on the behaviour and properties of the individual molecule. Thus in the 'eighties a new subject, Physical Chemistry, was taking shape, especially in the field of solutions, where Arrhenius gave it a fresh impulse with his theory of electrolytic dissociation which related the electrical conductivity of solutions to the dissociation of molecules into electrically charged ions. That again had applications in many fields, and with the help of Ostwald and Nernst physical chemistry quickly became a powerful new instrument.

And so in the 'nineties, when I and my contemporaries were learning chemistry, organic chemistry gave us a tidy logical picture in which the agreement between properties and structure showed clearly that the model represented a close approximation to the truth. In physical chemistry we got a picture of the dependence of chemical reactions and equilibria on the kinetics of the individual molecule or ion, and of the value of thermodynamics in giving generalised laws independent of any theory. Inorganic chemistry was more difficult; by then there were so many isolated facts to be remembered, and while the Periodic Table was a great help, there were many anomalies still to be explained.

Nineteenth-century chemistry had been based on the Newtonian atoms, those small, hard, indivisible, elementary particles of which all matter was thought to be composed, and its development was mainly that of an experimental science. The whole picture of molecular constitution had been built up by inference from macroscopic experiments, and there were no means of investigating the fine structure of matter to give some clue as to the nature of the atoms, of their chemical affinity that caused their reactions, or of their valency that determined their combining powers. The evidence of their spectra certainly suggested that their structures were far from simple.

Then suddenly there came a rapid succession of discoveries that threw an entirely fresh light on the whole subject and by 1914 had given chemists a new conception of the unity and sub-mechanics of their science.

The Period of Great Discoveries, 1895—1913.

In 1897 J. J. Thomson discovered the negative electron, showing that electricity is atomic and that the electron is common to all atoms. Becquerel had already discovered radioactivity in 1896, and Madame Curie isolated radium in 1898. These discoveries, together with Rutherford and Soddy's systematic investigation of radioactive charges, gave the first clue to the nature of the atom.

Roentgen's discovery of X-rays in 1895, with wave-lengths approximating to atomic dimensions, in the hands of von Laue and the Braggs proved a most powerful means of investigating the arrangement of atoms and ions in crystals and later the arrangement of the atoms in the molecule.

In 1911 Rutherford's discovery of the dimensions and nature of the nucleus led to his theory of the nuclear atom consisting of a small central positively charged nucleus with electrons rotating in orbits around it. Moseley in 1913, by examining the frequencies of the X-rays emitted by different atoms, proved that there are ninety-two elements with ordinal numbers corresponding to the number of charges on the nucleus, thus throwing an entirely new light on the Periodic Table. As a proof of the thorough way in which nineteenth century chemists had done their work, it is worth noting that of that complex and hitherto mysterious group of elements, the rare earths, fourteen had been separated and recognised as elements before Moseley's law was known, leaving only one of extreme rarity to be found.

The full significance of Rayleigh and Ramsay's discovery in 1895 of argon, the first of the rare gases, followed by Ramsay's discovery of the rest of the family, was now apparent. The arrangement of the electrons in their atoms was so stable that they showed no tendency to combination, and this was the basis of G. N. Lewis's and Kossel's theories of valency as dependent on the stability of an octet of electrons in the outer shell of the atom.

In 1901 Planck had shown that radiant energy had a certain atomic character, as it could only be emitted and absorbed in discrete quanta, the size of which was proportional to the frequency of the vibrations. The fundamental significance of this discovery to chemistry was not at first obvious, until Bohr in 1912 showed that the application of the quantum theory to the electron orbits in Rutherford's atoms could explain the structure of their spectra, the actual wave-lengths of which could be calculated in simple cases.

Then, just as all the tools for future development were in the chemist's hands, came the war of 1914, the first chemists' war, in which chemistry played a vital part in making explosives, in making synthetic products to counter the effects of a blockade and in the military use of gas and smoke. The effect of this was to intensify the effort directed to chemical research after 1918.

Chemistry in the Inter-war Years.

Demobilised from their war activities, chemists returned to their laboratories with fresh zest to take up again the work that had held so many exciting prospects in 1914. I remember Rutherford saying to me in 1919: "What's the use of going back to chemistry when Bohr will soon be able to calculate anything you can find out?" But Rutherford was the last person to dissuade anyone from experimenting, and it was in his own laboratory that the science of nuclear physics was born.

During the inter-war years chemistry has progressed with amazing speed, and its influence has been felt increasingly in the sister sciences of physiology, botany, agriculture, and geology. The main factors in its progress have come from physics, both from new physical techniques and from new physical theories. Progress has been on such a wide front that it is impossible to summarise, but there seem to me four outstanding achievements in the fields of atomic and molecular structure, of nuclear physics and isotopes, of the kinetics of chemical action, and of the organic chemistry of living processes.

Atomic and Molecular Structure.

Chemistry owes to physics the detailed knowledge that we now possess of the structure of molecules, derived from measurements of their X-ray diffraction, electron diffraction, Raman spectra, dipole moments, and their spectra from the infra-red to the ultra-violet. There has been a continuous development both of the technique and of its application in each field since 1919. Thanks to this we now know the distances between the centres of the atoms in any linkage, the position of the atoms relative to one another, the nature of the linkage, the heat of formation of the linkage and its resistance to deformation.

Simultaneously with this advance on the experimental side there has been a remarkable

development on the theoretical side which has stimulated experiment and has explained the causes underlying the behaviour of the atoms and molecules.

Till 1925 the Bohr-Rutherford atom held the field, the positively charged nucleus with electrons rotating round it in various orbits. From the purely chemical side it gave a qualitative explanation of the valencies of the elements, it distinguished between electrovalent, covalent, and co-ordinate links, and it explained most of the regularities of the Periodic System. It gave a quantitative basis for calculating the spectra of atoms and simple molecules, and with the hypotheses of electron spin and molecular vibration it accounted for the fine structure of spectra and their behaviour in a magnetic field.

But difficulties arose with the model atom as the electron sometimes appeared to behave as a particle and at others as a wave motion, a dilemma that was the basis of Heisenberg's Uncertainty Principle. The difficulty was solved by the new calculus of quantum mechanics, in which the properties of the atom are described by equations which admit of no simple physical interpretation such as a model. The test of their validity is the wonderful accuracy with which they can predict the behaviour of single atoms. Unfortunately in more complex systems great mathematical difficulties are involved in a rigid solution, and various methods of approximation have to be adopted. However, in spite of this, quantum mechanics has provided a new stimulus and a new interpretation in many fields, particularly in regard to valency. It enables the direction of the valencies of any atom in space to be calculated, and provides a much more subtle differentiation of the various types of linkage. The periodicity of the properties of the elements with increasing atomic number can be shown to be a necessary consequence of the geometrical symmetry of the electron fields. It explains too the quantum restrictions as a necessary consequence of the wave characteristics of the electron.

Isotopes.

The nucleus itself is mainly the concern of pure physics, but there is one important exception, the existence of isotopes, atoms with the same atomic number but with nuclei of different mass. By means of his mass spectroscope Aston showed that the chemical elements are nearly all mixtures of isotopes, and by measuring the amount of each present and its atomic weight he explained why chemical atomic weights are so far removed from whole numbers. The actual separation of the isotopes with identical chemical properties by physical means was one of the most laborious experimental problems with which chemists have been faced.

But a new significance was given to isotopes when the physicists found it possible by bombarding atomic nuclei with various particles to transmute them and often to produce isotopes with radioactive properties differing from those of the parent atom. Quite apart from their therapeutic importance, such isotopes could be used as tracer elements in chemical reactions and in living processes to track down the course followed by the atom in question.

Physicists also discovered the particles of which the nucleus is composed, the positron, the positive equivalent of the electron, and the neutron, whose unique properties as a projectile in nuclear bombardments makes possible the utilisation of atomic energy.

The Kinetics of Chemical Change.

This brings me to the next main field of progress, the kinetics of chemical reactions. It is generally true to say that no phenomenon is as simple as it seemed to the original discoverer, and of nothing is this so true as of the equations used to represent chemical reactions. Only last year our President's Bakerian Lecture was devoted wholly to the complexities of that first schoolboy equation: $2\text{H}_2 + \text{O}_2 = 2\text{H}_2\text{O}$.

The investigation of reaction rates has given scope for much ingenious experimental and mathematical treatment. It has involved the study of the lives of the individual molecules, the circumstances under which they can acquire a critical amount of energy, the effect of radiation, the effect of catalysts, and the significance of chain reactions. Great progress has been made, which has given us a much more intimate picture of the actual mechanism by which chemical reactions take place. The results are of profound interest for both theory and practice, as so often it is the rate of change that determines what is possible.

Organic Chemistry.

And lastly there is organic chemistry, when we must go back to where we left it about 1900. Its outstanding achievement has been the light it has thrown on the great systems of the materials and processes of living organisms. Organic chemistry has thus returned to the task for which

it was originally equipped by Lavoisier and for which he meant to use it, the discovery of the chemical reactions of the living body. Its success has been to reveal their complexity. With the techniques that have been developed by organic chemists for over a century they can now break down or build up the most complex structure of carbon atoms and the groups attached to them with a certainty that leaves no doubt as to what that structure is.

Here again physical methods have played an important part. X-Ray analysis of crystalline or regularly orientated material has revealed the details of its atomic and molecular structure. Infra-red spectra have made possible the identification of minute quantities of material differing only in small details of their structure. The modern methods of chromatography, the selective adsorption of substances in various media, allow of the separation of the constituents of complex mixtures available only in small quantities which otherwise could not be resolved. The ultra-centrifuge too has helped in the separation of complex molecules and the determination of their molecular weights. The technique of microchemistry, the handling and analysis of small quantities of organic material, has made possible the investigation of substances available only in small quantities and quickened the pace at which investigations can proceed.

The problem for the chemist, in conjunction with the physicist and the biologist, is to unravel the processes by which Nature builds up the structure of living organisms, and provides the materials that discharge the functions of their various parts.

The plant is the first stage in Nature's economy, as plants alone can assimilate the carbon dioxide of the air and nitrogen from inorganic sources and synthesise from them the carbohydrates, fats, and proteins that form the food of other organisms. The first success of chemists in this field was the determination of the structures of the simple plant products, such as the sugars, vegetable oils and fats, essential oils like the terpenes, rubber, alkaloids, and various dyestuffs and colouring matters like the anthocyanins. Many of these were synthesised in the laboratory, and X-ray analysis has confirmed the correctness of the structures assigned to them on the ground of chemical behaviour. A comparison of these structures shows that Nature makes use of the economy of prefabricated construction, as many of them are built up by different arrangements of the same groups of carbon atoms. Thus the carbohydrates are all built up of chains of six carbon atoms, but C_3 may be an intermediate stage in this grouping, as the groups $C_6 - C_3$ and $C_6 - C_3 - C_6$ frequently occur in plant products. The vegetable fats and oils are mostly built up of C_6 units forming chains containing twelve, eighteen, or thirty atoms, joined together by the C_3 of glycerin. The structural units C_6 and C_3 recur again in a number of substances where the chain of six carbon atoms has been converted into a ring as in the oil of cloves and similar substances. Two $C_6 - C_3$ groups provide the skeleton of many others, and with the addition of C_6 the skeletons of the catechins and anthocyanins. The aromatic oils, resins and rubber have been formed by a different route; they are built up from a C_6 unit with a branched carbon chain which may either condense to rings like the terpenes or polymerise to a long chain as in rubber.

But in spite of these regularities we have little knowledge of the methods by which Nature marshals these units in the living cell. Her catalytic methods are so specific in their actions and work so cleanly compared with ours that she is able to marshal these structural units to form complex molecules under the influence of surface forces exerted as it were by a template of existing molecules. The ease and certainty of Nature's methods is so intriguing and tantalising to the chemist working in a non-living environment.

It was quickly realised that many of the main constituents of living organisms, the polysaccharides and the proteins, had vastly greater molecules than these simple plant products, and here again X-rays have rendered decisive help. Cellulose, for instance, was found to consist of hundreds or thousands of glucose residues united in a straight chain, and forming the chain bundles which are the predominant structural element of the plant kingdom. In rubber the long carbon chains are folded higgledy-piggledy around one another, straightening when the rubber is stretched and giving it its elasticity. The discovery of formaldehyde phenol plastics by Baekeland in 1909 soon resulted in the synthesis of similar giant molecules in the laboratory and the study of their behaviour. Carother's classical investigation of the linkages which would produce these giant molecules led directly to the discovery of nylon, a nitrogenous synthetic fibre that is competitive with Nature's products.

Of all these giant molecules the proteins, which in one form or another enter into almost every living process, are the most significant. Emil Fischer's pioneer investigations showed that they all consist of various amino-acids linked together to form long chains. X-Ray analysis revealed the regular order in which the amino-acids alternate in the chains of different proteins and the position in space of the side groups, the projections from the chains that determine so

largely the specific properties of each. The proteins are divided into two great families, the fibrous and the globular, those in which the chains are extended like fibroin, the spider's web, and those in which they are coiled in a regular manner like albumin and hæmoglobin. The former class has again two main families, the keratin-myosin-fibrinogen group, including wool, hair, skin, nails, whalebone, muscle tissues, and the coagulating constituent of blood, and the collagen group including tendons, connective tissue, and cartilage. The knowledge of their chemical structure reveals something of the principles of Nature's engineering, of the way in which she provides for the necessary mechanical properties of the parts of an organism. And further it is beginning to throw light on the processes of growth, the synthesis of giant molecules by contact catalysis in living matter.

Great advances have been made in our knowledge of enzymes, those complex colloidal catalysts formed by living cells which enable the chemical changes that accompany and condition living processes to take place rapidly at ordinary temperatures. The isolation of some of them like urease, trypsin, and pepsin in a crystalline form was a great achievement. Some have proved to be pure proteins, while others, such as those responsible for the oxidation of food in the body, are proteins associated with various complex groups which can act as oxygen acceptors.

Then there are substances such as the vitamins, hormones, and auxins, small quantities of which exert such an immense effect on living functions. Vitamins are essential to normal life and healthy growth, and are all derived from foodstuffs. Their identification has played an important part in the modern treatment of nutrition, and the constitution of most of them is now known. Hormones are the chemical messengers, produced in one part of the body and exerting a most potent influence on others. Some of them, such as the sterols, and the active principles of others, such as adrenalin and thyroxin, have been isolated; their structures have been determined, and some of them have been synthesised. The knowledge gained in this way has been of the greatest value in curative medicine.

Lastly, there are the viruses, those minute carriers of disease that have been so hard to track down and isolate. Some of them have now been obtained in a crystalline form and have been shown to be nucleoproteins.

In addition to throwing light, in these and many other ways, on the complex molecules and the complex secrets of the chemical reactions on which the existence of life is dependent, chemists have synthesised many new substances which have important biological applications. Ehrlich's discovery of salvarsan in 1910 was an outstanding triumph. Its name "606" emphasises the number of attempts before a molecule was found that would destroy the spirochæte of syphilis without killing the patient. Later came the sulphonamides with their specific reactions against certain types of bacteria. Their power of stopping growth suggests that they are absorbed on the catalytic surfaces in place of some of Nature's prefabricated units of similar shape, and thus prevent the completion of the pattern and the formation of a new molecule. Their action has been likened to the jamming of a lock by a key that does not quite fit.

D.D.T. and gammexane come in another category. They are synthetic products of outstanding effectiveness in killing insect pests without hurting men or animals. Similarly a range of substances has been found which will kill weeds (dicotyledons) without damaging the growing crops which are monocotyledons.

One of the greatest triumphs of chemistry in the chemotherapeutic field has been the isolation of penicillin, and the elucidation of its structure, the last details of which were revealed by X-ray analysis, and finally its synthesis.

All these examples, and they are but a few of many, go to show what an effective instrument chemistry has become, working with her sister sciences in revealing both the possible combinations and permutations of the elements of which the world is made, and the nature of the processes associated with living organisms. But in addition, chemists have a great record of achievement in the application of all this accumulated knowledge to the service of mankind. And this brings me to the progress of chemical industry during the last hundred years.

Chemical Industry.

Our industry is, I know, of special interest to the Royal Society of Arts with its wonderful record of almost 200 years of activity devoted to the encouragement of the practical applications of scientific discovery. The progressive stages of civilisation have in fact been largely conditioned by the materials available to mankind. From the Bronze Age to the present age of

light alloys and plastics there has been a steady advance in the exploitation of natural materials to serve the needs of man, and in this the chemist has played the decisive rôle.

Chemical industry in 1841 was still in an embryo stage; it had not yet felt the effects of the great industrial expansion of the nineteenth century, or of the impact of science on industry. It was mainly concerned with the manufacture of acids, alkalis, and mineral salts, with the extraction of natural products like sugar and dyestuffs, and with various fermentation processes.

The first major development came from the progress of organic chemistry. Perkin's discovery in 1856 of mauve, the first synthetic dyestuff, started a new industry. One result was the first displacement of a natural product, when alizarin was synthesised in 1868, and the synthetic material quickly supplanted the cultivation of madder. Baeyer's synthesis of indigo in 1880 again led to the gradual displacement of the indigo crop.

With the rapid advance in the discovery of improved and faster colouring matters and the discovery of synthetic drugs like phenacetin and sulphonal, the organic industry grew rapidly. Although it had started in this country with Perkin, and Germans like Caro and Otto Witt came here to serve their apprenticeship, it was not long before Germany had secured the lead, mainly owing to her lavish investment in research. The scientific basis on which the organic industry had developed undoubtedly had a considerable influence on the development of the chemical industry as a whole.

In the heavy chemical industry the decisive episode in this country was I think the courageous and far-sighted decision of Ludwig Mond and John Brunner in 1872 to use the Solvay process for making soda. Their means were slender and several firms had already had to abandon the process. But Mond saw its possibilities, and for the first two years at Winnington he watched the process by day and night. The scientific control of the plant by which he achieved success and his skill in plant design marked the birth of chemical engineering in this country.

Other major factors were now at work to expand the scope of the industry. First came the demand for artificial fertilisers to meet the food demands of the rapidly growing industrial population. Then the availability of electrical energy from the dynamo gave a new impetus to the use of electrolytic methods to produce metals like aluminium, magnesium, and sodium, and alkali and chlorine, and of the electric furnace to make calcium carbide and other products.

The demand for explosives and the invention of gun cotton, dynamite, and high explosives built up another section of the industry. The peaceful uses of cellulose products—nitrocellulose, cellulose acetate, and viscose—provided another field of development, and in each new field the links between science and industry were drawn closer.

The successes of chemical engineering were achieved by plant design and process control. The design of plant was based on accurate quantitative knowledge of the reactions concerned, on securing maximum heat economy, on the use of an ever-increasing range of anti-corrosive materials, and on the use of the most efficient catalysts. Continuous control of processes was obtained by recording instruments at each stage and by analysis. The study of catalysis led to revolutionary changes first in the manufacture of sulphuric and nitric acids and ammonia and later in the whole range of the industry. The catalytic hydrogenation of vegetable oils was an outstanding contribution towards the supply of the world's demand for fats.

Then came the war of 1914, in which the chemical industry became almost a decisive factor by the production of explosives and fertilisers. In fact, without the Haber process for making ammonia, the blockade would quickly have compelled Germany's surrender. The war thus demonstrated the strategic importance of the chemical industry. To quote a sentence from the report of the Mission which I had the privilege of leading in 1919 to investigate the war uses of the German chemical factories: "In the future it is clear that every chemical factory must be regarded as a potential arsenal, and other nations cannot, therefore, submit to the domination of certain sections of chemical industry which Germany exercised before the war. For military security it is essential that each country should have its chemical industry firmly established". The lesson we learnt then was not forgotten.

As in pure chemistry, the inter-war period was a time of rapid development. The earlier development of synthetic chemistry had largely been in competition with Nature. Steinmetz, the genius of Schenectady, once said to the head of the I.G., "Bosch, I know you can make indigo cheaper than God, you may some day make rubber cheaper than God, but you will never make cellulose cheaper than God".

With the discovery of plastics and the vast possibilities of the synthesis of large molecules there has been some competition with natural products, such as nylon with silk, and synthetic rubber with the plantation product, but much progress has also been made in processing and

upgrading vegetable products, such as cellulose, starch, and vegetable oils, and in the use of farm by-products. The processing of foodstuffs, including crop drying, is another field in which chemical industry and agriculture are establishing a new community of interest. These developments are of great significance, as it means that industry is drawing increasingly on the revenue account instead of the capital account of the world's resources for its raw materials.

I must not omit, however, some reference to the remarkable technical progress of the petroleum industry in the inter-war years. The refining of crude oil was revolutionised by the use of catalysts, and most recently by the use of the so-called fluid catalyst, small particles suspended in a current of the reacting gases. In addition to making petrol of high octane value and other fuels, a new industry has been built up on the hydrocarbon gases from the cracking process and the natural gas from the oilfields. From them an immense variety of chemicals are now made, such as *isooctane*, synthetic rubber, and solvents of all kinds. Under the pressure of autarchy oil was made from coal, by hydrogenation and by the Fischer-Tropsch process, which is now expected to produce petrol and hydrocarbon gases at a price competitive with crude oil, starting from natural gas and using a fluid catalyst.

Once again we have seen how war has tested the resources of the chemical industry, when it proved its ability to produce, at a cost, whatever was needed from the available raw materials, whether it was aviation fuel, rocket fuel, synthetic rubber, or synthetic fibres. Chemical engineers too played a great part in the vast organisation, with all its attendant difficulties, necessary to separate the quantities of uranium 235 and plutonium in the state of purity needed for the atomic bomb. And their work opens up a vista of possibilities of the use of atomic energy for peaceful purposes.

Conclusion.

Thus in its industry, as in pure science, chemistry has a great record of achievement. Looking back at the state of knowledge when our Society was founded here in 1841, we see a wonderful century of progress. And in this the Fellows of the Society have always played a leading part. But it is well to remember that that swift advance has depended on the efforts of men in many countries working together with a common aim, with no tariffs or visas to hinder the flow of new ideas.

And I cannot help reflecting on the contrast between this record of achievement and the sorry state of the world to-day. Is it not paradoxical that with the understanding we have won of Nature's secrets, with our power to control nature in action, that the majority of mankind should still be suffering from malnutrition and many from endemic disease? This seems to me a challenge to science and not least to chemists. Is sufficient effort being devoted to the application of the knowledge we already possess? What should be the priorities? How can we ensure that the same concerted effort is made to use that knowledge for the peace and contentment of the world as made it such a potent factor in the war? That is the thought I would leave with you at the beginning of our second century.

The Development of Electrochemical Theories of the Course of Reactions of Carbon Compounds.

THE EIGHTEENTH FARADAY LECTURE, DELIVERED BEFORE THE CHEMICAL SOCIETY ON
JULY 16TH, 1947.

By SIR ROBERT ROBINSON, M.A., D.Sc., LL.D., P.R.S.

THERE are many tributaries to the river of scientific progress, and their contribution to the broad stream persists in spite of inevitable loss of individual form.

So, the modern theories of molecular structure and chemical reactions which flourish in the domain of physical chemistry, thermodynamics, and wave mechanics, are derived from many sources. It is my intention to speak of only one of these, namely that provided by the generalisations of their experience which organic chemists have been able to make in terms of the electronic conception of valency.

That these generalisations were a real forward step cannot be doubted, but the form in which they were expressed has naturally been altered in accordance with the successive advances in our knowledge of the fundamentals of chemical kinetics and atomic and molecular theory.

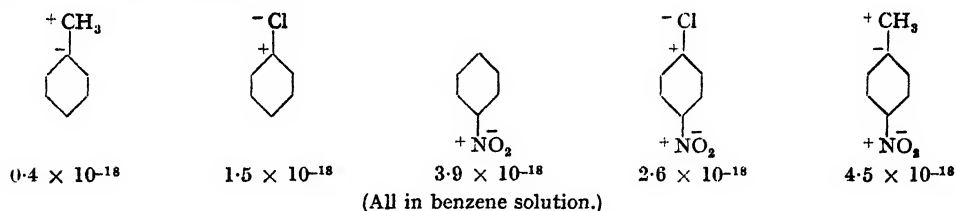

The identity of the ideas has not yet been lost, however, and the qualitative approach still affords a valuable framework for the elaboration of detail by means of the more searching methods of analysis which are now available. But the section of the subject that I have indicated is small only in relation to the whole; it is very complex in itself and is the outcome of developments in varied fields of work. It will be convenient to follow the thread suggested by the lecturer's contacts with the topic and by precedent and parallel investigations, but it is certain that, by a change of emphasis, many different lectures could be delivered under the same title.

After the discovery of the electron by Sir Joseph Thomson and the successive stages in the formulation of the electrical theory of the constitution of matter, the conceptions of the nature of chemical affinity and valency bonds were gradually adjusted, and attempts were made to explain the chemical properties of molecules as assemblages of electrons and positively charged nuclei. Some kind of electronic theory of valency became almost axiomatic, but, as the development showed, there was ample scope for divergent views of details of structure, of the nature of the forces involved, and of the interpretation of physical and chemical properties. The idea of covalency, the sharing of electrons by two nuclei, was adumbrated by Ramsay in 1908. Thomson and Stark developed more detailed theories, and were among the first to attack problems of organic chemistry on an electronic basis.

The speculative elaborations of Stark ("Die Elektrizität im chemischen Atom", Leipzig, 1915), who also advanced electronic explanations of optical properties, have not survived in their original form. Many of his suggestions may, however, be traced in later theories. A second epoch may be roughly defined as that of Kossel (*Z. Physik*, 1920, **1**, 395) and of Lewis (*J. Amer. Chem. Soc.*, 1916, **38**, 762; "Valence and the Structure of Atoms and Molecules", Amer. Chem. Monograph, 1923), characterised, at least in its earlier phases, by somewhat rigid conventions in regard to the chemical bond, and by great advances in our knowledge of the relation of structure to physical properties. In the third and present period the applications of wave mechanics are yielding more precise information in regard to the distribution of electrons in the molecules. In certain cases that distribution can even be determined from experimental observations of the reflexion of X-rays by crystals. These matters lie outside the purview of the present lecture. Indeed, the symbols which we still employ are largely independent of stereo-electronic considerations. The exceptions are those used for the polar molecules, to the study of which Debye has made such outstanding contributions, and for the ions, that is to say the bound and free ions. At every stage of the electrochemical theory these are our trusted guides.

Langmuir pointed out that trimethylamine oxide, formed from electrically neutral NMe_3 and an uncharged oxygen atom, must be $\text{Me}_3\text{N}^+\text{O}^-$ by the arithmetic of the electrons, and Sidgwick extended the idea to include many compounds containing the co-ordinate link $\text{A} \xrightarrow{(+)} \text{B} \xleftarrow{(-)}$ ("The Electronic Theory of Valency," Oxford, 1927). The existence of these dipolar groups has been fully established by experiment and has been correlated with a range of physical and chemical properties. The knowledge has been used to confirm the assumed orientation

of electrostatic doublets produced by simple substitutions. For example, on theoretical grounds Thomson showed that such a doublet should be present in the group C-Cl, and this is confirmed by the fact that methyl chloride has an electric moment, 1.97×10^{-18} e.s.u., in the gaseous state. The direction of the moment is shown by a comparison of the dipole moments (e.s.u.) of chlorobenzene, nitrobenzene, and *p*-chloronitrobenzene, because NO_2 , a dipole like an amine oxide, must be N^+O_2^- .

It is clear that the separate dipole moments due to C-Cl and C- NO_2 are in opposite directions in the molecule, or in other words they are in the same direction with respect to the nucleus. Substitution of methyl for hydrogen in the aromatic nucleus produces a small dipole moment in the opposite sense. We denote these displacements by the symbols :

Both Thomson and Lewis assumed that such doublets would exert an effective field, either directly or by induction through a chain of atoms, and gave in illustration the greater strength of the chloroacetic acids as compared with acetic acid. The operation of the electrical field on the carboxyl group will obviously enhance the stability of the anion produced by electrolytic dissociation. As expressed by Lowry the sheath of electrons moves towards the chlorine atom and thus bares the nuclei of the oxygen atoms, enhancing their repulsion on the attached proton.

Lewis pointed out that the effect diminishes as the chlorine atom is removed from the carboxyl. Thus α -chloropropionic acid is about as strong as chloroacetic acid, but β -chloropropionic acid is much weaker. γ -Chlorobutyric acid is still weaker, and the effect is hardly discernible in δ -chlorovaleric acid.

Dippy and R. H. Lewis (*J.*, 1937, 1008) noted an almost linear relation between the dipole moments and the electrolytic dissociation constants of a number of acids.

In the series of the dibasic acids we can study the effect of one carboxyl on the strength of another at varying distances.

Ionisation constants of dibasic acids.

	K_1	K_2
$\text{CO}_2\text{H}\cdot\text{CO}_2\text{H}$	7×10^{-2}	$3\text{--}7 \times 10^{-5}$
$\text{CO}_2\text{H}\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$	$1\cdot46\text{--}1\cdot63 \times 10^{-3}$	$2\cdot1(1\cdot4) \times 10^{-6}$
$\text{CO}_2\text{H}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$	$8\cdot1 \times 10^{-5}$	$3\cdot7 \times 10^{-6}$
$\text{CO}_2\text{H}\cdot[\text{CH}_2]_3\cdot\text{CO}_2\text{H}$	$4\cdot7(6\cdot9) \times 10^{-5}$	$2\cdot9 \times 10^{-6}$
$\text{CO}_2\text{H}\cdot[\text{CH}_2]_4\cdot\text{CO}_2\text{H}$	$3\cdot7 \times 10^{-5}$	$2\cdot4 \times 10^{-6}$
$\text{CO}_2\text{H}\cdot[\text{CH}_2]_5\cdot\text{CO}_2\text{H}$	$3\cdot23 \times 10^{-5}$	$4\cdot4 \times 10^{-6}$
$\text{CO}_2\text{H}\cdot[\text{CH}_2]_6\cdot\text{CO}_2\text{H}$	$2\cdot5 \times 10^{-5}$	$2\cdot4 \times 10^{-6}$
$\text{CO}_2\text{H}\cdot[\text{CH}_2]_7\cdot\text{CO}_2\text{H}$	$2\cdot7 \times 10^{-5}$	$2\cdot5 \times 10^{-6}$
	$1\cdot3 \times 10^{-3}$	$3\cdot4\text{--}5\cdot8 \times 10^{-6}$
	$2\cdot9 \times 10^{-4}$	$2\cdot4 \times 10^{-5}$
	$1\cdot5 \times 10^{-4}$	
$\text{Ph}\cdot\text{CO}_2\text{H}$	$6\cdot5 \times 10^{-5}$	

It is apparent that $\cdot\text{CO}_2\text{H}$ behaves like $\text{C}\cdot\text{Cl}$. As Thomson's electrostatic argument suggests,* it must be represented as $\overset{\delta+}{\text{C}}\overset{\delta-}{\text{O}}_2\text{H}$, and it is electron-attracting. But after dissociation the group becomes $\text{--}\bar{\text{CO}}_2$; there is now no question of a dipole,† but only of a negative charge which should repel electrons and conversely hold protons even at a distant point. The second dissociation constants clearly show that this anticipated reversal of the effect occurs.

The values quoted for K_2 are not always strictly comparable with one another, or with those for K_1 . The second dissociation constants were in some cases determined at 100° by the method of inversion of sucrose (cf. Smith, *Z. physikal. Chem.*, 1898, 25, 220). It may be noted that E. Q. Adams (*J. Amer. Chem. Soc.*, 1916, 38, 1503) has shown that if the first dissociation had no effect on the second, K_2 should be one-fourth of K_1 . When the carboxyl groups are far removed from one another, this relation was found to hold approximately (cf. Chandler, *J. Amer. Chem. Soc.*, 1908, 30, 694).

The case of isomeric acids differing in stereochemical configuration is particularly convincing.

Ionisation constants of stereoisomeric dibasic acids.

	K_1	K_2
$\begin{array}{c} \text{CH}\cdot\text{CO}_2\text{H} \\ \\ \text{CO}_2\text{H}\cdot\text{CH} \end{array}$	$9\cdot8 \times 10^{-4}$	$2\cdot7 \times 10^{-5}$
$\begin{array}{c} \text{CH}\cdot\text{CO}_2\text{H} \\ \\ \text{CH}\cdot\text{CO}_2\text{H} \end{array}$	$1\cdot3 \times 10^{-2}$	$2(2\cdot6) \times 10^{-7}$
$\begin{array}{c} \text{CMe}\cdot\text{CO}_2\text{H} \\ \\ \text{CO}_2\text{H}\cdot\text{CH} \end{array}$	$8\cdot5 \times 10^{-4}$	9×10^{-6}
$\begin{array}{c} \text{CMe}\cdot\text{CO}_2\text{H} \\ \\ \text{CH}\cdot\text{CO}_2\text{H} \end{array}$	$3\cdot8 \times 10^{-3}$	$2\cdot4 \times 10^{-7} (100^\circ)$

The *cis*-acids are much the stronger as monobasic acids but they are far weaker in the second ionisation step. The ratio of K_1 to K_2 for fumaric acid is about 36 and for maleic

* However, in opening a discussion on these topics in 1923 (Faraday Society) Sir Joseph Thomson classed Cl , OH , NH_2 , and CH_3 together ($\overset{+}{\text{C}}\text{--}\bar{\text{Cl}}$) and distinguished their effect from that of CN and NO_2 ($\bar{\text{C}}\text{--}\overset{+}{\text{CN}}$). This view appears to have been based on some kind of alternation and disregards the inductive transmission of the field of a doublet. Thus $\bar{\text{C}}\text{N}^+$ distributes a positive field over the atoms to which it is attached and, of the groups mentioned, $\bar{\text{CH}}_3$ is the only one that produces a negative field.

† This is not true of the sulphonic ion, SO_3^- . Thus K_2 for *p*-sulphobenzoic acid is $1\cdot4 \times 10^{-4}$ ($>K$ for $\text{Ph}\cdot\text{CO}_2\text{H}$, $6\cdot5 \times 10^{-5}$). There is other evidence that SO_3^- distributes a positive electric field over an attached group, and this is clearly due to its constitution $\text{--}\overset{+}{\text{S}}\overset{+}{\text{O}}_3^-$, the nearer double positive charge being more effective than the more remote triple negative charge.

acid about 50,000. Attention should be paid to the order of the phenomena only, as, apart from the experimental difficulties, the interpretation is complicated by the possibility of differences of solvation of the acids and their ions.

Many of these facts were established by the work of Walker, Ostwald, and Bone, Sprankling, and Sudborough fifty to sixty years ago, and Ostwald gave the acceptable explanation of them in general terms (*Z. physikal. Chem.*, 1889, **3**, 177).

The whole problem of the strengths of acids and bases (where the effects are naturally reversed) can be satisfactorily treated along similar lines, but, as Flürscheim was the first to show (*J.*, 1909, **95**, 718; 1910, **97**, 84), steric hindrance must be taken into account in many cases, for example in *o*-substituted benzene derivatives. We may regard the dissociation constant of a carboxylic acid as a measure of the electrical field over the dissociating group, provided that approach of solvent molecules is not hindered by steric conditions.

I have dwelt at some length on this clear case because of its historical importance and in order to place in juxtaposition with it, experimental results from which it can be seen that exactly analogous phenomena control the nitration of certain benzene derivatives in the *o*-, *p*-, or *m*-positions with respect to a substituent. With the acids we have an ionic equilibrium and the effect of an electric field is not surprising. But in the nitration case we have an effectively irreversible process and no obviously ionic reaction.

The work of Vorländer showed that the direct attachment of an 'onium group to the benzene nucleus gives substances that nitrate exclusively in the *m*-position (*Ber.*, 1919, **52**, 262, 274; Vorländer and Siebert, *ibid.*, p. 283). This may be compared with the *m*-nitration of nitrobenzene (benzoic acid, benzenesulphonic acid, etc.):

The "'onium" atom need not be nitrogen but may be sulphur, selenium, phosphorus, arsenic, antimony, bismuth, lead, or even iodine [Vorländer and Büchner, *Ber.*, 1925, **58**, 1898 (I); Vorländer and Schroedter, *ibid.*, p. 1900 (Bi, Pb); Michaelis and Soden, *Annalen*, 1885, **229**, 324 (a P compound not quite analogous); Ingold, Shaw, and Wilson, *J.*, 1928, 1280 (P, As, Sb); Baker and Moffitt, *J.*, 1930, 1722 (S, Se)].

The interpretation given by Vorländer laid emphasis on the direct union of the "'onium" atom to the nucleus and is no longer considered valid.

In 1902 Schultz and Bosch (*Ber.*, 1902, **35**, 1292) stated that phenylbenzylethylamine nitrated in the *m*-position in the benzyl group, and Noelting and Kregec (Bull. Soc. chim., 1916, **19**, 355) recorded the *m*-nitration of benzyldiethylamine, both in strongly acid solution. The significance of these isolated observations was not quickly recognised, mainly because there was no orientation theory that was generally considered satisfactory. A few years later interest was awakened and an active discussion arose in this country on the question of the actual substance that nitrates in the *m*-position. Was it the base or the salt? This was settled in favour of the latter view by Ing and the lecturer (*J.*, 1926, 1655) who found that benzyltrimethylammonium nitrate furnished nearly 90% of the *m*-nitro-derivative. In this quaternary salt the existence of free base is naturally impossible. The paper was entitled "The orienting influence of free and bound ionic charges", and the *m*-nitration in this and other cases was attributed to an electrical field produced by the cation over the molecule. The result was of great importance because it demonstrated that the charged centre need not be directly connected to the nucleus.

In a footnote it was stated that the work would be extended to β -phenylethyltrimethylammonium nitrate and γ -phenylpropyltrimethylammonium nitrate in order to determine the influence of the length of chain separating the charged centre and the nucleus. Even in the former case the nitration was chiefly in the *p*-position. Quantitative details of these and other examples were later provided by the extensive work of Ingold and his school.

It was found that, when a cationic charge is separated by a methylene group from the benzene ring, the nature of the 'onium atom is significant. Other things being equal the heavier atoms are the less effective, possibly because the distance from the aromatic nucleus is increased by their larger radius and the nuclear positive charge is more diffuse. Examination of the results demonstrates conclusively that the proportion of *m*-nitration is dependent on the intensity of the positive electric field over the nucleus.

R = CH₃·NMe₃⁺, 88%;¹ R = CH₃·CH₂·NMe₃⁺, 19%;² R = CH₃·CH₂·CH₂·NMe₃⁺, about 5%;³ R = PMe₃⁺, 100%;⁴ R = CH₃·PMe₃⁺, 10%;⁴ R = AsMe₃⁺, 98%;⁴ R = CH₃·AsMe₃⁺, 3·4%;⁴ R = SbMe₃, 86%;⁴ R = SMe₂⁺, 100%;⁵ R = CH₃·SMe₂⁺, 52%;⁵ 2-phenylbenzopyrylium salts⁶ and 2-phenylquinoline metho-salts,⁷ only *m*-nitro-derivatives were isolated, and in high yield.

¹ Ing and Robinson, *loc. cit.*; Goss, Ingold, and Wilson, *J.*, 1926, 2240. ² Goss, Hanhart, and Ingold, *J.*, 1927, 250. ³ Ingold and Wilson, *J.*, 1927, 810. ⁴ Goss, Ingold, and Wilson, *loc. cit.* ⁵ Baker and Moffit, *loc. cit.*; Pollard and Robinson, *J.*, 1930, 1765, found Ph·CH₂·SEt₃⁺, *m*-nitration, 28%. This fall, as compared with the benzyldimethylsulphonium salt, is probably due to reduction of the positive 'onium field of sulphur by a negative field due to the methyl groups. ⁶ Le Fèvre, *J.*, 1929, 2771. ⁷ Le Fèvre, *J.*, 1930, 2236.

Flürschheim and Holmes (*J.*, 1926, 1562) and Pollard and Robinson (*J.*, 1927, 2770) found cases in which the electrostriction of the cations by added salts diminished the percentage of *m*-nitration. Thus benzyldiethylamine in an excess of sulphuric acid gives 53·5% of the *m*-derivative. When ammonium sulphate was added the proportion fell to the region of 33%. The nitration of benzylpiperidine in nitric acid (*d* 1·5) gives about 70% of the *m*-nitro-base, and addition of trimethylammonium nitrate or rubidium nitrate, salts which are soluble in nitric acid, caused progressive reduction as more of the salts was added, until only about 20% of the *m*-derivative was produced. It was suggested that the accessibility of, for example, a sulphonium cation to electrostriction may be a part of the cause of the less intense field (as compared with a corresponding ammonium cation) that it exerts over the aromatic nucleus.

It was pointed out long ago by Holleman ("Die direkte Einführung von Substituenten in den Benzolkern", 1910, p. 469) that predominant *op*-substitution occurs at a higher rate and under milder conditions than predominant *m*-substitution.

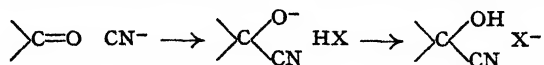

This is easy to understand in the series which has been discussed because the recent work of Bennett and Ingold and their collaborators has indicated that the effective nitrating agent, at least in sulphuric acid solution, is the nitroxyl ion, NO₂⁺. Obviously this will be repelled by a positive field and will enter the molecule the more easily the less intense the field. The relation indicated by this example is general and is often diagnostic of an ionic type of reaction. In regard to the actual rates in different cases Wibaut (*Rec. Trav. chim.*, 1915, 84, 241) found the order C₆H₅·CH₃ > C₆H₆ > C₆H₅Cl > C₆H₅Br in acetic anhydride solution. Using the method of competitive nitration, Ingold and Shaw (*J.*, 1927, 2918) calculated from their results that each *o*- and *p*-position in toluene is roughly thirty times as reactive as in benzene, and each *m*-position about twice as active as one of the positions in benzene. The ratio R_{C₆H₅R}/R_{C₆H₆} was found to be R = I, > 1; R = Br, 0·2; R = Cl, 0·01; R = F, 0·002. Ingold, Lapworth, Rothstein, and Ward (*J.*, 1931, 1959) working under somewhat different conditions increased the figures for toluene and found that one of the *m*-positions is about three times as active as one position in benzene. Although the assumptions made in the calculations hold only approximately and may be arguable, the general trend of the phenomena was established. It is in agreement with the theory outlined that the *m*-position of toluene should be activated (see below).

Excluding the cases (conjugated systems) considered later, all the data on benzene substitution can be shown to be in harmony with these principles. If we withdraw electrons from the nucleus as by substitution of halogens, nitro-groups, carboxyl groups, etc., for hydrogen in the side-chain we augment *m*-nitration. Introduction of methyl groups into the side-chain augments *op*-nitrations. Nitration has been studied very extensively but enough is known of sulphonation and halogenation to demonstrate that the orientation in these processes follows the same general lines. In order to be able to discuss why *m*-nitration occurs under the influence of a positive electric field, it is necessary to study other aspects—the reagents, and the behaviour of unsaturated systems.

The Classification of Reagents as Anionoid and Cationoid.—These terms introduced by Lapworth (*Manchester Phil. Soc.*, 1925; cf. *Nature*, 1925, 115, 625) implied that certain electrically neutral molecules exhibit reactions of ionic type. Thus the hydroxyl ion combines with a proton to form water, and when water combines with a proton to form the solvated hydrogen ion, the process is evidently analogous. Hence the water molecule is said to be anionoid or to be an anionoid complex. The terms are equivalent to electron-donor and electron-acceptor and also to Ingold's expressions nucleophilic and electrophilic, respectively.

When a neutral molecule is attacked by an ion, the site of a cationoid or anionoid position is easily located, and it was just such a case that led Lapworth to develop his system of incipient

alternate polarities. The reference is to the formation of cyanohydrins which were conclusively demonstrated, qualitatively and by kinetic studies, to result from the attack of cyanide ion on a carbonyl group. The resulting complex ion then takes a proton from a suitable source, such as water or an alcohol, or even from a molecule of hydrocyanic acid:

Thus pure hydrocyanic acid does not combine with aldehydes or ketones, but the alkali from a glass vessel is sufficient to start the succession of processes.

Hence the carbon of the carbonyl group is said to be "cationoid". All the characteristic reactions of carbonyl compounds conform to this view. By analogy we also class many similar groups as cationoid, for they evidently undergo the same type of reactions. These include carboxyl and especially the carboxylic ester group, the cyano- of nitriles, nitrosyl and nitroxyl groups.

The cationoid character of the carbon of -CO- could be deduced theoretically from the fact that oxygen has a greater affinity for the negative charge than carbon, but there is no such guide in the case of the carbon-carbon double bond, and a conclusion had to be based on what was already known of the characteristic behaviour of olefins. This knowledge was sufficient for the purpose but it was eked out by specifically designed tests, among which may be mentioned Gilman's demonstration that olefins are inert towards organometallic compounds.

Consideration of the reactions of the olefins showed that in general and under ordinary conditions, they are easily attacked by cations and cationoid reagents but are relatively inert to anions and anionoid reagents. They were therefore regarded as anionoid. But this only means that their additive reactions are *usually initiated* by electron-donation to reagents; there must always be a subsequent process in the course of which the second carbon of the system evinces cationoid character.

In the formation of cyanohydrins it is clear that the group $>\text{C}=\text{O}$ becomes $>\text{C}^+\text{O}^-$, and any part of this full displacement of an electron pair is conveniently represented by the symbols $\text{>}\overset{+}{\text{C}}=\text{O}$ or $\text{>}\overset{\delta+}{\text{C}}=\overset{\delta-}{\text{O}}$. Similarly any part of the full displacement of a pair of electrons in an olefin can be represented as $\text{>}\overset{+}{\text{C}}=\overset{-}{\text{C}}<$. The difference is that whereas the carbonyl is cationoid at (a) the olefin is anionoid at (b). There is complete analogy between the reactions of the olefins and those of the aromatic compounds which tend to retain their type, and therefore benzene, and all similar substances, are also classed as anionoid.

Saturated carbon, midway between lithium and fluorine, has little or no intrinsic tendency to be either anionoid or cationoid. Therefore alkyl groups exhibit either behaviour in accordance with the electrochemical character of the group or atom to which they are united. Thus a chlorine atom holds the covalency electrons tenaciously and tends to separate as an ion. An attached alkyl group is consequently cationoid. But metals easily relinquish electrons and hence the alkyls of organometallic compounds are anionoid.

The annexed table requires little further explanation and can, of course, be greatly extended.

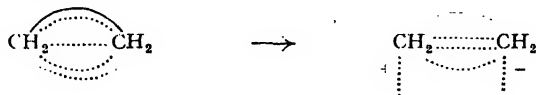

Anionoid.	Cationoid.
<i>Nucleophilic.</i>	<i>Electrophilic.</i>
<i>Electron-donating.</i>	<i>Electron-accepting.</i>
Active anions (OH^- , CN^- , etc.).	Active cations (H_3^+O , ϕN_3^+).
Anionoid complexes with unshared electrons (R_3N , ROH , etc.).	Atoms with incomplete electron configurations (neutral O; Co, Pt, etc.; BF_3 , AlCl_3).
Reducing agents ($\text{Fe}^{++} \longrightarrow \text{Fe}^{+++}$).	Oxidizing agents [$\text{Fe}(\text{CN})_6^{4-} \longrightarrow \text{Fe}(\text{CN})_6^{3-}$].
Metals as electron sources.	Halogens, nitric acid (in nitration), sulphuric acid (in sulphonations).
R in R_3Zn , RMgX , etc.	R in RCl , R_2SO_4 , NR^+ , etc.
$\text{:C}\equiv\text{C:}$, C_6H_6 , etc.	$\text{:C}\equiv\text{O}$ (at carbon), etc.
Free radicals.	Free radicals.

In all the classes the various representatives can be arranged in order of reactivity, and one general principle is that unshared electrons are better donors, the smaller their number.

to be the case, and it would also react with anionoid reagents. But once the electron donation from an ethylene molecule has commenced, strain is relieved, and the process can be continued. Hence the full displacement is assumed to occur only in the course of the reaction. Again the process is not one of interaction with halogen cations but with halogen molecules, because the concentration of the former, if they are present at all, must be extremely low and the kinetics would be inexplicable. Finally the concentration of hydroxyl ions in the strongly acid solution is certainly exiguous.

The Conjugated Systems.—(1) *Polyenoid.* In 1911 Hugo Kauffmann ("Die Valenz Lehre", Enke, Stuttgart) developed a theory of partial and distributed valency which he applied with success to the problem of auxochromes and to the constitutions of benzene and the triphenyl-methane dyes. He appears, however, to have regarded chemical affinity as a special kind of force and speaks of the valence fields becoming electric fields, if electrons are interposed. In other respects too, and particularly in the development, Kauffmann's views differed from those that the lecturer developed from 1916 (*J.*, 1916, 109, 1032, 1041; 1917, 111, 959; 1918, 113, 643; *Mem. Manchester Phil. Soc.*, 1920, 64, No. 4) and which were translated in 1922 into definite electronic symbols (Kermack and Robinson, *J.*, 1922, 121, 427).

It was postulated that a valency bond could be subdivided, to an unknown but large extent, and it was further assumed that molecules are polarised by such partial division of the bonds. The polarised complexes enter into reactions. Thus taking four subdivisions of a bond, for convenience only, the activation of ethylene was represented as

With this polarised form the reaction, say addition of bromine, could be initiated and it was supposed to be completed in the course of the process by further division and rearrangement of the valencies. This view differed from that of Thiele in that the partial valencies were derived from the normal valencies and were not additional to them. The schemes for butadiene illustrate this contrast of which the most significant aspect is the assumption of polarisation:

Here the signs on C^β and C^γ represented the polarity of the partial valencies from which the central partial bond was derived. It was an error to retain these signs after the part bond was formed, but the convention gave the right results in more complex systems.

Although these ideas were based from the commencement on the electronic theory of valency, use was made for some years of the partial polarised valency expressions. It was realised that the partial valencies labelled (−) represent available electrons, or part of an electron, and that those labelled (+) represent corresponding electron defect. Therefore the equivalent electronic symbol for polarised butadiene is:

This implies that a certain electron value, possibly quite a small fraction of one electron, becomes free on C^δ and that the resulting electron defect on C^γ is made up by the transfer of a corresponding electron fraction from the $C^{\alpha\beta}$ bond to $C^{\beta\gamma}$, and that this produces a corresponding electron defect on C^α . A very important feature of this representation is that, apart from the inevitable electron defect on one carbon atom, the number of quantised electrons in the configurations of the carbon atoms is unchanged. The mechanism of addition to this system will then be precisely analogous to that already discussed for ethylene. It will be noticed that the process transfers electron defect from C^γ to C^α but this event does not *always* occur. The left-hand arrow need not come into operation and, as experience shows, we may observe $\gamma\delta$ (or $\alpha\beta$) additions. It is obvious, and was clearly stated, that a double bond can transmit *any* effect of electron accession or recession and one or more double bonds can there-

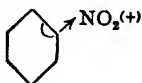

fore be interpolated in any system AB such that the quality of reactivity exhibited is due to a displacement of electrons from A to B, directly, or through an external circuit.

Much later Fuson (*Chem. Reviews*, 1935, 16, 1) called this the "Principle of Vinylogy". It is a theoretical potentiality which is not always realised in practice. The effects may be greatly damped, and there are special exceptions such as $R\cdot Cl$, $R\cdot CH=CH\cdot Cl$, the cause of which is apparent.

The polarised complexes of which butadiene is the type are called *polyenoid*. They include benzene and other aromatic hydrocarbons.

We are now in a position to consider why an electric field over the benzene nucleus should produce *op*-substitution or *m*-substitution according to its direction and intensity (Allan, Oxford, Robinson, and Smith, J., 1926, 409).

The reagent in nitration is cationoid; * it is looking for electrons. Therefore the first stage of the nitration of benzene could be represented as :

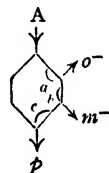

The second stage is the removal of the proton at the point attacked. That is also important but need not enter into the present discussion.

Now suppose we have a group (A) which promotes electron accession to the nucleus and a

general drift or repulsion of electrons as shown in the figure. Its effect will be a maximum at the carbon atom to which it is attached and less work will be needed to effect the polarisation (a) than (b) or (c) :

Thus *o*-substitution can be expected. If the reagent approaches the *m*-position substitution may occur through the independent operation of (b) but it will be far less facile. But if the reagent approaches the *p*-position and enters into tentative union with it, the defect on the *m*-carbon can at once be made up by a conjugative process (d) which will be favoured by the same circumstances that helped (a) :

Thus the push from (A) promotes *o*-substitution directly and *p*-substitution by conjugation. It is important to note that the process (b) cannot be assisted in a similar fashion, because in the expression

the number of electrons in the configuration of the *m*-carbon is increased.

We have seen that methyl is an (A) group; the percentage of *m*-nitration of toluene is 4 and the ratio of *o*- to *p*-nitration is about 3 : 2 (*o*-, 59% ; *p*-, 37%).

* It is not certain that NO_2^+ is the sole nitrating agent; electrically neutral cationoid complexes are probably operative under appropriate conditions.

A group (B) which attracts electrons is equivalent so far as the field effect is concerned to an imaginary (A) group at the *p*-position:

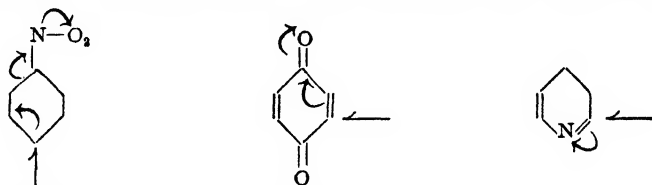

Hence by the argument already given we anticipate *op*-substitution with respect to (A). That is, *m*-substitution with respect to (B), or displacement of that group by the substituent. The latter phenomenon is often encountered.

Naturally this use of the imaginary (A) group must not be pressed too far. The group (B) is real and by its positive electric field it renders all the nuclear electrons less available and reduces the ease and velocity of the substitution reaction.

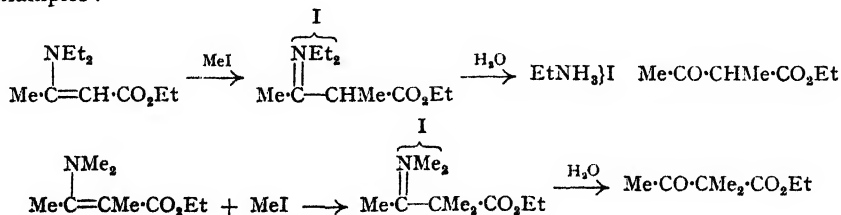

(2) *Catio-enoid*. The cationoid reactivity of the carbon of a carbonyl group has been attributed to the electronic displacement >C=O . This can be conjugated with a double bond and thereby the quality of reactivity of a carbonyl is transferred to a carbon of the ethenoid system C=C-C=O . It is another example of the $\alpha\gamma$ rule. Thus a cyanidion attacks the γ -carbon (usually denoted as β) in an unsaturated ketone. Consideration of these and similar cases led Lapworth (1920) to formulate his theory of alternate polarities expressed: $\text{C}^+=\text{C}^--\text{C}^+=\text{O}$. In this way he merely indicated the polarities which the various atoms seemed to display at the moment of reaction. The device led to some useful and interesting results but it was certainly taken too literally, and Lapworth's clearly stated reservations were often overlooked by other workers. Later (1922) he adopted a view similar to that suggested by the lecturer, but this was presented in a very general form which was somewhat difficult to assimilate.

In the aromatic series, catio-enoid systems may lie outside the nucleus, partly in the nucleus, or wholly in the nucleus. They give rise to typical reactions with *anionoid* reagents:

Examples are the hydrolysis of nitrosodimethylaniline and 1-chloro-2:4-dinitrobenzene, the amination and hydroxylation of nitrobenzene, quinones, and pyridine, etc. etc.

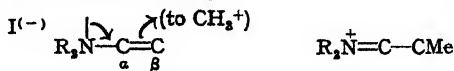

(3) *Hetero-enoid*. H. Decker (Decker and Klauser, *Ber.*, 1904, **37**, 523; Decker, *Ber.*, 1905, **38**, 2893) suggested that tervalent nitrogen could be conjugated with a double bond, and employed the Thiele symbol: $\text{C}=\text{C}-\text{N}^{\cdot}$. The experimental basis of the divided addition concerned only the action of acids and therefore the mobile proton. The lecturer (*J.*, 1916, **109**, 1038) showed that alkyl groups could be used to mark the position of combination as in the examples:

This latter case excludes the hypothesis

The basic nitrogen attached to the double bond has transferred, to unsaturated carbon, its own power of combining with a cationoid methyl group. The facts were established in the partial valency period and expressed in terms of that hypothesis. The electronic translation (1922) is much simpler and more convincing.

The unshared electrons (lone pair) of the nitrogen atom are used to increase the covalency with the nearest unsaturated carbon C α . This must release electrons of the double bond to C β which can thus bind the methyl group. At the same time the nitrogen acquires a positive charge to balance the iodion, for it started with unshared electrons which became shared in the process.

It is quite clear that this system must be definitely anionoid or electron donating. For though olefins are anionoid the tervalent nitrogen is far more strongly so, and here the nitrogen atom endows the unsaturated group with something of its own quality. Furthermore this type of conjugation is possible if the nitrogen atom is replaced by any atom which carries unshared electrons, and the order of activation will be that of the proton-affinity (or basic strength) of the hetero-atom: the greater that affinity the more reactive will be the anionoid carbon. Thus $\text{N}^- > \text{O}^- > \text{N} > \text{O} > \text{I} > \text{Cl}$ to mention a few of the possibilities. The C-alkylation of the sodio-derivative of ethyl acetoacetate which is derived from the enolic form, is seen to be analogous to the C-alkylation of the β -aminocrotonic esters. The most important examples are in the aromatic series, *e.g.*, the phenoxide ion, the aromatic amines, phenols and their ethers, halogenobenzenes. All the characteristic nuclear reactions of phenols and amines, *e.g.*, bromination, nitration, condensation with carbonyl compounds, etc., are with cationoid reagents, and all occur exclusively in the *op*-position. The conjugations

provide a much more definite mechanism of activation than that previously considered, and they take precedence over other effects. It has been suggested by J. W. Baker and Nathan (*J.*, 1935, 1845) that a methyl group can release electrons in a somewhat similar fashion:

The relation of this suggestion to the use of unshared electrons in the systems under discussion is not yet clear.

The case of chlorobenzene is very interesting because its nitration, for example, is far less facile than that of benzene itself. This was to be expected, for chlorine is known to be an electron-attracting group as we have already seen:

All the electrons of the nucleus are less available than they are in benzene. But even at this low level of reactivity the conjugative process determines where the donor electrons are to be found (see below, mesomerism).

Other important hetero-enoid systems are recognised in such substances as pyrrole, and account for the correspondence of its reaction types with those of phenol and dimethylaniline:

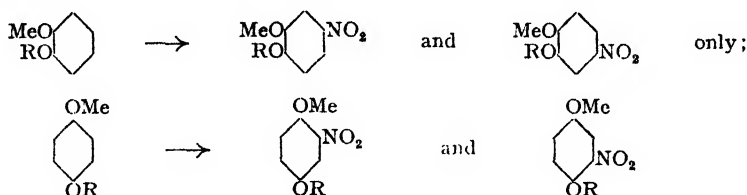

The α -positions are like the p -position in aniline, whereas the β -positions resemble the o -positions in aniline. They are all reactive as shown by the formation of tribromoaniline on the one hand and tetraiodopyrrole on the other.

The recognition of two kinds of conjugated changes of covalency with simultaneous increase or decrease of the unshared electrons of atoms such as oxygen or nitrogen as in

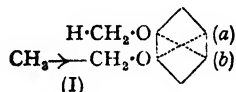

must be regarded as one of the milestones on the road we have travelled.

An Example of the Interaction of the Conjugated Polarisation and General Electric Effects.—A very important aspect of the lecturer's views was experimentally illustrated by a carefully selected case (three preceding papers were discussed by Allan, Oxford, Robinson, and Smith, *loc. cit.*; Lea and Robinson, *J.*, 1926, 411; Oxford and Robinson, *J.*, 1927, 2239; Fawcett and Robinson, *J.*, 1927, 2415; Clarke, Robinson, and Smith, *J.*, 1927, 2647; Smith, *J.*, 1931, 251). This was the mono-nitration of alkyl ethers of catechol and quinol (OMe, OR) which proceeds quantitatively. The proportions of the products can be determined accurately by thermal analysis.

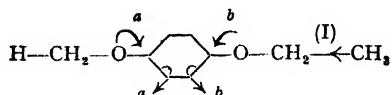

If we consider the case of the ethyl ether of guaiacol, there are two hetero-enoid systems directing p -substitutions as indicated by the dotted lines :

The oxygen of the methoxyl group directs the substituent to (b), that of the ethoxyl group to (a). In the ethoxyl group a hydrogen of the methoxyl group is replaced by methyl, and this, as we know from strengths of acids and bases and from the dipole moment of toluene, will repel electrons relative to the effect of hydrogen. Hence the system terminating in (a) should be reinforced and the directive power of ethoxyl should exceed that of methoxyl; which is actually found to be the case. Taking MeO, 100 we find EtO, 135. But on increasing the size of R in OR, the directive power rises to a maximum and then falls: Pr^oO, 150; Pr^oO, 128; *n*-BuO, 123.

The effect (I) (inductive or general) is evidently also exerted on the oxygen of the methoxyl as the stereochemical conditions suggest that it should be, and the distributed direct effect partly neutralises that exerted through the chain. But in the quinol series this is no longer true :

The push of the methyl now assists (b) and actually opposes (a). Hence the directive power of EtO (164) is higher than that found in the catechol series. And with larger groups it continues to increase (Pr^oO, 180; *n*-BuO, 186; *n*-C₁₆H₃₃O, 212).

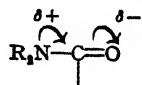

An electron-attracting group is p -nitrophenyl, and here the circumstances are reversed. In the catechol series NO₂·C₆H₄·CH₂O, 67, and in the quinol series, 38. The distributed pull on the electrons of the oxygen atoms in the former case results in a higher directive power than the pull in the latter case acting on the oxygen of the nitrobenzyloxy-group alone. One apparent exception was noted in the benzyloxy-group (113 in the catechol series, 107 in the quinol series), but the differences are small and the value in the catechol series is suspect. In the course of the Faraday Society discussion in 1923, it was stated that the polarity theories

explained everything and predicted nothing. The lecturer thereupon made a prediction as follows :

- (1) That the *para*-chlorobenzyloxy-group would have a greater orienting power than *meta*, and
- (2) that the *para*-nitrobenzyloxy-group would have a weaker orienting power than the *meta*.

In 1927 the first prediction was justified (*p*-, 82; *m*-, 69), but the *m*- and *p*-nitrobenzyloxy-groups had nearly the same directive powers (67), in the catechol series. The anticipated effect was, however, noted with the nitrobenzamido-groups in the acylated *p*-phenetidine series (EtO, 100; *p*-, 190; *m*-, 226).

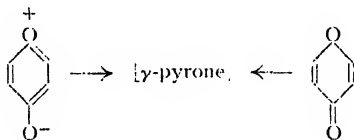

The Neutralised Systems.—If a strongly cationoid group is attached to a strongly anionoid group, e.g., N to CO, electron transfer occurs in the molecule under all conditions :

The result is in this case to diminish the basic character of N and the cationoid character of C of CO and to produce a definite dipole evinced by the physical character of the amides. In a similar way the characters of the carboxylic acids and their derivatives receive a very convincing explanation. As always the groups can be separated by one or more double bonds, and the extent of the neutralisation depends on the affinity of the nitrogen and oxygen, or what corresponds to them in other examples, for their respective charges.

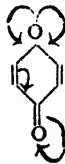

The Condition of Molecules in the Resting State.—Both Lapworth and the lecturer postulated a certain degree of polarisation in normal molecules of an unsymmetrical nature, but paid little attention to the matter because their chief concern was with reactions. The existence of electromeric displacements in the normal molecules of the conjugated complexes was, however, always mentioned in lectures in various centres on these topics and in University teaching from 1922. Indeed, the views expressed in regard to neutralised systems such as the amides, and the references to their physical and chemical properties, were meaningless without this assumption.

In the case of certain classes of compounds the idea was emphasised, and the pyrones, for example, were recognised as intermediate between the fully polarised hydroxypyrylium betaine and the usual neutral formula (Armit and Robinson, *J.*, 1925, 127, 1604) :

Arndt, Scholz, and Nachtwey (*Ber.*, 1924, 57, 1903) put forward a similar view of "Zwischenstufe" based on the properties of a series of thiopyrones. They did not interpret their hypothesis in terms of electronic displacements.

Another way of representing the matter is to say that the pyrones are normally

and it will be noticed that this is merely a neutralised system of ester type, $-O-CO-$, in which a double bond is interpolated in two places. There is, however, the additional circumstance that the pyrylium nucleus is aromatic, and that was considered to be an important factor in producing a closer approximation to the pyrylium betaine than would otherwise be the case.

Ingold and Ingold (*J.*, 1926, 1310) introduced the convenient term "mesomerism" for this electromeric effect in normal molecules, and an outstanding contribution on the experimental side was made by L. E. Sutton. Using the method of measurement of dipole moments he was able to recognise the mesomerism of many aromatic compounds containing hetero-

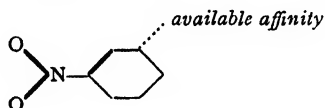

enoid and catio-enoid systems as well as those in which both are present and may be partly neutralised. The direction of the mesomeric displacement was not necessarily in the same sense as the dipole. Thus the dipole in chlorobenzene was in the direction $\text{Cl}-\text{C}_6\text{H}_5 \leftarrow$ as the

theory of the general effect demands. A small counteracting mesomeric effect $\text{Cl}-\text{C}_6\text{H}_5 \rightarrow$ was detected by comparison of the moment of chlorobenzene with that of *tert.*-butyl chloride (*Proc. Roy. Soc.*, 1931, **133**, 668). This work was a remarkable physical confirmation of the validity of the hypotheses which have briefly been expounded, for it was found that all *op*-directive groups examined increased the density of electrons in the aromatic nucleus and all *m*-directive groups decreased it. Methods for determining the occurrence and extent of mesomerism have been developed by Pauling and others, but they belong to the modern period. The device of writing down the possible structures and estimating the contribution which each makes to the actual condition of the molecule is a calculus and not a theory of structure, though it has often been misunderstood as such.

Conclusion.—Many important tributaries have been omitted from this account and the river has not been followed to the sea. Thus the work of Claus, Werner, and Flürscheim had a most important influence on the thoughts of chemists. Flürscheim's development of the theory of alternating and variable affinity was especially valuable. It gave the results now regarded as correct in many cases, as in the hetero-enoid systems :

but failed to meet our requirements in the catio-enoid systems :

The speculations of Vorländer and Fry likewise contained useful detailed suggestions but were eventually seen to be out of the direct line of progress. The lecturer has perforce had to omit all reference to the stereochemical aspects, such as the Mills–Nixon effect, to W. Baker's applications of chelation, to tautomerism, dissociating systems, and molecular rearrangement, as well as to many other topics of great interest. In particular he has not mentioned the neutral free radicals and atoms, which can be anionoid, *or* cationoid, *or* homopolar.

It seems peculiarly appropriate that a Faraday Lecture should deal with molecular electrical phenomena, although they are of a very simple kind, in relation to properties of the derivatives of benzene, a substance which Faraday discovered. We owe to him the first studies of dielectrics and as a twig from this tree we take the measurement of dipole moments. Above all he was a great electrochemist and was convinced that electricity and chemical affinity could be identified. His Laws of Electrolysis, considered from the point of view of atoms and ions, bear much the same relation to the atomic theory of electricity that the Law of Multiple Proportions bears to the atomic theory of the elements.

In the Faraday Lecture of 1881, Helmholtz said : " Now the most startling result of Faraday's Law is perhaps this. If we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid concluding that electricity also, positive as well as negative, is divided into definite elementary portions which behave like atoms of electricity ".

The logic is inescapable and yet we must admire the acumen and courage of the remark.

Without forgetting the work of Volta, Davy, and Berzelius, and of many other real pioneers in the middle and later periods, we are right to honour the memory of Michael Faraday, the most illustrious of the founders of a science of electrochemistry.

239. Theory of Chromatography. Part II.* Chromatograms of a Single Solute.

By E. GLUECKAUF.

Chromatograms of single solutes, in particular the case of sigmoid isotherms, are treated theoretically and measured experimentally. The form of the chromatograms resulting from the different isotherms and the movement of their characteristic points are shown and calculated (see Figs. 1—6). Adsorption and exchange isotherms can be calculated from chromatographic elution curves (see Figs. 7 and 9). Comparison of an isotherm, determined in this way, with directly determined equilibrium values shows a good agreement (see Fig. 5), and the chromatographic method gives a much larger number of points for less experimental work.

Symbols :

c , concentration in milliequivs. per c.c.

$q = f(c)$, amount of solute taken up by 1 g. of adsorbent (including pore space) in equilibrium with c (m.-equiv./g.).

$f^*(c) = q - ac$, the amount actually adsorbed on the adsorbent.

a , pore space per g. of adsorbent (c.c./g.).

v , volume of developing solution used (c.c.).

v^0, c^0, q^0 , volume and concentration of original solution, and amount adsorbed per g. in equilibrium with c^0 .

x , distance from the top of the column, measured in g. of adsorbent.

$m = v^0 c^0$, amount of solute used (m.-equiv.).

μ_c , amount of solute in the column behind a given point \bar{x} of concentration \bar{c} on the rear boundary.

μ_c' , amount of solute in front of a given point \bar{x} of concentration \bar{c} on the front boundary.

Indices in italics refer to characteristic points of the chromatogram, shown in the diagrams :

u to the undeveloped front (see Fig. 2, A, B).

w to the front of a fully developed chromatogram (see Figs. 2, C and 6, D).

s to the sharp undeveloped rear boundary (see Fig. 4, A).

r to the sharp rear boundary of a fully developed band (see Fig. 4, B).

o to the point of concentration 0 in a diffuse boundary (see Figs. 2, 4, 6).

d to the point of concentration c^0, q^0 in a diffuse boundary (see Figs. 2, 4, 6).

e, e', f , and e are used for points on a partially diffuse boundary (see Fig. 6).

(a) *Chromatographic Equations for Single Solute Isotherms.*—Chromatography is the name given to the process of separation by continuous fractional adsorption, because of its earlier applications to the separations of coloured substances, though this limitation no longer obtains. The normal procedure is to pour a solution of the solutes to be separated on to the top of a column filled with adsorbent and allow it to percolate into the column, a process which may be accelerated by applying suction at the bottom or, better, pressure at the top. After this original solution is taken up by the column, and has formed a band, further amounts of pure solvent are added at the top, dissolving the band of adsorbed solutes from the rear and slowly carrying it through the column, a process called "development." During the development stage the band usually spreads, whereby its local concentration decreases and, as the individual solutes move with different speed through the column, partial or complete separation takes place.

The regions in the front and rear of the adsorption band are called "boundaries," and these may be "sharp" or "diffuse" according to the type of adsorption isotherm obtaining for the particular case of adsorbent, adsorbate, and solvent. (The boundaries are always diffuse if the flow of solvent is too fast to permit local equilibrium to be reached; see Part IV.) In the case of multiple solutes the word "boundary" is applied to all parts where concentration gradients exist.

The movement of any type of boundary is governed by the principle of mass-conservation, which means that, if we consider the solute content of a very thin section of the chromatographic band, its increase (or decrease) is given by the difference of the inflowing and the outflowing solute.

The movement of the band can be considered in two ways.

We can mentally fix our eyes on a given particle of the solute. Then this point of fixed mass within the band of a single solute, the concentration of which may, e.g., be c^0 , moves with a given amount of solvent v according to (1) (see Wilson, *J. Amer. Chem. Soc.*, 1940, 62, 1583) :

$$[\Delta x / \Delta v]_m = c^0 / f'(c^0) \quad \dots \dots \dots (1)$$

Alternatively, we may follow the movement of a point of constant concentration in a diffuse boundary (see Fig. 2, C, curve A—B), which is described by equation (2) (see De Vault, *ibid.*, 1943, 65, 532; Weiss, *J.*, 1943, 297) :

$$[\Delta x / \Delta v]_c = dc / df(c) = 1 / f'(c) \quad \dots \dots \dots (2)$$

* For Part I, see *Proc. Roy. Soc.*, 1946, A, 186, 35.

Finally, we have the integrated equations for the amount of solute in the chromatogram between the concentrations \bar{c} and $c = 0$, which in the case of a diffuse rear boundary (see Fig. 2) is

$$\mu = \bar{x}f(\bar{c}) - v\bar{c} \quad (3)$$

(Glueckauf, *Nature*, 1945, 156, 748) and for a diffuse front boundary (see Fig. 4):

$$\mu' = (v + v^0)\bar{c} - \bar{x}f(\bar{c}) \quad (4)$$

FIG. 1.

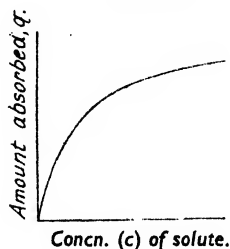

FIG. 2.

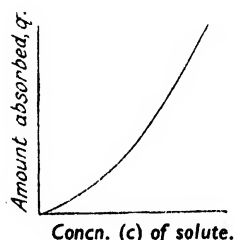

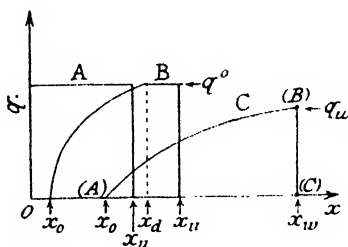

FIG. 3.

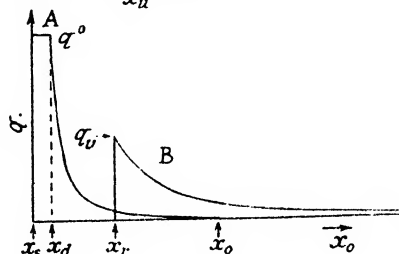

FIG. 4.

FIG. 1.—Normal isotherm concave against c -axis.

Abscissa = distance from top of column.

Ordinate = amount absorbed per g. of column material.

(A) Original band. (B) Incomplete development. (C) Complete development. (A)–(B) Diffuse rear boundary, (B)–(C) sharp front boundary.

FIG. 3.—Isotherm convex against c -axis.

FIG. 4.—Development of a band of solute with isotherm as in Fig. 3.

(A) Original band. (B) Complete development.

Equation (3) actually comprises equation (1).

The combinations of these equations represent all the relevant conditions of the various parts of the chromatograms (some of which have already been given by Weiss, *loc. cit.*).

For an adsorption isotherm concave towards the c -axis (see Fig. 1) we get (for subscripts see Figs. 2, A, B, C):

$$x_0 = v/f'_{(0)} \quad (5a)$$

$$x_d = v/f'_{(c^0)} \quad (6a)$$

$$x_u = (v + v^0)c^0/f'_{(c^0)} \quad (7a)$$

$$x_w = m/(f'_{(c_w)} - c_w f'_{(c_w)}) \quad (8a)$$

where c_w is defined by

$$v = m f'_{(c_w)} / (f'_{(c_w)} - c_w f'_{(c_w)}) \quad (9a)$$

For an adsorption isotherm convex towards the c -axis (see Fig. 3) we get (for subscripts see Figs. 4, A, B):

$$x_0 = (v + v^0)/f'_{(0)} \quad (5b)$$

$$x_d = (v + v^0)/f'_{(c^0)} \quad (6b)$$

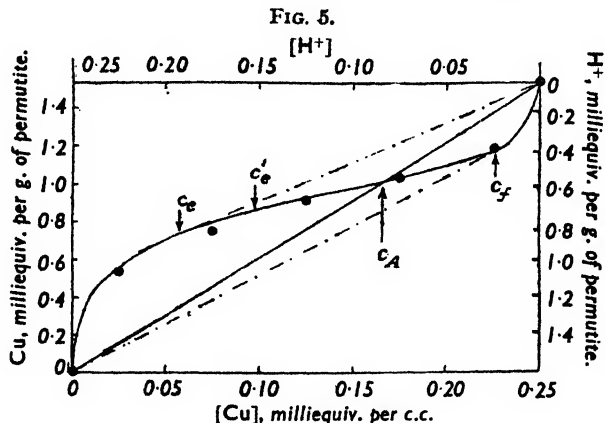

$$x_s = v c^0 / f'_{(c^0)} \quad (7b)$$

$$x_r = m / (c_r f'_{(c_r)} - f'_{(c_r)}) \quad (8b)$$

where c_r is defined by

$$v + v^0 = m f'_{(c_r)} / (c_r f'_{(c_r)} - f'_{(c_r)}) \quad (9b)$$

Slightly more complicated are the conditions in the case of sigmoid isotherms. These are particularly frequent in ion-exchange systems on zeolites, permutites, and exchange resins, in cases where both ions are taken up with similar affinity (see, *e.g.*, Rothmund and Kornfeld,

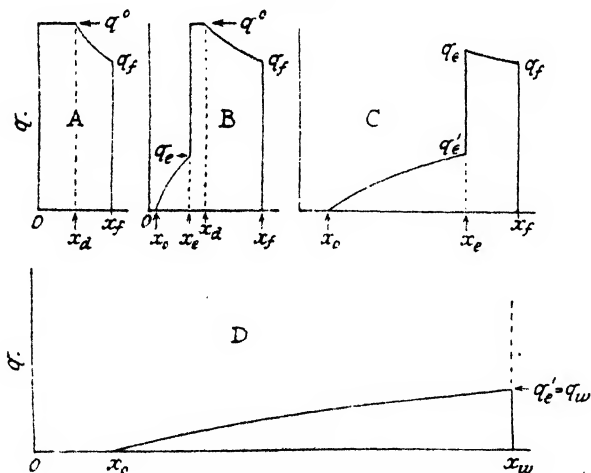

Example of sigmoid isotherm.

Exchange isotherm of H^+ and Cu^{++} on Zeo-carb H.I. for a total concentration in solution of 0.25N.

Abscissa: Cu^{++} concentration in solution (milli-equiv. per c.c.).
 Ordinate: Cu content of zeo-carb (milli-equiv. per g. of zeo-carb).
 Curve: isotherm obtained from chromatographic data.
 Points: isotherm points from direct equilibrium measurements.

Z. anorg. Chem., 1918, 103, 129, for the case of $Na-NH_4$ and $Ag-Tl$). Though two ions are involved in any isotherm, they can nevertheless be treated as simple systems, for, under the conditions of constant total concentration existing during the elution process, there is only

FIG. 6.

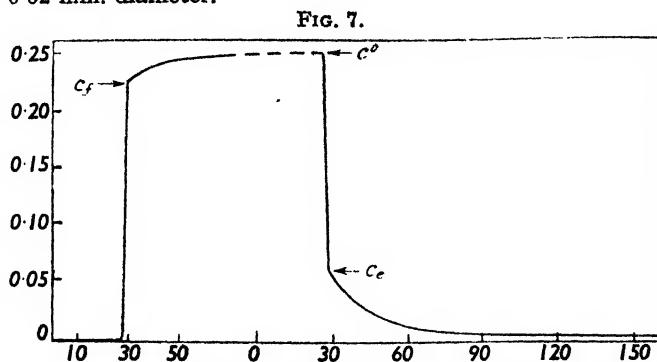

Development of a band of solute with sigmoid isotherm.

- (A) Original band. (C) First stage of development completed.
 (B) Development incomplete. (D) Complete development.

one freely variable concentration. Bands in every respect identical with those produced by adsorption phenomena are obtained by using a solution of the original cation of the permutite as developing agent.

In the case of sigmoid isotherms, chromatograms are obtained which, at first, have partly diffuse and partly sharp boundaries both in front and rear. In the later stages of the develop-

the recorder. (The residual cupric ion was eluted with $2N-H_2SO_4$, which removed it quickly, and then titrated.) To avoid non-equilibrium phenomena, the permutite material was ground to a grain size of 0.02 mm. diameter.

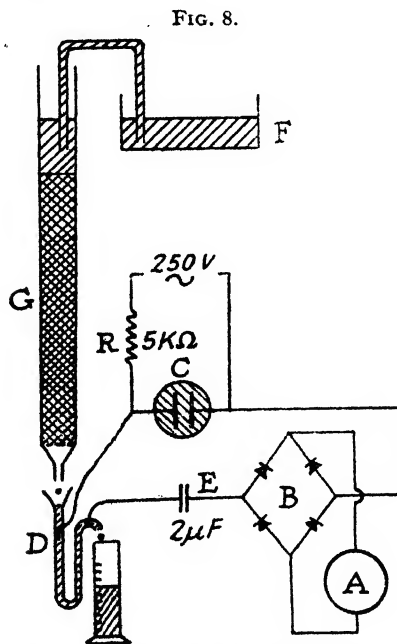

Measured elution curve of a solute with sigmoid isotherm.

Abscissa: volume of eluate (c.c.).

Ordinate: concentration of eluate, milliequiv./c.c.

(Compare with the band shown in Fig. 6B.)

Arrangement for the automatic registration of concentrations in the eluate.

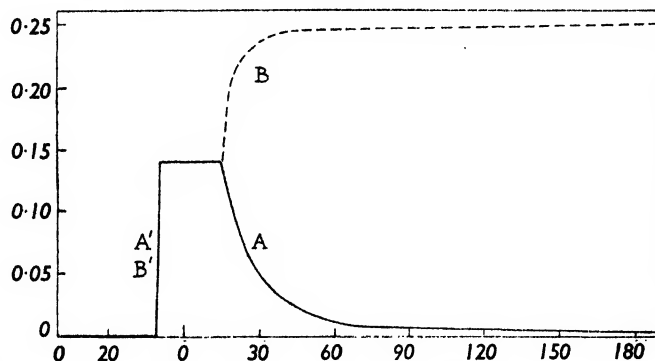

- (A) Recording μ -ammeter (0—100 μ A.).
- (B) Full-wave rectifier.
- (C) Neon voltage-stabiliser.
- (D) Capillary with Pt electrodes for resistance measurement of eluate.
- (E) Condenser 2μ F.
- (F) Constant level for constant dropping speed.
- (G) Column filled with 5 g. of Zeo-carb.
- (R) 5000 Ω resistance.

The eluate consists at first of $0.25N-H_2SO_4$. The front of the copper arrives at a threshold volume $v_t = 29$ c.c. Its concentration rises sharply to a value of $c_f = 0.225$, as one would expect from the theory (eqn. 12) which fixes this concentration as the point where the tangent from the origin ($c = 0$), touches the isotherm (see Fig. 5). Thence the concentration rises asymptotically to the original value $c^0 = 0.25$ milliequiv./c.c.

After passing a sufficiently large amount of copper solution through the column to convert the zeo-karb completely into Cu-zeo-karb, this "undeveloped band" was now "developed" with 0.25N-H₂SO₄, whereby the rear boundary of the copper band was obtained. Here, too, the concentration fell at first sharply to a value of $c_e = 0.060$ milli-equiv./c.c. [which again is in agreement with the theory (eqn. 14), representing the point in Fig. 5 where the tangent from the point $c^0 = 0.25$ milliequiv./c.c. touches the exchange isotherm]. With continued elution, the copper concentration exhibits the normal behaviour and falls asymptotically to zero (see Fig. 7).

Thus the greater part of the isotherm, between $c_e = 0.060$ and $c_f = 0.225$, cannot be calculated from the chromatographic data of this experiment, as these concentrations do not appear in the chromatogram. Boundaries covering the whole concentration range can, however, be obtained by saturating the column with solute of the concentration (c_i) existing at the point of inflexion (or near by), and then (i) eluting with pure solvent (acid) and (ii) saturating the column with the concentration c^0 . From the first experiment (elution of a copper band) results a diffuse rear boundary which permits the calculation of the adsorption data between c_i and 0; in the second case (elution of an acid band) is obtained a diffuse boundary between c_i and c^0 .

FIG. 9.

Measured "elution curves" of a solute with sigmoid isotherm, suitable for determination of the isotherm by means of eqn. (3) or (4).

∞	0.250		—	—	7.50	1.500

Italicised values are measured directly. Other values of cols. 1, 2, 3 are taken from the registered elution curves. Col. 6 in Table I is the sum of cols. 4 + 5. Col. 6 in Table II is (5.65 + col. 5 - col. 4). The figure 5.65 represents $(f^*(c_i) + \alpha c^0)x$, i.e., the amount of solute in the column at the time of the change-over. $\Delta\mu$ is the eluate between two evaluated points, i.e., the product of Δv and the average concentration. The amount μ left in the column is obtained by adding all the $\Delta\mu$'s to the amount finally left in the column and measured directly.

In either case no discontinuous "rear" boundaries are obtained, because from this point (c_i) no tangent can be drawn to any other part of the isotherm.

The elution curves shown in Fig. 9 A, B are obtained in the following way: Through a column of acid Zeo-karb (5 g.) was passed a solution of $0.14N\text{-CuSO}_4 + 0.11N\text{-H}_2\text{SO}_4$ which approximately corresponds to the mixture at the point of inflexion of the isotherm. The copper arrived in the eluate with a sharp front boundary ($v_t = 40$ c.c.). Then the solution was changed, $0.25N\text{-H}_2\text{SO}_4$ (see curve A) being used for the elution of the copper, and (see curve B) in a second experiment $0.25N\text{-CuSO}_4$ for the elution of the hydrogen ions. In either case a diffuse rear boundary was obtained beginning at about 14.5 and 15.3 c.c. respectively after the change-over.

From these two curves the complete exchange isotherm can be calculated. Curve A can be evaluated according to eqn. (3):

$$f^*(\bar{c}) = [\mu_c + (v - \alpha x)\bar{c}]/x \text{ (see Table I).}$$

Curve B can be evaluated in two ways: It can be considered as the rear boundary of a hydrogen-ion band, and then eqn. (3) applies, with c referring to the hydrogen-ion concentrations. Alternatively, it can be considered as the partial front of a pure copper-ion band moving against a mixed solution, in which case eqn. (4) applies [though with some modification on account of the chromatographic tube containing originally some Cu (c_0)]. Integration for these conditions leads to:

$$f^*(\bar{c}) = f^*(c_0) + [(v + v^0 - \alpha x)\bar{c} - \mu_c]/x$$

where $f^*(c_0)$ is obtained from Table I, or from the threshold volume $v_t = 40$ (frontal line A'B' of Fig. 9) by means of

$$f^*(c_0) = v_t c_0/x - \alpha c_0 \text{ (see eqn. 1a).}$$

From the experimental data ($v_t = 40.0$ c.c., $c_0 = 0.140$, $x = 5$ g., $\alpha = 1.20$ c.c./g.) follows a value for $f^*(c_0) = 0.953$ milli-equiv./g., in good agreement with 0.962 found from Table I. The agreement of the equilibrium values of the exchange isotherm calculated in Tables I and II is shown in Fig. 5. Here the continuous curve represents the isotherm obtained by the chromatographic method, and circles mark points determined by direct equilibrium measurements. The obvious advantage of the chromatographic method of measuring isotherms, especially if the concentration of eluate can be measured continuously, is that a single experiment gives an almost unlimited number of equilibrium points of the isotherm.

(c) *Gas Adsorption Columns* (added in proof, August, 1947).—The considerations about the distribution of solutes in an adsorption column apply equally to the case of gases adsorbed from an air stream in adsorption columns. In the recently published experimental observations of Barrow, Danby, Davoud, Hinshelwood, and Staveley (this vol., p. 401), the different cases of Figs. 1 and 2, A and of Figs. 3 and 4, A are found when air containing carbon tetrachloride and water vapour respectively is passed through a charcoal column. The removal of the adsorbates from the column by passing clean air through (see their Figs. 7, 8, and 11, 12) corresponds to a development with pure solvent and is represented by Figs. 2B, C and 4B of this paper and by the corresponding equations. The above-mentioned experiments with gases also show clearly the effect of non-equilibrium phenomena, which are more fully discussed in Part IV.

DURHAM COLLEGES IN THE UNIVERSITY OF DURHAM.

[Received, November 20th, 1946.]

240. Theory of Chromatography. Part III. Experimental Separation of Two Solute and Comparison with Theory.

By J. I. COATES and E. GLUECKAUF.

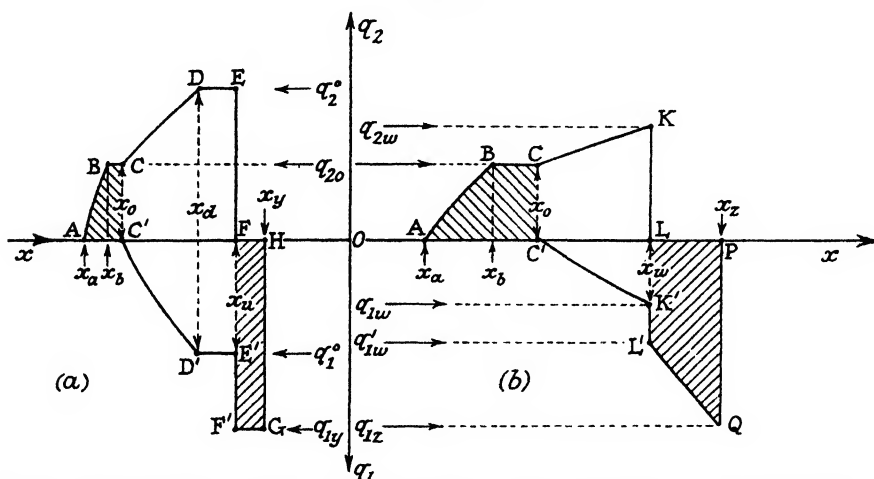

The results obtained in Part I (*Proc. Roy. Soc.*, 1946, A, 186, 35) for chromatograms of two solutes are summarised in Tables I—V, giving the features and movements of the important parts of binary chromatograms (see Fig. 1) at various stages of the development. The results are given both for the general case and for the special case of the Langmuir isotherm.

The agreement of these calculations with quantitative elution experiments is shown for a chromatographic separation of Cu^{++} and Mn^{++} on Zeo-karb H.I. (see Fig. 2, 3, and 4), the exchange of which follows approximately an isotherm of the Langmuir type.

(a) *Summary of Part I.*—A normal binary chromatogram has, according to whether it is fully developed or not, a distribution of solutes as shown in Fig. 1b and 1a, respectively. (Some

modifications may occur if the isotherm has an infinite slope at zero concentrations, as, e.g., in the case of the Freundlich isotherms; see Part V.) The movement of any given point of such a chromatogram can be given in general mathematical terms, but only in the case of the Langmuir isotherm (see eqn. 1) can the essential differential equation (2), defining the relationship of coexistent concentrations c_1 and c_2 in the mixed band, be solved. Once this function is known for a given case of initial concentrations c_1^0 and c_2^0 , the adsorption isotherm $q_1 = f_1(c_1, c_2)$ can be replaced in the mixed band by the pseudo-isotherm $q_1 = F_1(c_1)$ (eqn. 3), so that the problem is thereby reduced to the case of a single solute isotherm. In this way the difficulty mentioned by de Vault (*J. Amer. Chem. Soc.*, 1943, 65, 532) of obtaining the full differential $df_{1(c_1, c_2)}/dc_1$ is being solved. The essential data for the development of a binary chromatogram are given in Tables I—V, with full reference to the corresponding parts in Fig. 1a, b. In these tables, the pore space of the adsorbent has not been considered. Correction for this can be made by

FIG. 1.

Diagrammatic representation of binary chromatogram (a, partly developed; b, fully developed), showing the amounts q_1 and q_2 adsorbed per g. of adsorbent at various distances x from the top of the column. The subscripts and figures are referred to in Tables III—VII giving quantitative information on the movements of points and boundaries.

The pure front band of solute 1 and the pure rear band of solute 2 are hatched.

substituting $(v - \alpha x)$ for v , or by replacing $f_{(c)}$ by $f_{(c)} + \alpha c$, whichever is more convenient. The equations may be used for the calculation of both chromatograms and elution curves according to whether they are applied to a constant value of v (giving a relation between the "length" x and c) or to a constant value of x , the total adsorbent in the column (giving a relation between the volume of eluate v and its concentration c).

(b) *Conclusions of Practical Interest derived from the Equations of Part I for Separation of Two Solutes.*—(1) For the Langmuir type of isotherm, separation is facilitated by working at high adsorption densities, but no advantage is derived from using high solute concentrations when the adsorbent is already fairly saturated.

(2) If this is done, the amount of adsorbent and also the amount of developing solution required for complete separation are proportional to $(m_1 + m_2)$, i.e., to the total quantity of the solutes. A rough practical rule for the minimum amount X_0 of adsorbent required for complete separation would be $X_0 = L^0/(\Delta x_1/\Delta x_2 - 1)^2$ where L^0 is the amount of adsorbent taken up by the original undeveloped band, and Δx_1 and Δx_2 are the displacements of the rear of the pure single-solute bands produced by equal amounts of developing solvent; Δx can easily be determined if the pure solutes are available. More than the amount X_0 is required for a good spatial separation of the bands.

(3) If solutes are so difficult to separate that no complete separation, but only enrichment can be achieved, it is always an advantage to develop with a solution containing a third and more strongly adsorbed solute of at least equal concentration. Here the amount of adsorbent required to separate the solutes is approximately only $X_0 = L^0/(\Delta x_1/\Delta x_2 - 1)$ but, as the two bands do not separate, a mixed band always remains on account of non-equilibrium effects

(see Part IV). The displacements Δx_1 and Δx_2 have to be determined in the absence of the third solute. It is obvious that development with a third solute gives the advantage of requiring shorter columns only if $(\Delta x_1/\Delta x_2 - 1) \ll 1$. Other advantages of using a third solute, like the greater mobility in the case of very strongly adsorbed solutes, are independent of this consideration.

EXPERIMENTAL

The experiments were carried out with columns containing 60 g. of acid Zeo-karb H.I. The attainment of equilibrium (see subsequent paper) is of particular importance in the case of chromatography with ion exchangers, for the diffusion in these is somewhat slower than, e.g., in alumina. However, by using a grain size of 0.01 mm. diameter and a flow velocity of 0.001 cm./sec. (corresponding to one drop in two minutes), elution curves were obtained which were even better than those obtainable with the apparently faster alumina of equal grain size. This seems to be due to a different effect altogether. Acid Zeo-karb when taking up larger ions like copper or manganese, undergoes a noticeable

TABLE I.

Fundamental equations.

	General isotherm.	Langmuir isotherm.
Adsorption isotherm	$q_1 = f_1(c_1, c_2)$ $q_2 = f_2(c_1, c_2)$	$q_1 = a_1 c_1 / (1 + b_1 c_1 + b_2 c_2)$ $q_2 = a_2 c_2 / (1 + b_1 c_1 + b_2 c_2)$. . . (1)
Condition for coexistent concentrations in the mixed band	$df_1(c_1, c_2)/dc_1 = df_2(c_1, c_2)/dc_2$ can be integrated graphically for a given case of c_1^0 and c_2^0 (see Part V)	$a_2 b_1 c_1 = a_1 b_2 c_2 \lambda - (a_2 - a_1) \lambda / (1 + \lambda)$, where λ can be obtained from the same equation with $c_1 = c_1^0$ and $c_2 = c_2^0$. In the following, λ is considered a known constant (2)
Pseudo-adsorption isotherms in mixed band	$q_1 = F_1(c_1)$ $q_2 = F_2(c_2)$ $\left\{ \begin{array}{l} \text{obtainable from} \\ \text{relationship} \\ \text{between coex-} \\ \text{istent values} \\ \text{of } c_1 \text{ and } c_2 \end{array} \right.$	$q_1 = A_1 c_1 / (1 + B_1 c_1)$ $q_2 = A_2 c_2 / (1 + B_2 c_2)$ where $A_1 = a_1(1 + \lambda) / (1 + \lambda + \delta)$ $B_1 = b_1(1 + \lambda) / \lambda$ $A_2 = a_2(1 + \delta)(1 + \lambda) / (1 + \lambda + \delta)$ $B_2 = b_2(1 + \lambda)$ $\delta = (a_2 - a_1) / a_1$ (3)
Movement of a given mass-point of solute 1 (and <i>vice versa</i> for solute 2) in the mixed band	$\left[\frac{\Delta x}{\Delta v} \right]_{m_1} = c_1 / f_1(c_1, c_2) = c_1 / F_1(c_1)$	$= (1 + b_1 c_1 + b_2 c_2) / a_1 = (1 + B_1 c_1) / A_1$. . . (4)
Movement of point of given concentrations c_1, c_2 in a diffuse boundary	$\left[\frac{\Delta x}{\Delta v} \right]_{c_1, c_2} = 1 / F'_1(c_1) = 1 / F'_2(c_2)$	$= (1 + B_1 c_1)^2 / A_1 = (1 + B_2 c_2)^2 / A_2$ (5)
Amount of solute in the chromatogram between the points of concentrate c and $c = 0$ (c within the mixed band)	$m_{1(a-x)} = x f_1(c_1, c_2) - v c_1$ $m_{2(a-x)} = x f_2(c_1, c_2) - v c_2$	Same (6)

TABLE II.

Important concentrations in the chromatogram (see Fig. 1a, b).

TABLE IV.

Amount of solute in different parts of the chromatogram.

Part of chromatogram.	Ref. to Fig. 1a, b.	General isotherm.	Langmuir isotherm.
Pure rear band of solute 2 (developed or undeveloped)	Area $ABCC'$	$v \frac{(F'_{2c_{2w}} - c_{2w} \cdot F'_{2c_{2w}})}{F'_{2c_{2w}}}$	$v \delta^2/B_2$ (21)
Pure front band of solute 1 (undeveloped)	Area $FE'F'GH$	$(v + v^0)c_1^0(1 - c_2^0 \cdot f_{1c_1} c_1^0 / c_1^0 \cdot f_{2c_2} c_2^0)$	$(v + v^0)c_1^0(a_2 - a_1)/a_2$ (22)
Solute 1 in mixed band (developed)	Area $C'K'L$	$v(F'_{1c_{1w}} - c_{1w}F'_{1c_{1w}})/F'_{1c_{1w}}$ (see c_{1w})	$B_1 v c_{1w}^2$ (see c_{1w}) (23)

The other parts are obtainable by difference from m_1 or m_2 .

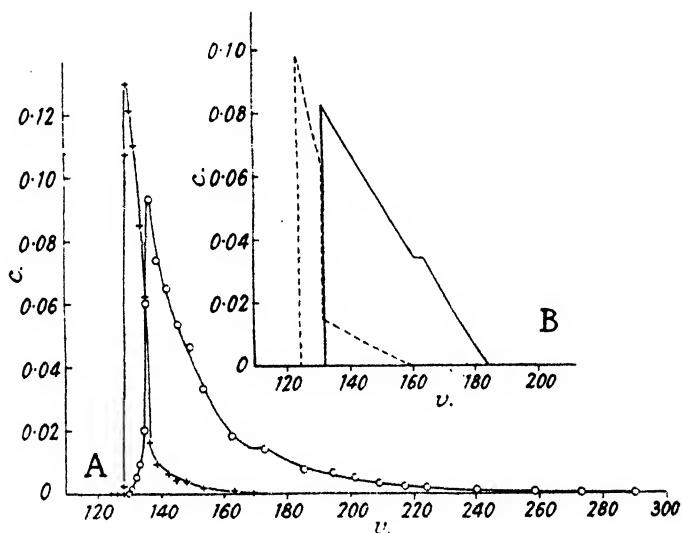

TABLE V.

Conditions for complete separation.

	General isotherm.	Langmuir isotherm.
Minimum amount of adsorbent required	$X_0 = m_2/(F_2(c_{20}) - c_{20}F'_2(c_{20}))$	$X_0 = m_2B_2/A_1\delta^2$ (24)
Minimum volume of developing solvent required	$V = m_2/(F_2(c_{20})/F'_2(c_{20}) - c_{20})$	$V = m_2B_2/\delta^2$ (25)

swelling, which has a stabilising effect on the front boundary of the ion band. For instance, if one side of the boundary should get in advance of the rest, the flow resistance on this side increases on account of the swelling, so that the other parts of the boundary can catch up. The effect is so marked that an ion band can be passed through a 1 m. column of 1" diameter, without showing a noticeable tilt in the circular front boundary.

FIG. 2.

Eluted chromatogram (fully developed) for partial separation of (1) Mn^{++} and (2) Cu^{++} on 60 g. of Zeo-karb H.I. Development with 1N- H_2SO_4 . Experimental conditions: $m_1 = 0.6$ milliequiv., $m_2 = 2.0$ milliequiv., $c_1^0 = 0.1N$, $c_2^0 = 0.4N$. Isotherm constants: $a_1 = 2.12$, $b_1 = 2.3$, $a_2 = 2.35$, $b_2 = 2.56$. $\alpha = 0.7$ c.c./g. Grain size of Zeo-karb 0.01 mm. Flow velocity ~ 100 c.c./24 hours. Note the exceedingly sharp front boundary due to reduction of non-equilibrium phenomena.

(B) Elution curve calculated with the equations of Tables I—III for a Langmuir isotherm with the above constants.

The columns used had a diameter of 1 cm. and were filled with suspended acid Zeo-karb H.I., the usual method of tapping and stuffing being employed. Equally good results were obtained if the tubes were filled with large quantities of material at a time, these being allowed to settle while the whole tube was subjected to constant vigorous vibrations by means of a bell movement clamped to the tube. This method saves much labour with large tubes and produces a very uniform sedimentation of the particles.

The elution curves were obtained by collecting, with an automatic device, fractions of the eluted solution, and analysing these by titration. Within the limits of the analytical error, the recovery of the solutes from 60 g. of Zeo-karb appeared to be 100%, but varying losses were obtained when working with alumina (see also Jacobs and Tompkins, *Trans. Faraday Soc.*, 1945, **41**, 403, Fig. 4).

Results.—Considerable difficulty was experienced in finding a binary system which follows a Langmuir isotherm (see eqn. 1). The nearest approach was found in the exchange isotherms of cupric, manganese, and hydrogen ions on exchange resins (Zeo-carb H.I. and H.I.P) for 1N. and higher total concentrations, and then only when more than 50% of hydrogen ions were present. For a lower hydrogen-ion ratio, the isotherm attains a sigmoid form, and for lower total concentration it changes increasingly towards the Freundlich type (see Part II, Fig. 5). However, within the region of

$$[Cu] + [Mn] < [H]$$

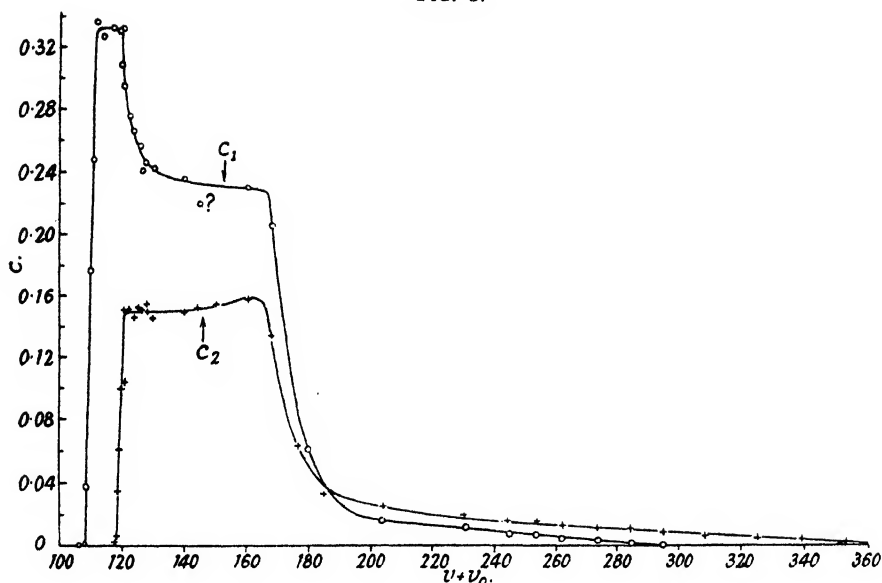

and

$$[Cu] + [Mn] + [H] = 1 \text{ milliequiv./c.c.} \quad . \quad . \quad . \quad (26)$$

the exchange isotherm can be well represented over the greater part of its course by equations of the type

$$q_{Mn} = q_1 = K_1[Mn]/([H] + K_2[Mn] + K_3[Cu]) \quad . \quad . \quad . \quad (27)$$

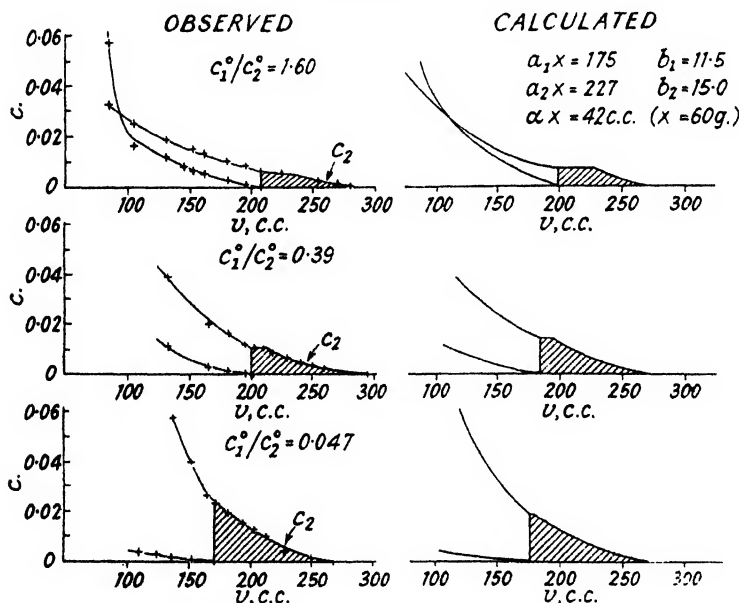

FIG. 3.

Elution curve for two solutes (development incomplete.)

Eluted chromatogram ("development" incomplete) of (1) Mn^{++} and (2) Cu^{++} on 60 g. acid Zeo-karb H.I. Development with 1N- H_2SO_4 . $c_1^0 = 0.23\text{N}$, $c_2^0 = 0.16\text{N}$.

FIG. 4.

Observed and calculated rear boundary effects for different ratios of the initial concentrations c_1^0/c_2^0 . Note that the form of and amount separated in the pure rear band depends on c_1^0/c_2^0 . Calculation acc. to Tables I—IV.

and vice versa for q_{0u} . Eliminating $[\text{H}]$ by means of the condition of constant total concentration (eqn. 26) we obtain Cu-Mn isotherms

$$q_{\text{Mn}} = K_1[\text{Mn}]/\{1 + (K_3 - 1)[\text{Mn}] + (K_4 - 1)[\text{Cu}]\} \quad . \quad . \quad . \quad 28)$$

and similarly for q_{Ca} . These equations are formally identical with the Langmuir isotherm (eqn. 1).

At the very lowest metal concentrations [$(c_1 + c_2) < 0.03N$], rather more metal ions are taken up than correspond to the rest of the isotherm, which means that at the lowest concentrations all the constants a and b become larger.

Apart from reasons of their simple determination, copper and manganese had been chosen because they represent solutes which are, on this adsorbent, very difficult to separate. Their exchange affinities differ less than those of nickel and cobalt on alumina and they thus afford a particularly stringent test for both theory and practice.

Fig. 2A shows the measured elution curve of a manganese-copper separation in a column 1 m. long containing 60 g. of acid Zeo-karb H.I. In spite of the considerable length of column and the consequent increase of all disturbing factors, the theoretically vertical front boundaries were found to be exceedingly sharp—not only did the self-sharpening front boundary of pure manganese rise up within 1 c.c. of eluate, but even the practically non-self-sharpening front boundary of the copper against the frontal band of manganese is almost completely contained within 2 c.c. of eluate. It can therefore be assumed that equilibrium is almost complete at every point of the column. (For a detailed discussion on non-equilibrium phenomena at boundaries, see Part IV.)

Fig. 2B gives the elution curve calculated on the basis of the given constants (see legends of Fig. 2) by means of the equations deduced in Part I (*loc. cit.*) which are summarised at the beginning of this paper. In these calculations the pore space $\alpha = 0.7$ c.c./g. of adsorbent, which had been determined by direct measurement, has been taken into consideration.

The agreement between experiment and calculation is quite good except at the tail end of the chromatogram where the concentrations are very low and where, as mentioned before, the constants of the isotherm become larger. As a result, the tail is considerably longer than would be the case for a "pure" Langmuir isotherm and the concentration (c_{20}) at the front of the pure rear band of solute 2 is consequently reduced. Agreement is particularly good for the front part of the chromatogram, in particular for the threshold volume, and the sharp rise in the concentration of solute 1 at the inter-front (at $v = 36$ c.c.), which is to be expected for solutes of very similar adsorption affinity, is clearly shown.

The not inconsiderable disagreement in the details of the rear boundaries is of particular interest, because it shows the enormous sensitivity of the form of the rear boundary against minor variations in the form and shape of the isotherm.

If the isotherm is calculated from the rear boundaries of both the experimental and the calculated elution curve on Fig. 2, the two isotherms are practically indistinguishable between the concentrations of 0.02 to 0.09 milliequiv./c.c., as is seen from the following data :

[Cu].	q_{Ca} (milli-equiv./g. of Zeo-karb).	
	Calc. from exp. chromatogram.	Calc. for Langmuir isotherm.
0.093	0.176	0.175
0.065	0.130	0.1315
0.038	0.083	0.0835
0.019	0.046	0.044
0.006	0.017	0.014
0.002	0.007	0.005

The difference at the very lowest concentrations, which are practically inaccessible to ordinary equilibrium measurements, can thus with the greatest ease be recognised and calculated from the rear boundary of a chromatogram.

It is apparent therefore that, with the exception of threshold values, there is little hope of being able to calculate the shape of chromatograms if only the approximate forms of the isotherms are known. The value of the theory lies rather in the opposite direction in that it provides a convenient tool for the calculation of the isotherms, in particular of multiple isotherms from chromatographic data.

An example of a chromatogram where "development" has not been completed is shown in Fig. 3. Here the two front boundaries rise up steeply within about 3 c.c. of eluate. There follows the flat non-developed section, after which a rapid fall in the concentrations of both solutes takes place which, owing to small deviations in the isotherm, is again sharper than one would expect for the Langmuir type.

Fig. 4 shows the details of a few measured rear boundaries. Though relatively less important for the technical separation, these rear parts form a good test of the theory. Both c_{20} and the amount μ_2 separated at the rear are, according to the theory, dependent on the ratio c_1^0/c_2^0 of the initial concentrations, which in these three experiments have been varied over a wide ratio. The agreement between the calculated and the observed elution curves is as good as can be expected. Not only c_{20} and μ_2 , but also the form of the rear band of pure solute 2 and the position of the point where solute 1 becomes zero, clearly show the trend demanded by theory.

241. Theory of Chromatography. Part IV. The Influence of Incomplete Equilibrium on the Front Boundary of Chromatograms and on the Effectiveness of Separation.

By E. GLUECKAUF and J. I. COATES.

It is shown that in the chromatographic column, under the usual working conditions, complete local equilibrium is not obtained. A theory is developed for the effect of incomplete equilibrium on chromatographic boundaries, and the form of observed boundaries agrees with those calculated. On decrease of grain size and flow velocity, equilibrium becomes more complete, and then some chromatographic separations can be effected with ease which are impossible by the usual methods; e.g., the separation of nickel and cobalt ions on alumina.

(a) *Chromatographic Boundaries.*—The influence of incomplete local equilibrium is very similar to a diffusion effect and so shows itself most markedly at the boundaries of the chromatograms where high concentration gradients exist. Normal binary chromatograms when fully developed have, in the absence of disturbing effects, the form shown in Fig. 1 of the preceding paper. We may distinguish here two types of boundaries: (i) sloping rear boundaries such as AB , CD , and $C'D'$, and $L'Q$, and (ii) sharp front boundaries such as the threshold boundary HG or PQ and the inter-boundary EF , $E'F'$ or LK , $L'K'$ which is the front of solute 2. As has been shown by De Vault (*J. Amer. Chem. Soc.*, 1943, 65, 532) the two front boundaries have normally (i.e., for isotherms concave against the c -axis) self-sharpening properties. This means that, even if by some artificial means HG were made sloping, it would again become vertical during the process of development—at least theoretically. This self-sharpening tendency increases with the curvature of the isotherm and it is nil for linear isotherms (see De Vault, eqn. 7).

In the case of the threshold boundary HG , the self-sharpening effect is usually very considerable, as linear single-solute isotherms are rare. In the case of the inter-boundaries EF the corresponding function depends essentially on the "exchange" isotherm between the two solutes. If the two solutes are very different and easily separable, this boundary, too, usually shows considerable self-sharpening, but if the two solutes are very similar, the exchange isotherm is practically linear and then this effect is negligible. The inter-boundary is then referred to as a non-sharpening front boundary.

(b) *Attainment of Complete Equilibrium.*—In order to study the effect of non-equilibrium and diffusion phenomena, chromatographic elution curves were measured, using adsorbents of different grain size. The adsorbents were ground to a diameter as low as 0.01 mm. (as compared with the commercial grain sizes of about 0.08 mm.), and a uniform grain size was obtained by elutriation in air streams of varying velocity.

The flow rate of the solvent in the chromatographic column was varied from 0.001 cm./sec., which means 1 drop in 2 mins. for a tube of 1 cm. diameter, to the usual flow rates of 10–60 drops per min.

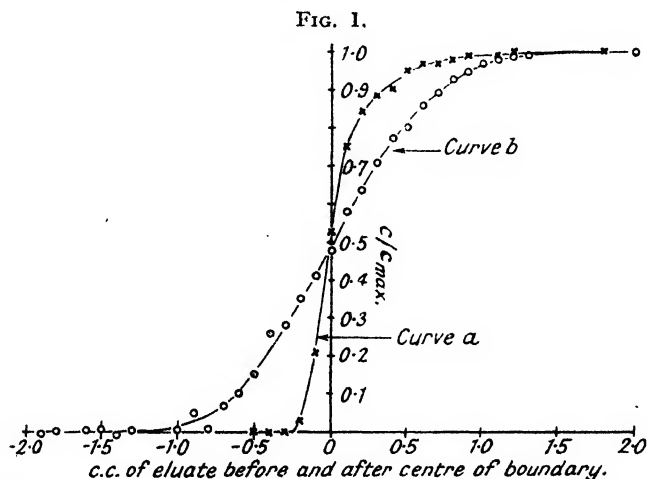

Systematic experiments showed that the quality and sharpness of non-sharpening inter-boundaries, e.g., such as between copper and manganese ions on Zeo-karb H.I. or H.I.P., continuously increased with reduction of grain size and flow rate. There must be an optimum flow rate, as the latter can obviously not be infinitely decreased without introducing disturbances on account of diffusion. But this latter effect is so small compared with the non-equilibrium effect and other disturbances that even at the lowest flow rates used an improvement was still noticeable compared with faster flow rates.

Under the conditions mentioned above ($d = 0.01$ mm., $F = 0.001$ cm./sec.), we were able to obtain, for a column of 1 m. length, non-sharpening inter-boundaries between 0.6 and 1 cm., and self-sharpening front boundaries extending on one occasion over only 0.10 cm., the former corresponding to 0.5–1%, the latter to 0.1% of the threshold volume.

That these conditions are not obtained with the usual practice can be seen from Fig. 10a of Weil-Malherbe (*J.*, 1943, 303), which contains about the best chromatographic experiments published. Here a non-sharpening front (benzpyrene on silica gel) extends over 25% of the threshold volume, and a strongly self-sharpening one (benzpyrene on alumina) over 12% of the threshold volume. A check on the form of non-sharpening front boundaries is therefore essential in all experimental work connected with the study of elution curves and, in particular, in such cases where elution curves are used for the calculation of adsorption equilibria (see Glueckauf, *Nature*, 1945, 156, 748, and Part II).

Although it is apparent that non-equilibrium phenomena can easily occur in the case of exchange materials, it is not usually realised that the same, though perhaps to a lesser degree, also applies to the so-called "adsorbents" like alumina and calcium carbonate, as adsorption takes place not only on the surface, but also inside the grains. The reason for this is that most experimenters investigating the form of bands have worked with single solutes which usually have strongly self-sharpening fronts. These maintain a reasonable sharpness even if considerably disturbed by non-equilibrium phenomena. Consequently, observers are easily deceived by this appearance of moderately sharp fronts, which are usually taken as proof of the absence of non-equilibrium phenomena.

How far the process of wishful thinking can go is shown, *e.g.*, by Jacobs and Tompkins (*Trans. Faraday Soc.*, 1945, **41**, 401, Fig. 1, Curve A), who convinced themselves—with the help of the equilibrium curve applied to a diffuse non-equilibrium boundary—that, in spite of the very diffuse eluted front which they found, the front of the adsorbate in the column

Experimentally measured boundaries. (a) Self-sharpening threshold boundary of $N-CoCl_2$ solution in column of acid Zeo-karb. ($\times - \times - \times$) (compare with curve calculated for $bc^0 = 10$ in Fig. 4). (b) Non-sharpening inter-boundary between frontal band of $^{59}CoCl_2$ and mixed band of $^{59}CoCl_2$ and $^{60}CoCl_2$ in same column of Zeo-karb ($\bigcirc - \bigcirc - \bigcirc$) (symmetrical S shape).

must have been very sharp. By doing so, they overlooked the fact that a sharp front of adsorbate moving through the column must deliver the solute at the end in an equally sharp-fronted elution curve—simply by reason of the conservation of matter (for details see eqn. 5).

The non-equilibrium phenomena, however, become very obvious when fronts are concerned which have little or no self-sharpening properties, *e.g.*, the boundary of one solute against another of similar adsorption affinity. As it is just such a boundary which occurs at the point of separation of two similar solutes (boundary EF in Fig. 1 of Part III), these non-equilibrium effects greatly reduce the efficiency of the separation.

(c) *Form of the Disturbed Self-sharpening Front Boundary.*—No theory has so far been given for the theoretical form of a front boundary disturbed by non-equilibrium phenomena in the case of a non-linear isotherm. Weiss (*J.*, 1943, 301; eqns. 59–62 and Fig. 5) has produced a schematical representation for the case of a linear isotherm which, however, apart from the diffuseness, does not really represent the experimental facts (see our Fig. 1, curve b, showing that the measured elution curve of a front boundary for a strictly linear isotherm has a symmetrical sigmoid form. A similar conclusion has also been reached by Klotz, *Chem. Rev.*, 1946, **39**, 243). A satisfactory theory for the case of the linear isotherm has been produced by Dr. H. London which, however, has not yet been published.

In the case of a self-sharpening front boundary caused by a non-linear isotherm, the general differential equations become very complicated, but, after the front has travelled some distance, a final form is attained which can be represented by a simple equation. Here the effects of non-equilibrium and self-sharpening just balance each other. For simplicity the calculations are carried out for the "undeveloped" chromatogram where the front has the original concentration c^0 .

In the case of non-equilibrium, the usual chromatographic equation of mass conservation (see Part II, eqn. 2), viz.,

$$[\Delta v/\Delta x]_e = df^*_{(e)}/dc + \alpha \quad (1)$$

changes to

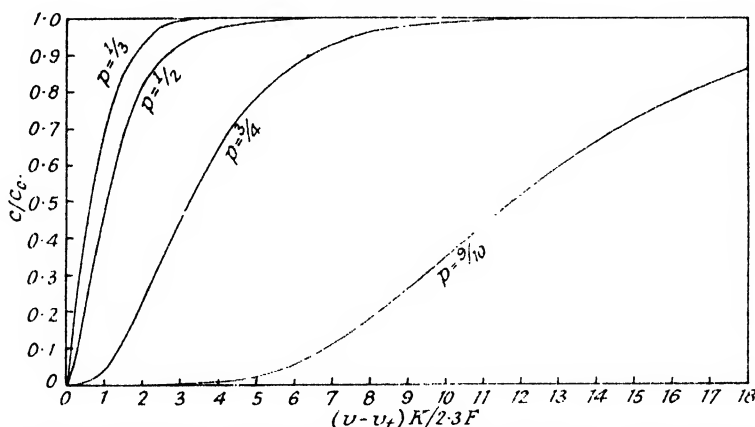

$$[\Delta v/\Delta x]_e = dq^*/dc + \alpha \quad (2)$$

where q^* is the amount actually adsorbed, the missing amount ($f^*_{(e)} - q^*$) being due to disequilibrium. When at a given point (x) of the front boundary the concentration rises during the passage of the front through this point, q^* is, with good approximation, represented by the equation

$$dq^*/dt = K(f^*_{(e)} - q^*) \quad (3)$$

which means that the rate of diffusion into the grains is essentially proportional to the amount still required to produce equilibrium. Here K is a diffusion factor (the inverse of the time in which a grain of adsorbent reaches $1/e$ of its equilibrium adsorption), and $K = D/(\eta d)^2$, where D is the diffusion constant of the solute in the solid material, d is the grain diameter, and $\eta (< 1/2)$ depends on the geometry of the grains.

FIG. 2.

Self-sharpening front boundaries for solutes obeying Freundlich isotherms $q = ac^p$ for different values of p .

After competition between the self-sharpening and the non-equilibrium effects has resulted in a final form of the front boundary, the whole front boundary and thus also the point of concentration c move with the usual velocity of the sharp undeveloped front boundary

$$[\Delta v/\Delta x]_e = f^*_{(e)}/c^0 + \alpha \quad (4)$$

It follows from equations (2) and (4) that in this final state

$$dq^*/dc = f^*_{(e)}/c^0 \quad (5)$$

This means that, no matter what the form of the equilibrium isotherm, q^* must always be a linear function of c . Eliminating q^* by means of (5) in (3) and replacing t by v/F (where F = flow velocity of solvent, in c.c./sec.), we get

$$dc/dv = (K/F)[f^*_{(e)} \cdot c^0/f^*_{(e)} - c] \quad (6)$$

Equation (6) has a particularly simple form in the case of the Freundlich isotherm

$$f^*_{(e)} = A \cdot c^p \quad (7)$$

Integration of (6) then leads to the equation for the elution curve of a disturbed self-sharpening front (final state):

$$v - v_t = \frac{-F}{K(1-p)} \cdot \log [1 - (c/c^0)^{(1-p)}] \quad (8)$$

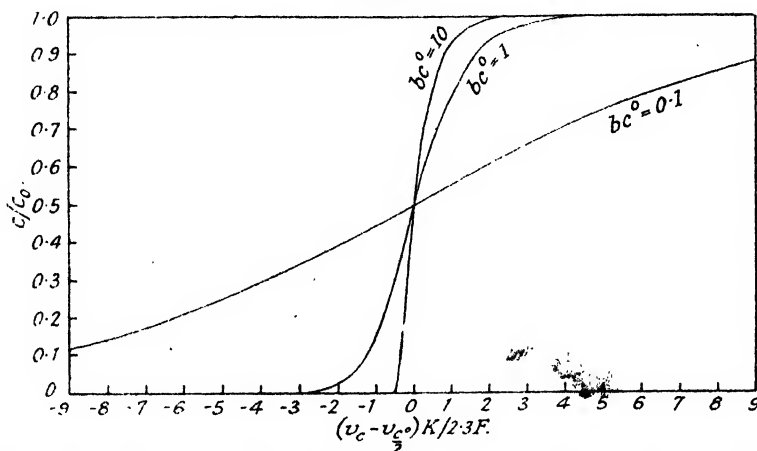

Similarly one obtains for the frontal distribution in the column

$$x_f - x = \frac{-F}{K(1-p)} \cdot \frac{c^0}{f^*_{(e)}} \cdot \log [1 - (q^*/q^0)^{(1-p)}] \quad (9)$$

where x_f is the most advanced point of the front boundary. Equation (8) requires that the length of the eluted front is independent of the concentration c^0 , which is perfectly shown in Jacobs and Tompkins's Fig. 2 (*loc. cit.*, p. 402). Equation (8) also shows the effect of p on the slope and extension of the front boundary, which is demonstrated in the experiments of Weil-Malherbe (*loc. cit.*, Fig. 10a), though not quantitatively, since, with the short columns used, the final state is not attained for values of p near unity.

Fig. 2 gives the theoretical curves of eluted front boundaries in the stationary state for various values of p . It shows that for small values of the Freundlich exponent p (e.g., $p = \frac{1}{2}$) the front rises sharply but reaches the maximum (c^0) only asymptotically. For comparatively large values of p it has a sigmoid form, which for $p = \sim 1$ reaches both the values $c = 0$ and $c = c^0$ asymptotically.

FIG. 3.

Self-sharpening front boundaries for solutes obeying Langmuir isotherm $q = ac/(1 + bc)$ for different values of bc^0 .

Equation (8) also shows that the question of grain size and flow rate comes into play to a very marked extent only when very similar substances have to be separated, where the inter-boundary is due to an exchange isotherm which, for very similar substances, is almost linear ($1 - p = \sim 0$; thus $v - v_c = \sim \infty$). No final state is attained by the front boundary when $p = 1$ (linear isotherm), under which conditions there is no self-sharpening effect, and, consequently, the slope of such a front boundary continues to decrease indefinitely.

Very similar conditions arise in the case of the Langmuir isotherm

$$f^*(c) = ac/(1 + bc) \quad (10)$$

Here integration of eqn. (6) leads to the equation for the elution curves :

$$v_c - v_c^0 = -\frac{K}{F} \left[\frac{1}{bc^0} \cdot \log (c^0 - c)/c + \log 2 (c^0 - c)/c^0 \right] \quad (11)$$

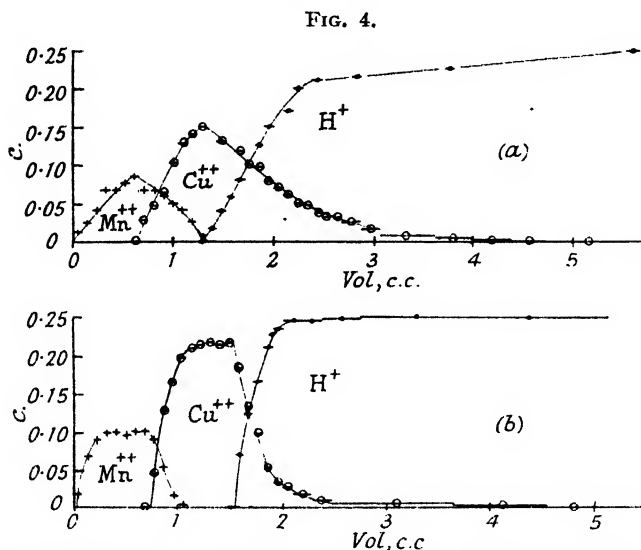

The form of the front boundary here depends on bc^0 which, according to the physical interpretation of the Langmuir isotherm, is the ratio of covered to free adsorbing surface. As can be seen from Fig. 3, the self-sharpening tendency increases with bc^0 , i.e., with increasing surface saturation. A comparison with Fig. 2 shows that there is a complete parallelism in the form of the front boundaries for the two isotherms, small values of p corresponding to large values of bc^0 and vice versa.
